Introduction

Dysphagia is caused by various conditions such as stroke and neurodegenerative diseases and results in malnutrition, dehydration, choking, and ultimately death. The prevalence of dysphagia in older adults is high. For example, 48% of community-dwelling subjects aged 70 years or older and 73% of institutional residents were reported to have the disorder (Cabre et al. 2009). The reason for this high prevalence of dysphagia in older adults is the concomitant increase in the prevalence of diseases causing dysphagia and reduced swallowing function associated with aging *per sé* (Wirth et al. 2016). Furthermore, older adults with dysphagia are often asymptomatic and may be easily overlooked by healthcare professionals. Unidentified dysphagia may be recognized from avoidance of food and/or liquids which trigger choking or aspiration. Notwithstanding the presence of symptoms, dysphagia is an apparent risk factor for malnutrition and dehydration as it reduces dietary and liquid intake (Foley et al. 2009; Carrion et al. 2015).

Interestingly, it has been reported that both sarcopenia and malnutrition can cause dysphagia or delayed recovery of swallowing function (Maeda and Akagi 2016; Nishioka et al. 2017a; Wakabayashi 2014). Evaluating nutritional status and/or sarcopenia using swallowing function in older adults may improve not only nutritional status but also functions and activities including swallowing capacity. Based on these findings, we have proposed a concept of rehabilitation nutrition that incorporates simultaneous intervention of rehabilitation and nutrition (Wakabayashi and Sakuma 2014). This chapter focuses on (1) screening tools and classification of dysphagia, (2) concept, characteristics, and diagnostic diagram of dysphagia caused by sarcopenia (sarcopenic dysphagia), and (3) the concept and clinical implication of rehabilitation nutrition, a method used to comprehensively evaluate swallowing function and sarcopenia.

Screening, Classification and Diagnosis of Dysphagia

Nurses and other medical professionals often perform dysphagia screening in clinical practice. The main purpose of dysphagia screening is to identify patients at risk of dysphagia who are likely to require detailed assessment offered by speech and language therapists, rehabilitation doctors, etc. Screening tools should therefore be simple, have high sensitivity against actual dysphagia, and be able to be performed at the bedside (Table 1). Classification of severity and a detailed examination of swallowing function are required to assess dysphagia

Table 1 Validity of common screening tools for dysphagia

Tools	Sensitivity	Specificity	Reference
EAT-10(Japanese ver.)[a]	0.758 0.522	0.749 0.897	DSS $\leq$ 4 (Suspected aspiration) DSS $\leq$ 6 (Suspected dysphagia)
WST(3 oz)[b]	0.76	0.59	Videofluoroscopic modified barium swallow examination (observation of swallow)
MWST (3 ml)[c]	0.553	0.808	Videofluorography (aspiration)
RSST[d]	0.981	0.658	Videofluorography (aspiration of any volume of barium)
Pulse oximetry[e]	0.56–0.87	0.39–0.97	$\geq$2% desaturation
Pulse oximetry + swallow test[e]	0.73—0.94	0.63–0.76	Coughing, choking, voice change, subjective assessment of aspiration, or $\geq$2% desaturation
Cervical auscultation[f]	0.23–0.94	0.50–0.74	Dysphagia, penetration, aspiration, or pharyngeal residuals

severity and make decisions on dysphagia treatment. The following section describes screening tools for dysphagia, a method for classifying severity, and diagnostic examination methods.

Screening Tools

EAT-10

The EAT-10 is a 10-item questionnaire for dysphagia screening developed by Belafsky et al. (2008). Each lower order item of the EAT-10 is a subjective evaluation of dysphagia, with scores ranging from 0 points (no problem) to 4 points (severe problem). The 10 components of the EAT-10 are as follows: (1) my swallowing problem has caused me to lose weight; (2) my swallowing problem interferes with my ability to go out for meals; (3) swallowing liquids takes extra effort; (4) swallowing solids takes extra effort; (5) swallowing pills takes extra effort; (6) swallowing is painful; (7) the pleasure of eating is affected by my swallowing; (8) when I swallow food it sticks in my throat; (9) I cough when I eat; and (10) swallowing is stressful. If the total score is 3 points or more, the subject is suspected of having dysphagia. Cronbach's alpha coefficient for the test has been reported to be 0.960, indicating high internal consistency, while a high correlation coefficient calculated using the test-retest method (0.72–0.91) indicated good reproducibility.

Burgos and colleagues examined the validity of the Spanish version of EAT-10 and showed Cronbach's coefficient alpha was 0.87 (Burgos et al. 2012). In Japan, the authors developed a Japanese version of EAT-10 and verified its reliability and

validity (Wakabayashi and Kayashita 2014). This showed that Cronbach's coefficient alpha was high (0.946), while a validity test showed a significant negative correlation between EAT-10 and DSS as the standard reference of dysphagia severity. In cases with an EAT-10 score of three or more, the sensitivity to aspiration was 0.758 and the specificity was 0.749. Interestingly, the inability to reply to the EAT-10 *per sé* had a high specificity for dysphagia (sensitivity 0.489, specificity 0.951), which may be effective for defining dysphagia. In older adults who require long-term care, the EAT-10 showed a significant association with nutritional status and ADL (Wakabayashi and Matsushima 2016). However, an evaluation of the psychological characteristics of the EAT-10 using Rasch analysis showed weak structural validity and internal consistency, item redundancy, and a lack of easy and difficult items (Cordier et al. 2016).

WST/MWST

The WST estimates the possibility of aspiration by evaluating cough and changes in voice or respiratory status after swallowing 3 oz of water. In 1992, DePippo et al. developed the WST as a screening tool for aspiration (DePippo et al. 1992). The test results were related to aspiration confirmed by VF, with a sensitivity and specificity for aspiration of 76% and 59%, respectively. Another version of the WST which uses a smaller volume of water (30 mL) was proposed in Japan by Kubota et al. (1982). Later, Saito and his colleagues modified Kubota's test as the MWST that used only 3 ml of water (Saito 2000). In the MWST, the assessor pours 3 ml of cold water to the floor of the patients' oral cavity and instructs the patient to drink it. The assessor then evaluates the presence of swallowing, cough, and change in voice and respiratory status and classifies the findings into five categories (Table 2). If the grade is 4 or more, patients repeat the test again and describe the worse categories. With a cut-off value of grade 3, the sensitivity to discriminate aspiration was reported to be 0.553 and the specificity 0.808 (Osawa et al. 2013). When combined with the food test, the sensitivity was high (0.90), whereas the specificity was rather low (0.56) (Tohara et al. 2003).

RSST

The RSST is a simple screening tool that involves touching the skin surface of the hyoid bone and thyroid cartilage with the forefinger and middle finger, respectively, and repeat saliva swallowing in 30 s (Oguchi et al. 2000). If the hyoid bone and thyroid cartilage completely overcomes each finger, this is counted as 1 by the

Table 2 Scoring method of MWST

Score of 1	Inability to swallow
Score of 2	Dyspnea after water swallowing
Score of 3	Cough or dysphonia after water swallowing
Score of 4	Subject was able to swallow the water but unable to perform either of two dry (saliva) swallows within 30 s
Score of 5	Subjects was able to complete swallowing the water and both dry swallows

assessor. If the count is less than three times in 30 s, the patient is suspected as having a swallowing problem. The RSST has a high correlation with the findings of VF. The sensitivity of the test has been reported to be high and ranged between 0.80 and 0.98 especially for discriminating aspiration, whereas the specificity was 0.54–0.66 (Oguchi et al. 2000). If the patients can understand the methodology of the RSST, it is a useful screening test that anyone can perform without the risk of choking.

Pulse Oximetry

Pulse oximetry is a simple, noninvasive screening method that involves attaching a small probe to a fingertip and estimating oxygen saturation in the arterial blood based on the difference in absorbance of red and infrared light. Aspiration may occur when oxygen saturation decreases after ingestion of food and drinking water. The sensitivity of the method ranges between 73% and 87% with a specificity of 39–87% for aspiration confirmed by VF or FEES using the change in oxygen saturation before and after swallowing. Lower validity has been reported in older adults and patients with respiratory disease (Ramsey et al. 2003). A combination of the water test and oxygen de-saturation showed a sensitivity of 73–98% and specificity of 63–76% for coughing, choking, and voice changes, indicating the method has good validity as a screening test for dysphagia (Bours et al. 2009).

Cervical Auscultation

Cervical auscultation is a clinical examination for estimating transfer of food and liquid through the pharynx and/or the presence of residual food by listening to swallowing sounds. A stethoscope is commonly used for cervical auscultation, while other devices have been used in some cases such as microphones, accelerometers, and Doppler sonars. A systematic review showed that the sensitivity and specificity of cervical auscultation for dysphagia ranged from 23% to 94% and 50–74%, respectively. This review concluded that the method should not be used alone to identify dysphagia (Lagarde et al. 2016).

Classification of Dysphagia Severity

FOIS

The FOIS is a method for classifying oral intake ability and is based on the actual condition of the patients' nutritional intake (Table 3). Severity is classified into seven levels according to the combination of oral intake and alternative nutrition, from stage 1 (nothing by mouth) to stage seven (total oral diet with no restrictions). The method has high reproducibility with a kappa coefficient of 0.86–0.91, indicating a degree of interexaminer coincidence. The correlation coefficient between the FOIS and dysphagia severity based on VF was reported to be 0.54 (Crary et al. 2005).

FILS

The FILS is a classification method for dysphagia severity developed in Japan. The investigator classifies severity into 10 levels based on observations of the

Table 3 Grading methods of FOIS

Level	Types of intake
1	Nothing by mouth.
2	Tube dependent with minimal attempts of food or liquid.
3	Tube dependent with consistent oral intake of food or liquid.
4	Total oral diet of a single consistency.
5	Total oral diet with multiple consistencies but requiring special preparation or compensations.
6	Total oral diet with multiple consistencies without special preparation, but with specific food limitations.
7	Total oral diet with no restrictions.

patient's eating: (1) "No swallowing training is performed except for oral care"; (2) "Swallowing training not using food is performed"; (3) "Swallowing training using a small quantity of food is performed"; (4) "Easy-to-swallow food less than the quantity of a meal (enjoyment level) is ingested orally"; (5) "Easy-to-swallow food is orally ingested in one to two meals, but alternative nutrition is also given"; (6) "The patient is supported primarily by ingestion of easy-to-swallow food in three meals, but alternative nutrition is used as a complement"; (7) "Easy-to-swallow food is ingested orally in three meals. No alternative nutrition is given"; (8) "The patient eats three meals by excluding food that is particularly difficult to swallow"; (9) "There is no dietary restriction, and the patient ingests three meals orally, but medical considerations are given"; and (10) "There is no dietary restriction and the patient ingests three meals orally (normal)." The method has high sensitivity to changes in the state of ingestion, with reliability between evaluators being 0.70 to 0.90, reliability within evaluators 0.83–0.90, and a strong correlation coefficient between the FILS and FOIS of 0.96–0.99 (Kunieda et al. 2013).

Diagnostic Tests

VF

VF is an examination that involves feeding modified food containing barium to a patient, taking X-rays from the side or front and recording fluoroscopic images (Fig. 1). The advantage of VF is that it directly evaluates how patients masticate and form an alimentary bolus for transfer from the oral cavity to the stomach. However, the limited testing time required to avoid excessive radiation exposure and problems conducting inspections of patients who find it difficult to maintain the same position in a wheelchair are well-known limitations. The unpalatable and uncomfortable texture of barium may also influence the test results (Jaffer et al. 2015). VF can evaluate functional abnormalities such as nasopharyngeal closure dysfunction, delayed swallowing reflex, morphologic abnormalities of organs associated with swallowing, pharyngeal residues, aspiration, and gastroesophageal reflux. The test can be used not only for decision-making of favorable food texture or patient' posture during eating, but also as a gold standard for diagnosing dysphagia. As a consequence, it is one of the most common clinical examinations in rehabilitation practice.

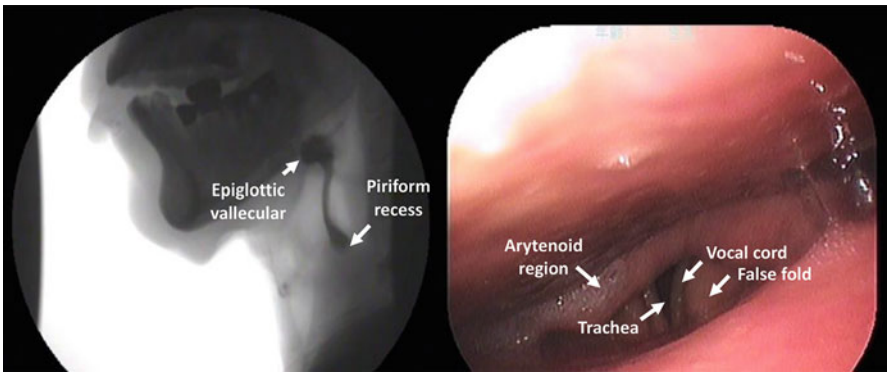

Fig. 1 VF and FEES. (*Left*) VF showing barium in the epiglottic vallecular passing through the esophagus during normal swallowing. (*Right*) FEES demonstrated in the arytenoid region, vocal cords, and false folds beyond the walls of the oropharynx

FEES

FEES is another well-known diagnostic test in which a fiberscope is inserted from the nasal cavity to directly observe the pharynx (Fig. 1). FEES is less invasive, can be evaluated safely and conveniently, and is effective for diagnosing patients with dysphagia. Unlike VF, there is no radiation exposure. When the patient undertakes the compensation method of swallowing, the clinician can directly see the swallow and is able to provide feedback and instructions on effective swallowing on a screen (Jaffer et al. 2015). On the other hand, FEES cannot evaluate esophageal function, the upper esophageal sphincter, or determine the moment of swallowing.

Sarcopenic Dysphagia

As proposed by Rosenberg in 1988, sarcopenia initially represents an age-related loss of muscle mass and function (Rosenberg 1997). Skeletal muscle mass decreases significantly with age with lean body mass being 9% lower between 65 and 74 years and 12% lower at ages >75 years, compared with that measured between 35 and 44 years (Atlantis et al. 2008). Although the original concept of sarcopenia focused on decreasing skeletal muscle mass, recent consensus has changed to also include a decline in muscular strength and physical function. The cause of sarcopenia has also been changed to include not only aging but also nutritional deficit, inactivity, and disease (Chen et al. 2014; Cruz-Jentoft et al. 2010). Nutritional deficiency plays an important role in all causes of sarcopenia. In fact, 76% of older hospitalized patients with disuse and sarcopenia were shown to have malnutrition (Sanchez-Rodriguez et al. 2016). Healthcare professionals should therefore carry out nutritional assessment of older adults with sarcopenia.

Dysphagia is often caused by various diseases, especially in subjects older than 70 years (Cabre et al. 2009). Although the major cause of overt dysphagia in older adults

is central nervous system disease such as stroke, aging itself can also cause a functional decline in swallowing (presbyphagia) (Wirth et al. 2016; Wakabayashi 2014). A nutritional deficit and/or sarcopenia may also evoke dysphagia and delayed recovery of swallowing function. In 1996, Veldee et al. showed that protein energy malnutrition may cause dysphagia through immunological deterioration, fatigue, decline of respiratory muscle strength, and decreased swallowing muscle mass. (Veldee and Peth 1992). Tongue pressure was reported to be lower in community-dwelling older adults with aspiration compared to that measured in those without aspiration (Butler et al. 2011). This suggested that declining swallowing muscle strength may exacerbate swallowing function. We also found that stroke rehabilitation patients undergoing tube feeding with severe malnutrition risk, which is related closely with sarcopenia, had the worst recovery to achieving full oral intake (Nishioka et al. 2017a). Indeed, in daily clinical practice, we sometimes found that older adults with sarcopenia showed dysphagia in spite of no apparent causable disease such as stroke. These cases raised the possibility that dysphagia may be caused by sarcopenia of the swallowing muscles, namely sarcopenic dysphagia.

Sarcopenic dysphagia occurs when it is difficult to swallow due to sarcopenia of the generalized and swallowing muscles (Wakabayashi 2011, 2014). The swallowing muscles include the intrinsic muscle of the tongue and the mimic, masticatory, suprahyoid, infrahyoid, palatal, pharyngeal, and esophageal muscles. The mechanism of sarcopenic dysphagia is considered to be a two-step process. Older adults with presbyphagia and age-related sarcopenia causing aspiration pneumonia may subsequently have their muscle decline aggravated by invasion, disuse, or nutritional deficiency during treatment of pneumonia, resulting in complete sarcopenic dysphagia (Fig. 2). Confirmation of this concept was reported by Kuroda and colleagues who demonstrated an association between feeding swallowing function and arm muscle circumference, suggesting the possibility of sarcopenic dysphagia (Kuroda and Kuroda 2012). Similarly, sarcopenia was shown to be an independent explanatory factor for swallowing disorders in older hospitalized patients (Maeda et al., 2016a), with low skeletal muscle mass being a risk factor for the onset of dysphagia 60 days after hospital admission (Maeda and Akagi 2016). These findings indicate sarcopenia may cause dysphagia in older subjects.

Rehabilitation and nutritional care should both be provided for this type of dysphagia (Wakabayashi and Sakuma 2014; Clave and Shaker 2015). At this time, although there are no unified definitions and diagnostic criteria for sarcopenic dysphagia, a provisional diagnostic algorithm has been proposed by the working group on sarcopenic dysphagia (WGSD). We are currently verifying the validity and reliability of this algorithm (Fig. 3).

Concept and Assessment Method of Rehabilitation Nutrition

Dysphagic patients often have malnutrition with its prevalence being 2.4 times higher than in subjects with normal swallowing function. This relationship is not seen in the acute phase but often is seen during the rehabilitation stage (Foley et al.

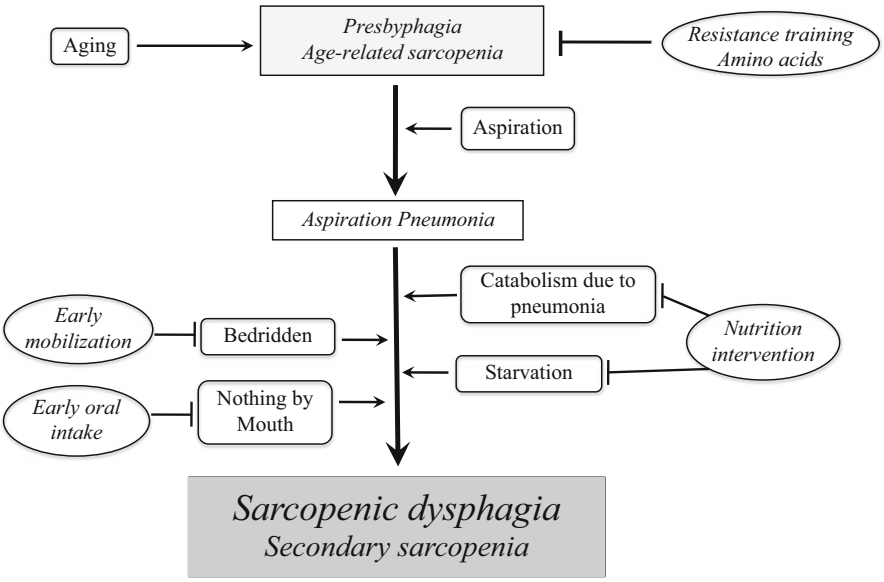

Fig. 2 Underlying cause and progression of sarcopenic dysphagia in older adults. Sarcopenic dysphagia may develop in frail older adults with presbyphagia and age-related sarcopenia. When these people develop aspiration pneumonia there is a rapid exacerbate sarcopenia of generalized- and swallowing muscle. The underlying cause of sarcopenia development may be disuse during acute care (sometimes unnecessarily), inappropriate nutritional care, or muscle catabolism due to stress responses to pneumonia and comorbidity. As a result, muscle weakness deteriorates (secondary sarcopenia) and sarcopenic dysphagia becomes obvious

2009). It has been reported that 17% of older adults with dysphagia had malnutrition, while 34% were at risk of malnutrition (Carrion et al. 2017). When malnutrition and dysphagia co-exist, the 1-year mortality reached 65% (Carrion et al. 2015). In other words, older people with dysphagia, especially those who are receiving long-term swallowing rehabilitation, are more likely to develop malnutrition and have a poor prognosis. It is therefore necessary to evaluate the presence and cause of malnutrition and sarcopenia as well as swallowing function in these patients.

We advocate rehabilitation nutrition as a concept that includes comprehensive evaluation and rehabilitation and nutritional care intervention for people with disabilities and/or older adults (Wakabayashi and Sakuma 2014). Rehabilitation nutrition for people with a disability and frail older people is defined as (1) holistic evaluation by ICF of the presence and causes of nutritional disorders, sarcopenia, and excess or deficiency of nutrient intake, (2) rehabilitation nutrition diagnosis and rehabilitation and nutrition goal setting, and (3) achieving the highest body functions, activities, participation, and QOL by improving nutritional status, sarcopenia, and frailty using "nutrition care management that takes into account rehabilitation" and "rehabilitation that considers nutrition." Rehabilitation nutrition is a process that includes: (1) rehabilitation nutrition assessment and diagnostic reasoning, (2) rehabilitation nutrition diagnosis, (3) rehabilitation nutrition goal setting, (4) rehabilitation nutrition intervention, and (5) rehabilitation nutrition

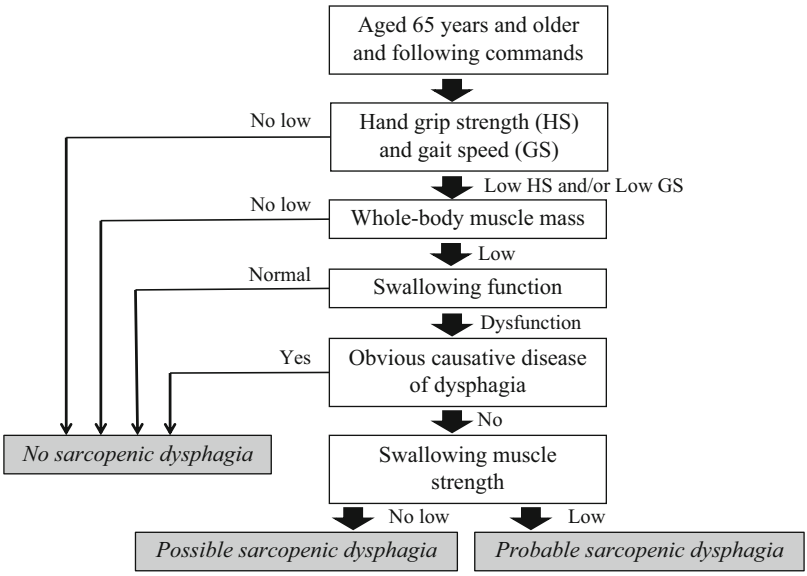

Fig. 3 Proposed diagnostic algorithm for sarcopenic dysphagia. This algorithm is for use in adults aged 65 years or older who can follow an instruction. Sarcopenic dysphagia is suspected if the individual has low handgrip strength or low gait speed, low general muscle mass, swallowing dysfunction, and no causative disease of dysphagia. Subjects with low swallowing muscle strength (using tongue pressure) are classified as possible sarcopenic dysphagia, while those without this finding are classified as probable sarcopenic dysphagia

monitoring. Using this concept enables comprehensive evaluation of older adults with dysphagia and sarcopenia undergoing rehabilitation.

To screen for dysphagia, it is desirable to use the screening tool described above that can be performed simply and noninvasively at the bedside such as the EAT-10, MWST, or RSST. Nutrition screening should be conducted on all older subjects who receive rehabilitation using validated tools such as the NRS 2002 (inpatient), MUST (home), MNA, or its short form version (older adults) or SGA (Kondrup et al. 2003). If the patients cannot answer the questions in these nutritional screening tools due to aphasia, post cerebral aphasia, or cognitive impairment, they can obtain help to complete the screening from family or a caregiver. Calf circumference in the nonparalyzed side (male $\leq$ 31 cm, female $\leq$ 30 cm) is effective for nutritional screening in poststroke patients where body weight measurement is difficult due to contracture or paralysis (Nishioka et al. 2017b).

Sarcopenia should be classified using consensus-based criteria such as EWGSOP (Cruz-Jentoft et al. 2010) or AWGS for Asian populations (Chen et al. 2014). However, it is often difficult to measure body composition, grip strength, and walking speed in patients with cognitive impairment or hemiplegia. For measuring muscle mass, calf circumference can be substituted for patients with decreased muscle mass as $<$34 cm for males and $<$33 cm for female (Kawakami et al. 2015). More than 90% of patients in whom it was difficult to measure walking

speed were shown to have sarcopenia using only measurements of grip strength and muscle mass (Maeda et al. 2016b). It is therefore possible to identify sarcopenia with a high probability using only muscle mass and strength in patients who require assistance to mobilize.

Policies and Protocols

When dysphagia is suspected in elderly people requiring rehabilitation, we first evaluate the possibility of a swallowing disorder using a simple and validated questionnaire such as the EAT-10. If it is possible that the patient has a swallowing disorder, the WST/MWST or the RSST is performed to increase the likelihood of the presence of dysphagia. Accurate diagnostic methods such as VF and VE are carried out to diagnose patients suspected of having a swallowing disorder or to determine the posture and food type required to avoid aspiration. In order to determine treatment policy, it is useful to classify the severity using methods such as the FOIS or the FILS. Because dysphagia in older adults is often accompanied by sarcopenia and malnutrition, potential causes of dysphagia, we suggest that it is necessary to carry out concurrent assessment of sarcopenia and nutritional status. Consensus-based criteria proposed by the EWGSOP or the AWGS (for Asian population) should be used to define sarcopenia. Validated tools such as the NRS2002, MNA, MUST, or SGA are recommended to screen for malnourished patients. The concept of rehabilitation nutrition is useful for comprehensive assessment of older adults with disabilities. The rehabilitation nutrition care process includes rehabilitation nutrition assessment and diagnostic reasoning, rehabilitation nutrition diagnosis, rehabilitation nutrition goal setting, rehabilitation nutrition intervention, and rehabilitation nutrition monitoring.

Dictionary of Terms

- **Sensitivity** – The proportion of the subjects with positive test results among those who actually have a certain disease or symptom. A test with high sensitivity is useful for rule out.
- **Specificity** – The proportion of the subjects with negative test results among those who do not have a certain disease or symptom. A test with high specificity is useful for obtaining a definitive diagnosis.
- **Cronbach's coefficient alpha** – Cronbach's coefficient alpha is an index of the correlation between the scores of individual items. If the coefficient is ≥ 0.80, the correlation is considered excellent, while a coefficient < 0.50 correlation is considered low.
- **Sarcopenia** – A syndrome characterized by progressive and generalized loss of skeletal muscle mass and strength caused by aging, disuse, diseases, and/or nutritional deficit and associated with increased risk of adverse outcomes such as physical disability, poor quality of life, and death.

- **ICF** – The unified framework for comprehensive assessment of people with disabilities proposed by the World Health Organization. The framework has three layers that include body functions and structure, activities and participation that influence health, and environmental and personal factors.

Summary Points

- Dysphagia is observed in 48–73% of institutional or hospitalized older patients.
- Dysphagia in older adults is caused by diseases and/or aging itself (presbyphagia).
- Dysphagia screening tools should be simple, noninvasive, and able to be carried out at the bedside.
- Using validated screening tools such as EAT-10, WST/MWST, and RSST is recommended in the clinical setting.
- Classification methods of dysphagia severity determine the degree of the condition in greater detail than screening tools and are fundamental for decision making on dysphagia treatment.
- Validated classification methods include the FOIS and FILS.
- VF and FEES are used as the gold standard for diagnosing dysphagia.
- Sarcopenic dysphagia is a new concept as a cause of dysphagia.
- Sarcopenic dysphagia is defined as difficulty swallowing caused by sarcopenia of the generalized and swallowing muscles.
- A consensus-based diagnostic flowchart for sarcopenic dysphagia has been proposed; its prerequisite is the presence of dysphagia, presence of sarcopenia in the whole body and swallowing muscles, and no significant causative disease of dysphagia.
- The combination of rehabilitation and nutritional assessment and intervention based on rehabilitation nutrition is effective in older adults with sarcopenia and dysphagia.
- Rehabilitation nutrition is a new concept for comprehensive evaluation and intervention based on ICF that has the aim of improving nutritional status, sarcopenia, and frailty in older adults with disabilities.

Abstract

Wasting syndromes such as malnutrition, starvation, sarcopenia, and cachexia have been increasingly recognized in health care and are the subject of significant research endeavors internationally. It is the purpose of this chapter to compare the characteristics (definitions and diagnosis, etiology, prevalence and outcomes) of each of these conditions in older adults. Protein-energy malnutrition is a syndrome caused by the inadequate bioavailability of energy and/or protein over time, leading to the catabolism of lean tissues with or without loss of fat mass, occurring most frequently in older adults. Malnutrition prevalence ranges from 10% to 50% depending on the setting. Simple starvation is a physiological state referring to the metabolic alterations, such as hypophosphatemia and the production of ketones as the primary energy source, which are activated in a state of food and nutrient deprivation, but when it causes physiological consequences it is clinically referred to as malnutrition. Starvation-related malnutrition is only diagnosed when protein-energy malnutrition is caused by food and nutrient deprivation over a long period of time in the absence of disease processes and inflammation. Sarcopenia is the loss of muscle mass, strength, and function that occurs due to age-related changes in physiology and ranges in prevalence from 10% to 50% depending on age group. Cachexia is a complex syndrome which presents with the loss of body weight, predominately skeletal muscle, as a result of metabolic abnormalities related to disease processes. Cachexia may be considered as a type of disease-related malnutrition and ranges in prevalence from 10% to 50% depending on the underlying disease. Malnutrition, starvation, sarcopenia, and cachexia result in the catabolism and subsequent dysfunction of multiple organ systems and skeletal muscle, leading to poor patient outcomes such as physical dysfunction, hospitalizations, poor quality of life, and increased risk of death.

Introduction

In1974 Dr Charles Edwin Butterworth Jr put the first spotlight on wasting syndromes in older adults when he published "The Skeleton in the Hospital Closet" (Butterworth 1974). Since then, wasting syndromes such as malnutrition, sarcopenia, and cachexia have been increasingly recognized in health care and are the subject of significant research endeavors internationally (Krumdieck 1998). However, despite over 40 years of research aimed at improving the nutritional status of older adults; malnutrition, sarcopenia, and cachexia remain highly prevalent worldwide in the community, hospitals, and residential aged care (Watterson et al. 2009). In addition, there is significant confusion in the literature and in clinical practice between malnutrition, starvation, sarcopenia, and cachexia (Tzankoff and Norris 1978). Therefore, it is the purpose of this chapter to explore the current evidence regarding the definition and diagnosis, etiology, prevalence and outcomes of each of these conditions in older adults.

Malnutrition in Older Adults

Definition and Diagnosis

The term "malnutrition" traditionally refers to any state of an individual resulting from the inadequate and/or excessive intake of nutrients. Each nutrient has a range of intake that is required for optimal health, and an intake below or above this is associated with impaired physical function (2005). However, over time the term "malnutrition" has come to be frequently used to refer to "protein-energy malnutrition" (PEM), a

syndrome caused by the inadequate bioavailability of energy and/or protein, leading to the catabolism of lean tissues with or without loss of fat mass, occurring most frequently in older adults (2008). Other nutrients may also be deficient; however, the lack of sufficient energy and/or protein is the defining etiological characteristic of PEM (2015). However, there is no international consensus on the definition of PEM, nor even its name, as it is also referred to as "protein-energy undernutrition" or "protein-calorie malnutrition." The loss of lean tissues (comprising 35–50% of total body weight in healthy adults) with or without fat mass presents clinically as decreased body weight, evidence of muscle wasting, and compromised homeostasis in organ function, blood cells, and immune cells (Pleuss 2005).

Reflecting this variable clinical presentation, there is no single measure able to diagnose PEM. Instead, a diagnosis is reached through a global examination by a highly-trained health professional of an individual's medical status, anthropometry, biochemistry, dietary intake, nutrition-related symptoms, and a physical examination. To support this process, health professionals frequently use a "nutrition assessment tool" to gather the required information and to guide interpretation. Although not all clinicians and researchers utilize a nutrition assessment tool to make a diagnosis of PEM, it is considered best-practice to do so and is increasingly required in health care facilities (Watterson et al. 2009). There are three nutrition assessment tools which are validated for use in older adults; these are the Mini Nutritional Assessment (MNA) (Guigoz and Vellas 1997), the Subjective Global Assessment (SGA) (Detsky et al. 1987), and Scored Patient-Generated Subjective Global Assessment (PG-SGA) (Marshall et al. 2016b).

Protein-energy malnutrition may also be defined and diagnosed by its severity and cause. Reflecting the amount of body weight lost and/or severity of muscle wasting in a certain time-frame, an individual may be categorized as "mildly malnourished," "moderately malnourished," or "severely malnourished." However, there is also no consensus as to how each of these categories is defined and usually is based upon the nutrition assessment tool utilized or the amount of weight lost in a certain period.

In 2012, the Academy of Nutrition & Dietetics (AND) and the American Society for Parenteral and Enteral Nutrition (ASPEN) reached a consensus on the set of etiology-based diagnostic characteristics for PEM (White et al. 2012). There were three etiology-based diagnostic criterion agreed upon, which are outlined in Fig. 1. Beyond these three categories, the consensus definition also categorizes PEM as severe or nonsevere (moderate), based on the degree of inadequate energy intake, weight loss, fat loss, muscle wasting, fluid accumulation, and grip strength (White et al. 2012).

Etiology

Protein-energy malnutrition is a condition that develops over time, with a latency period ranging from days to years depending on the initial nutritional state of the individual and the severity of malnutrition-causing symptoms and environments. Inadequate energy and protein can be caused by: (1) not consuming sufficient dietary

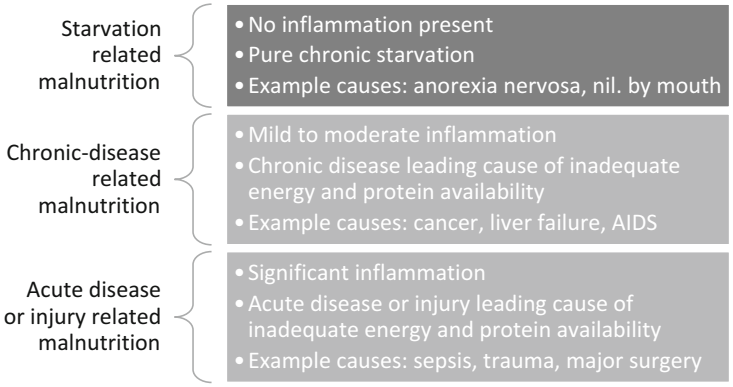

Fig. 1 Consesus etiology-based protein-energy malnutrition definitions (Adapted from White et al. 2012). The characteristics of the three subtypes of protein-energy malnutrition, which differ primarily on the cause of malnutrition. AIDS, acquired immune deficiency syndrome

sources of energy and protein to meet an individual's nutrient requirements, which is exacerbated in states of hypermetabolism or (2) not absorbing the energy or protein consumed. Additionally, it should be highlighted that in any one person, there may be one or many contributing causes.

There are innumerable causes of inadequate energy and protein dietary intake, examples of which are shown in Fig. 2. When hypermetabolism is present, the body's demand for energy and protein increases significantly and may in some cases double (Marshall 2017). This is often confounded by a low level of nutrition knowledge, where older adults may fail to recognize increased nutrient requirements or the types of foods required to prevent malnutrition (Marshall et al. 2016a). Similarly, not absorbing the consumed energy and protein also has diverse causes, including:

1. *Diseases related to maldigestion and malabsorption*. Examples are short bowel syndrome, gastrointestinal catabolism as a result of malnutrition, gastritis, inflammatory bowel syndrome, cystic fibrosis, pancreatic and liver diseases, and bariatric surgery.
2. *Diseases related to excessive nutrient losses*. Examples are diarrhea, steatorrhea, vomiting, protein losing enteropathy, surgical drains, stomas, fistulae, hemodialysis, and blood loss.

Prevalence

The prevalence of PEM varies widely according to the setting and the geographical location but also varies according to the age group of a sample as well as the diagnostic tool used. Cereda and associates recently published a meta-analysis of PEM prevalence, diagnosed by the MNA, in older adults (>60 years) according to

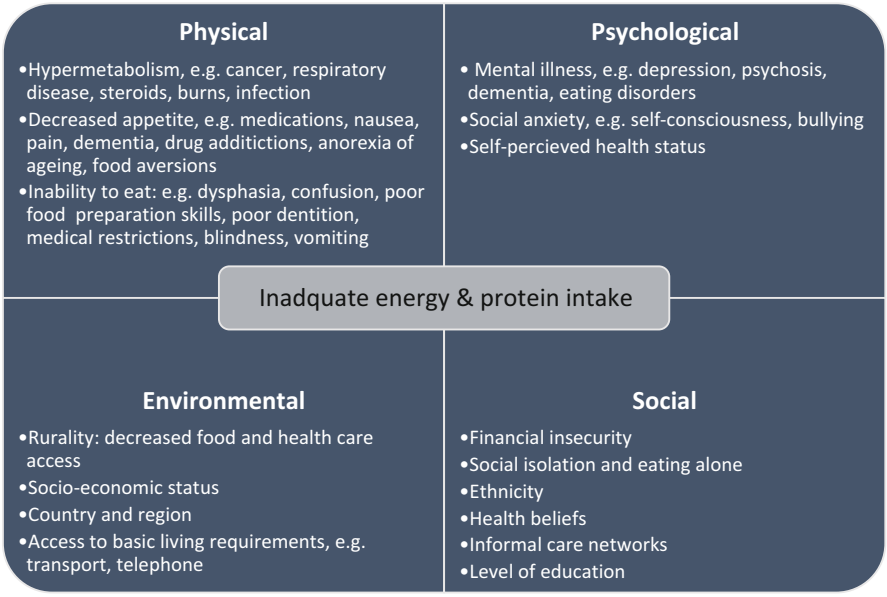

Fig. 2 Social, environmental, physical, and psychological factors which decrease a person's ability to consume adequate energy and protein (Marshall 2017). These are diverse and overlapping risk factors which increase the chances that an older adult will consume less energy and protein in their food, which in turn increases the chances they will become malnourished

health care setting (Cereda et al. 2016). The highest prevalence was found in long-term care (29%; $n = 23$ studies) and rehabilitation and subacute care (29%, $n = 15$ studies), followed by acute care (22%, $n = 66$ studies) and nursing homes (18%, $n = 44$ studies), then home care services (9%, $n = 15$ studies), out-patients (6%, $n = 37$ studies) and the community (3%, $n = 58$ studies) (Cereda et al. 2016). Additionally, this meta-analysis found that the prevalence of PEM, according to the MNA, was consistently and significantly higher in European countries as opposed to Asian countries across all settings, although other geographical locations were not described for comparison (Cereda et al. 2016).

However, reviews and diagnostic studies have found that the MNA considers fewer patients as malnourished than other tools including the SGA, PG-SGA, and ICD, and therefore true PEM prevalence may be higher (Marshall 2016; Marshall et al. 2016b).

The impact of rurality on the prevalence of malnutrition has not been evaluated in a meta-analysis; however, a review in the rehabilitation and subacute setting found that the highest prevalence was found to be in rural settings (53–65% in rural Australia, 32–49% in urban Australia, all measured using the SGA) (Marshall 2016). There are many social, cultural, economic, and physical changes that occur in ageing, which increases the risk of protein-energy malnutrition; where many of the risk factors outlined in Fig. 2 are more likely to occur in older adults. Research has consistently found age to be a risk factor for increasing risk of malnutrition

(Agarwal et al. 2012). In Europe ($n = 15{,}043$ participants, $n = 325$ hospitals, $n = 25$ countries), every 10 years of life was found to increase risk of PEM by 14% (OR: 1.14 [95% CI: 1.09–1.19]; $P < 0.0001$).

Outcomes

The physiological and psychosocial consequences of malnutrition are significant and diverse (Agarwal et al. 2016). Confusion, fatigue, and weakness, common symptoms of malnutrition, are often attributed to other conditions leading to frequent misdiagnosis and under-recognition of malnutrition (Wellman and Kamp 2008). Malnutrition causes systemic catabolism of fat mass and lean tissues, including vital organs of the liver, heart, respiratory system, and skeletal muscle mass (Figs. 3, 4, and 5). Catabolism of these lean tissues cause a disruption in homeostasis in nearly all physiological systems, leading to diverse health outcomes (Figs. 3, 4, and 5). In addition to those shown in Figs. 3, 4, and 5, malnutrition also causes fluid and electrolyte imbalances which may further affect kidney and cardiac function. The combination of decreasing function in multiple organ systems as a result of malnutrition increases risk of mortality. Malnutrition has been found to be an independent risk factor for death, with studies finding the risk of death doubled in hospital (RR: 2.63 [95% CI: 1.55–5.27] $P < 0.05$) (Correia and

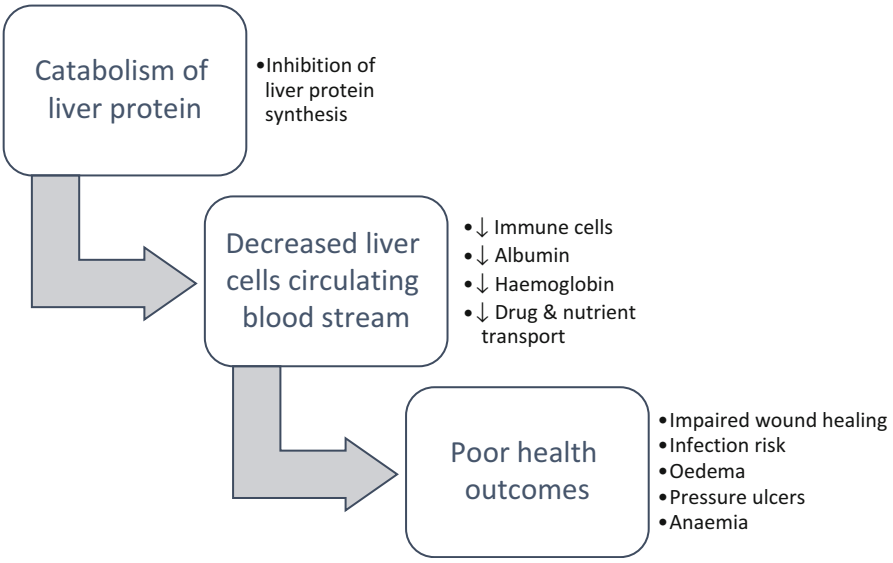

Fig. 3 The physiological process and health outcomes related to liver catabolism as a consequence of protein-energy malnutrition (2006; Stratton et al. 2003; Pleuss 2005; Ferreira et al. 2011; Martyn et al. 1998). This figure describes how the breakdown of liver mass and function which occurs in malnutrition will have increased risk of impaired wound healing, infection, swelling, pressure sores, and anemia

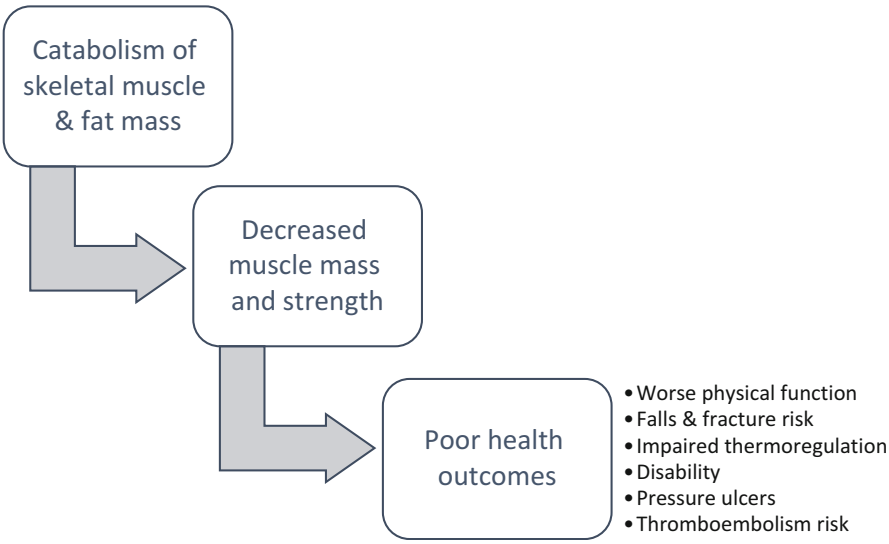

Fig. 4 The physiological process and health outcomes related to skeletal muscle and fat mass catabolism as a consequence of protein-energy malnutrition (2006; Stratton et al. 2003; Pleuss 2005; Ferreira et al. 2011; Martyn et al. 1998). This figure describes how the breakdown of muscles and loss of fat which occurs in malnutrition will have increased risk of impaired physical function, falls and fractures, body temperature regulation, pressure sores, and obstruction of blood flow

Waitzberg 2003) (OR: 1.92 [95% CI: 1.09–3.34] $P = 0.023$) (Agarwal et al. 2013) and more than tripled in the year following discharge (HR: 3.41 [95% CI: 1.07–10.87] $P = 0.038$) (Charlton et al. 2012).

As would be expected with such significant poor health outcomes, individuals who are malnourished may experience a lower quality of life, apathy, depression, self-neglect, hypochondriasis, poor self-efficacy, poor body image, confusion, decreased interest in food, loss of libido, and engage less frequently in social activities (2006; Bottone et al. 2012; Marshall et al. 2014). Additionally, these poor health outcomes caused by malnutrition contribute a significant economic burden, where the cost of treating a patient with malnutrition in the UK is more than double the cost of treating a well-nourished patient due to the increased use of health-related resources (Guest et al. 2011). Using data on health care utilization by people with malnutrition, it was recently estimated that the cost of treating the health problems associated with malnutrition in the UK is in excess of £13 billion per year (Elia and Stratton 2005). In the USA, disease-related malnutrition in the community setting was found to have an annual burden of USD$156.7 billion (£120.2 billion) to society, the large majority of which was due to medical complications associated with malnutrition (Snider et al. 2014). In order to offset the great patient and economic burden, it is essential that the condition is addressed by a multidisciplinary team with the support of the health care system, the community, and society in general.

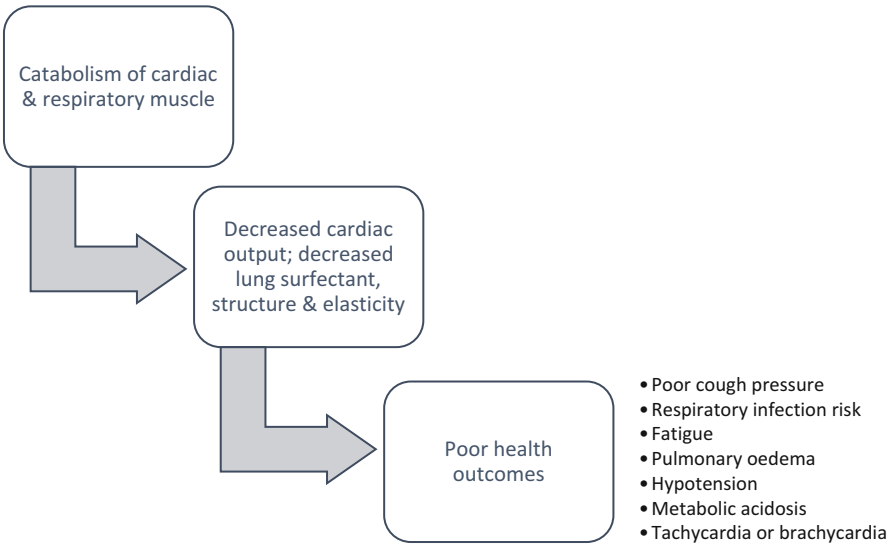

Fig. 5 The physiological process and health outcomes related to respiratory and cardiac muscle catabolism as a consequence of protein-energy malnutrition (2006; Stratton et al. 2003; Pleuss 2005; Ferreira et al. 2011; Martyn et al. 1998). This figure describes how the breakdown of the heart and lungs which occurs in malnutrition will have increased risk of lung infections and water retention, fatigue, low blood pressure, poor coughing, and other heart problems

Starvation in Older Adults

Definition and Diagnosis

Simple starvation is a physiological state referring to the metabolic alterations, such as hypophosphatemia and the production of ketones as the primary energy source, which are activated in a state of food and nutrient deprivation, but when it causes physiological consequences it is clinically referred to as malnutrition (Gallagher 2008; Litchford 2008). Some definitions of starvation are analogous to PEM, that is, a chronic inadequate intake of protein and energy, causing a loss of both fat-mass and fat-free mass (Thomas 2007); which is reflected in starvation being one of the etiology-based definitions of PEM (Fig. 1). Starvation-related malnutrition is only diagnosed when PEM is caused by food and nutrient deprivation over a long period of time in the absence of disease processes and inflammation (White et al. 2012).

Extended periods of starvation may also lead to marasmus, another form of malnutrition also called adapted starvation defined as uncomplicated starvation without inflammation (Gallagher 2008; Litchford 2008). Again, this definition of marasmus, or adapted starvation, is analogous to starvation-related malnutrition. Starvation may also refer to the deprivation of particular nutrients, for example, the deprivation of protein when carbohydrate is regularly consumed may lead to

kwashiorkor, which is also a form of malnutrition characterized by hypoalbuminemia (Gallagher 2008). Overall, starvation may be an important component of malnutrition in some clinical situations, but starvation-related malnutrition should be used as a clinical diagnosis to enhance consistency in terminology across health care facilities and disciplines (White et al. 2012).

Etiology

Starvation-related malnutrition (Fig. 1) is due to pure chronic starvation or anorexia nervosa (White et al. 2012). The social, environmental, physical, and psychological factors which cause PEM (Fig. 2) may also be the cause of starvation-related malnutrition, excepting disease states accompanied by inflammation. One of these physiological causes that occurs in older adults is the "anorexia of ageing," which refers to little to no dietary intake related to the decreased appetite which occurs as part of normal ageing (Visvanathan 2003). Appetite is controlled by interactions between the cortex, limbic system and midbrain, as well as peripheral inputs from the gut, adipose tissue, and endocrine system (Visvanathan 2003). These processes may work less efficiently with increasing age leading to consumption of a less varied and lower quality diet (Visvanathan 2003). However, poor appetite leading to starvation and subsequently weight loss and/or malnutrition is not part of the normal ageing process and is preventable (Huffman 2002).

Prevalence

There is no data regarding the prevalence of starvation-related malnutrition as opposed to PEM in general. However, starvation-related malnutrition may be more likely to be the type of PEM found in older adults living in the community, as malnutrition diagnosed in health care facilities is likely to be acute, disease or injury-related, associated with the reasons for admission.

Outcomes

After several days of starvation, the gastrointestinal tract begins to atrophy, reducing its absorptive capacity; however, with recommencement of nutrient intake, absorptive capacity is returned within days (Beyer 2008). During extended starvation, several organ systems modify their metabolism. Liver gluconeogenesis decreases the production of glucose, and kidney production of glucose increases. The substrates used in liver gluconeogenesis originate from skeletal muscle, which releases glycogenic amino acids, pyruvate, and lactate to be used for gluconeogenesis via the Cori cycle (Gallagher 2008). In the renal gluconeogenesis, the glutamine released by skeletal muscle is deaminated to alpha-ketoglutarate which is used to produce glucose (Gallagher 2008).

Apart from catabolism of lean tissues such as skeletal muscle, fat loss also occurs in starvation-related malnutrition which provides a more stable energy source than glucose produced by gluconeogenesis (Gallagher 2008). During starvation, low insulin levels allow fatty acids to be released from adipocytes and transported to the liver, where they form ketones. Ketones then enter the blood stream and are able to be used as an energy source (Gallagher 2008).

These processes reveal the varying clinical presentation in starvation-related malnutrition as opposed to forms caused by injury or disease; where starvation-related malnutrition more typically presents with low fat and muscle mass, other forms of malnutrition may occur with a the loss of lean tissues only (White et al. 2012).

In terms of poor health outcomes, these are the same for starvation-related malnutrition and PEM in general, excepting outcomes related to low fat mass such as increased fracture risk, may be more common (Stratton et al. 2003).

Sarcopenia in Older Adults

Definition and Diagnosis

The term "sarcopenia," derived from the Greek words "sarx" (flesh) and "penia" (loss), was coined by Professor Irwin Rosenberg in 1989 to describe age-related loss of muscle mass (Baumgartner et al. 1998). Eventually, with improved understanding of sarcopenia, loss of muscle quality, strength, and function or "dynapenia" were also linked with loss of muscle mass (Morley et al. 2014). Under the auspices of four international working groups, namely, European Working Group on Sarcopenia in Older People (EWGSOP), the European Society for Clinical Nutrition and Metabolism Special Interest Groups (ESPEN-SIG), the International Working Group on Sarcopenia (IWGS), and the Society of Sarcopenia, Cachexia and Wasting Disorders, consensus definitions of sarcopenia were released (Table 1) (Cruz-Jentoft et al. 2010; Fielding et al. 2011; Morley et al. 2011; Muscaritoli et al. 2010). These consensus definitions led to sarcopenia being recently recognized as a disease entity in the International Classification of Diseases with its own unique ICD-10 code (Anker et al. 2016).

All four definitions call for the quantification of muscle mass and muscle strength along with measuring deficits in muscle function (Scharf and Heineke 2012). Currently, several parameters are available to measure age-related sarcopenia. A summary of available diagnostic methods along with advantages and limitations is shown in Table 2. With the development of its own unique disease classification code, it is extremely important for identifying the most suitable biomarker for correctly diagnosing, monitoring, and treating sarcopenia (Scharf and Heineke 2012).

Etiology

The etiology of age-related sarcopenia is multifactorial. Declines in nutritional intake, malabsorption of nutrients, reduced physical activity levels, progressive and irreversible loss of motor neurons, although normal in ageing, result in loss of

Table 1 Consensus definitions of sarcopenia. There is no perfect or completely accepted definition of sarcopenia. These are the different recognized definitions put forth by various organizations. EWGSOP, European Working Group on Sarcopenia in Older People; ESPEN-SIG, European Society for Clinical Nutrition and Metabolism Special Interest Groups; IWGS, International Working Group on Sarcopenia

Working group	Definition
European Working Group on Sarcopenia in Older People (EWGSOP) (Cruz-Jentoft et al. 2010)	The presence of: Low skeletal muscle mass AND Low muscle strength (e.g., handgrip) OR Low muscle performance assessed by walking speed or muscle power The presence of all three conditions indicates "severe" sarcopenia
International Working Group on Sarcopenia (IWGS) (Fielding et al. 2011)	The presence of: Low skeletal muscle mass AND Low muscle function assessed by walking speed AND/OR Increased fat mass
Society of Sarcopenia, Cachexia and Wasting Disorders (Morley et al. 2011)	The presence of: Loss of muscle mass AND Limited mobility in the absence of specific diseases of muscle, peripheral vascular disease, disorders of the central and peripheral nervous system, or cachexia
European Society for Clinical Nutrition and Metabolism Special Interest Groups (ESPEN-SIG) (Muscaritoli et al. 2010)	The presence of: Low skeletal muscle mass AND Low muscle strength assessed by walking speed

muscle mass and function (Cruz-Jentoft et al. 2010; Malafarina et al. 2012). Older adults confined to bed due to illness or trauma are highly prone to loss of muscle mass (Malafarina et al. 2012). Age-related loss of immunity causes an increase in inflammatory cytokines and is associated with reduction in muscle mass and strength in older adults (Malafarina et al. 2012). Deterioration in levels of hormones such as estrogen, testosterone, and insulin-like growth factors also contribute to the development of sarcopenia (Malafarina et al. 2012). Coexisting conditions such as osteoporosis, obesity, and type 2 diabetes are also associated with sarcopenia in older adults (Cruz-Jentoft et al. 2010; Malafarina et al. 2012).

Prevalence

Ageing is associated with a 1% decline in muscle mass per decade from 30 years of age, accelerating to approximately 8% loss of muscle mass along with a 10–15% loss of leg strength per decade from the age of 40–70 years (Kim and Choi 2013). After the age of 70 years, this escalates to 15% loss in muscle mass and 25–40% loss in leg strength per decade (Kim and Choi 2013). Although age-related loss of muscle mass is greater in

Table 2 Diagnosis of sarcopenia (Adapted from Scharf and Heineke 2012; Yu et al. 2016). There are various methods available to test if a patient has sarcopenia. This table outlines these and summarizes their benefits and limitations. BIA, Bioelectrical impedance analysis; CT, Computed tomography; DEXA, Dual-energy X-ray absorptiometry; EWGSOP, European Working Group on Sarcopenia in Older People; MRI, Magnetic resonance imaging. SARC-F has no full non-abbreviated title

	Method	Description	Advantages	Limitation
Imaging-related quantification of muscle mass	Magnetic resonance imaging (MRI)	Calculates segmental and total muscle mass; assesses muscle quality through assessing fat infiltration in muscle; quantifies edema and visceral organs	High quality image resolution; accurately quantifies and determines quality of whole-body and regional adipose tissue and skeletal muscle tissue; safe	Expensive; requires specialized setting, trained staff, and specific software; time-intensive; non-portable
	Computed tomography (CT)	Reconstructs image when x-ray attenuation through tissues is detected; identifies adipose tissue, skeletal muscle, bone, visceral organs, and brain tissue	High quality image resolution; accurately quantifies and determines quality of body composition at tissue-organ level; identifies total and regional adipose tissue and skeletal muscle tissue	Expensive; requires specialized setting, trained staff,and specific software; time-intensive; non-portable; considerable radiation
	Dual-energy X-ray absorptiometry (DEXA)	Using low radiation x-rays can differentiate between bone and soft tissue allowing for fat mass to be estimated from soft tissue; assesses bone mineral density	Determines fat, lean and bone tissue for whole body and specific regions; non-invasive, fast; accurate	Requires specialized setting, trained staff, and specific software; hydration and thickness of tissue can influence measurements
	Bioelectrical impedance analysis (BIA)	Measures total body water to estimate fat- and fat-free mass	Portable, simple to use, inexpensive, no radiation exposure, quick	Hydration status and presence of edema can distort results; limited use in those with BMI > 34 kg/m^2 as likely to underestimate fat mass

(*continued*)

Table 2 (continued)

	Method	Description	Advantages	Limitation
Functional tests for muscle performance	EWGSOP algorithm	Measures gait speed and handgrip strength	Low cost; standardized test; simple to use	Results confounded by comorbidities (degenerative and inflammatory conditions); lacks validation studies; not useful in patients with arthritis in hand
	SARC-F questionnaire	Assesses 5 domains: strength, independence, rising from chair, climbing stairs and falls history	Rapid; cost-effective; no measurements required	Low sensitivity

males, sarcopenia-related loss of function and increased disability is greater in women at threefold versus males at twofold (Kim and Choi 2013). Sarcopenia has been identified in 1–30% of community-dwelling older adults, 14–33% of those living in aged care facilities, 10% of those in acute care, and in 50% of those aged over 80 years (Cruz-Jentoft et al. 2014). Prevalence of sarcopenia is also noticeably high in conditions such as stroke (53%) and hip fractures (71%) due to rapid muscle loss associated with denervation and inflammation, respectively (Morley et al. 2014).

Outcomes

Almost 40% of the total body mass and 75% of the body's cell mass is comprised of skeletal muscle, which has a pivotal role in mobility and function (Lang et al. 2010). Age-associated sarcopenia has major ramifications on health-related outcomes in older adults (Fig. 6).

Cachexia in Older Adults

Definition and Diagnosis

Cachexia is a complex syndrome which presents with the loss of body weight, predominately skeletal muscle, as a result of metabolic abnormalities related to disease processes (Evans et al. 2008). The 2008 consensus definition of cachexia is:

Fig. 6 Consequences of sarcopenia (Developed from Lang et al. 2010 and Rolland et al. 2008). These are the poor health outcomes which can be caused by having the condition of sarcopenia

> Cachexia is a complex metabolic syndrome associated with underlying illness and characterized by loss of muscle with or without loss of fat mass. The prominent clinical feature of cachexia is weight loss in adults (corrected for fluid retention) or growth failure in children (excluding endocrine disorders). Anorexia, inflammation, insulin resistance and increased muscle protein breakdown are frequently associated with cachexia. Cachexia is distinct from starvation, age-related loss of muscle mass, primary depression, malabsorption and hyperthyroidism and is associated with increased morbidity. (Evans et al. 2008)

Cachexia is further defined by consensus in the form of "cancer cachexia," the ongoing loss of skeletal muscle mass (with or without fat loss) which cannot be fully reversed by nutrition support and leads to progressive functional impairment. The loss of lean tissues in cancer cachexia is caused by inadequate dietary intake combined with abnormal metabolism (Fearon et al. 2011). Cachexia has been further staged into cachexia and pre-cachexia. The consensus diagnostic criteria and definition of pre-cachexia according to the 2015 ESPEN consensus paper (Muscaritoli et al. 2010) is shown in Fig. 6. However, this ESPEN consensus paper did not provide

Pre-cachexia (all criteria must be met)	Cachexia (weight loss and 3 of the 5 other criteria must be met)
• Underlying chronic disease • Unintentional weight loss ≤5% usual body weight during past 6-monhts • Chronic or recurrent systemic inflammatory response • Anorexia or anorexia-related symptoms	• Weight loss of ≥5% in 12-months (or BMI <20kg/m^2) • Decreased muscle strength • Fatigue • Anorexia • Low fat-free mass index • Abnormal biochemistry (increased inflammatory marekrs, anaemia or hypoalbuminurea)

Fig. 7 The consensus definitions and diagnostic criteria of pre-cachexia according to Muscaritoli et al. (2010) and cachexia according to Evans et al. (2008). These are the criteria which help define if a person has pre-cachexia or cachexia

diagnostic criteria for cachexia; therefore, the diagnostic criteria and definition of cachexia by a 2008 consensus paper is also shown in Fig. 7 (Evans et al. 2008).

There is disagreement in the literature as to whether cachexia is a type of malnutrition (i.e., disease-related malnutrition) or is a separate condition. Some consensus publications state expert agreement that they are separate conditions, where not all malnourished patients are cachectic, but all cachectic patients are malnourished (Muscaritoli et al. 2010). However, this statement will still hold true with the acceptance that cachexia is the same condition as disease-related malnutrition, as both are caused by disease in the presence of inflammation. This is reflected in a more recent consensus statement by ESPEN, which considers disease-related malnutrition and cachexia to be essentially the same condition due to the similarities in presentation and etiology. However, it should be noted that not all persons with chronic-disease related malnutrition may be diagnosed as having cachexia, and further clinical examination should be undertaken to evaluate the level of inflammation in the individual (Cederholm et al. 2015).

Etiology

Conditions which predispose to cachexia and disease-related malnutrition are those that present with systemic inflammation including cancer, chronic infection, chronic kidney disease, chronic obstructive pulmonary disease, AIDS, rheumatoid arthritis, chronic heart failure, and liver failure (Evans et al. 2008; Muscaritoli et al. 2010). The loss of skeletal muscle in cachexia is a result of increased resting energy expenditure mediated by elevated levels of proinflammatory cytokines (e.g., TNF-α, IL-1, IL-6) and decreased anti-inflammatory cytokines (e.g., IL-4, IL-12, IL-15) (Bauer et al. 2006; Muscaritoli et al. 2010). This systemic inflammation causes metabolic abnormalities including a prolonged acute phase protein response, increased muscle proteolysis, and impaired lipid, carbohydrate, and protein metabolism (Bauer et al.

2006; Muscaritoli et al. 2010). Therefore, cachexia is purported to not respond to typical dietary intervention which aims to provide a high protein-high energy diet, and instead other treatment approaches are being explored such as omega-3 fatty acids and mixtures of elemental amino acids (Dewey et al. 2007; Eley et al. 2007), and states of malnutrition and sarcopenia have been described as a "pre-cachectic state," where nutritional intervention may have the most benefit (Evans et al. 2008). However, some research has shown that nutrition intervention may impact upon the pathogenesis of cachexia, although nutrition intervention alone is insufficient to treat the condition (Wilson and Morley 2003; Evans et al. 2008; Isenring and Teleni 2013).

Prevalence

The global prevalence of cachexia is estimated to be 1% of the patient population, which equates to approximately nine million people (von Haehling and Anker 2014). However, the prevalence of cachexia is complicated by the lack of an overall accepted definition and diagnostic criteria, as well as most criteria being difficult to assess, such as the need for measurement of overall lean body mass (e.g., via DXA scans) and assessment of biochemistry (Tan and Fearon 2008). Additionally, the prevalence of cachexia is expected to vastly differ according to the underlying disease process (e.g., cancer versus cardiac failure or pancreatic cancer versus lung cancer) and population characteristics. Following a brief review of the literature, the prevalence of cachexia as reported in various studies is 10–50% (Table 3).

Outcomes

The loss of lean tissues in cachexia results in the dysfunction of multiple organ systems seen in malnutrition (Figs. 4, 5, and 6). However, the weight loss in cachexia differs from the weight loss in malnutrition; although both are characterized by the loss of lean tissues, the loss of lean tissues compared to fat mass is accelerated in cachexia (Bauer et al. 2006). Cachexia also significantly increases the risk of death beyond the rate seen in standard protein-energy malnutrition and is one of the primary causes of death in cancer (Bauer et al. 2006). The increased risk of death in cachexia may be due to the detrimental effect that decreased lean tissues has on the efficacy of medical treatment, such as increased risk of complications, and lower doses and duration of chemotherapy (Donohoe et al. 2011).

Policies and Protocols

National and state-based health services in many countries have a nutrition care policy which aims to address geriatric wasting syndromes such as malnutrition, sarcopenia, and cachexia. Policies for health services typically address nutrition

Table 3 The prevalence of cachexia in different disease states and populations. This table reports the prevalence of cachexia, as a percentage of various populations with other diseases as specified

Underlying disease	Study	Population sample	Reported prevalence (%)
Cancer, all types	Von Haehling and Stefan, 2014 (von Haehling and Anker 2014)	Estimated for entire European population	30
Unresectable pancreatic cancer	Tan and Fearon, 2008 (Tan and Fearon 2008)	Unclear	20
Resectable pancreatic cancer	Bachmann et al. 2008 (Bachmann et al. 2008)	$N = 277$, mean age 64–65 years, 35% female. Germany	41
Colorectal cancer	Thoresen et. al. 2013 (Thoresen et al. 2013)	$N = 77$, mean age 63 years, 47% female. Norway & Canada	28
Chronic obstructive pulmonary disease	Von Haehling and Stefan, 2014 (von Haehling and Anker 2014)	Estimated for entire European population	35
Chronic heart failure	Von Haehling and Stefan, 2014 (von Haehling and Anker 2014)	Estimated for entire European population	10
Chronic heart failure	Christensen et al. 2013	$N = 238$. Not further described	11
Chronic heart failure	Anker et. al. 1997 (Anker et al. 1997)	$N = 171$, mean age 60 years, 11% female. United Kingdom	16
Severe rheumatoid arthritis	Von Haehling and Stefan, 2014 (von Haehling and Anker 2014)	Estimated for entire European population	10
End stage chronic kidney disease	Von Haehling and Stefan, 2014 (von Haehling and Anker 2014)	Estimated for entire European population	50

screening and assessment but may also address the provision of food and monitoring systems (2011). In recognition of the high burden of malnutrition, the United States of America has mandated compulsory nutrition screening upon admission to any health care facility (2017). In the United Kingdom, although individual health services may have policies to manage malnutrition, there is no policy at the national level, and instead there is a guidance document (2015). Nutrition policies may also be supported by malnutrition pathways or nutrition care protocols, which guide clinicians to implementing best-practice, for example, the Malnutrition Action Flowchart in Australia (Banks).

Outside of the health service, there is generally poor development and implementation of malnutrition policies in community and residential aged care settings, as each organization is independent and managing malnutrition may not be part of accreditation standards. However, there are some facilities which are proactive in

addressing this problem and many non-government organizations have arisen to support implementation of malnutrition policies and pathways, such as Managing Adult Malnutrition in the Community (Brotherton et al. 2012) and the UK and Canadian Malnutrition Task Forces (2017a, c).

Dictionary of Terms

- **Acute disease or injury related malnutrition** – Protein energy malnutrition caused by factors related to acute disease or an injury in the presence of a high degree of inflammation.
- **Cachexia** – A complex syndrome which presents with the loss of body weight, predominately skeletal muscle, as a result of metabolic abnormalities related to disease processes.
- **Disease related malnutrition** – Protein energy malnutrition caused by disease-related processes in the presences of a mild to moderate degree of inflammation.
- **Protein energy malnutrition** – A syndrome caused by the inadequate bioavailability of energy and/or protein over time, leading to the catabolism of lean tissues with or without loss of fat mass, occurring most frequently in older adults.
- **Sarcopenia** – The loss of muscle mass, strength, and function that occurs in ageing.
- **Starvation-related malnutrition** – Protein energy malnutrition due to pure chronic starvation or anorexia nervosa but is also affected by social, environmental, physical, and psychological risk factors.

Summary Points

- Protein-energy malnutrition, a syndrome caused by the inadequate bioavailability of energy and/or protein over time, leading to the catabolism of lean tissues with or without loss of fat mass, occurring most frequently in older adults.
- Inadequate energy and protein intake in malnutrition can be caused by not consuming sufficient dietary sources of energy and protein to meet an individual's nutrient requirements, which is exacerbated in states of hypermetabolism, and/or not absorbing the energy or protein consumed. This is further impacted by psychological, environmental, social, and economic risk factors.
- Malnutrition causes systemic catabolism of fat mass and lean tissues, including vital organs of the liver, heart, respiratory system, and skeletal muscle mass.
- Simple starvation is a physiological state referring to the metabolic alterations, such as hypophosphatemia and the production of ketones as the primary energy source, which are activated in a state of food and nutrient deprivation, but when it causes physiological consequences it is clinically referred to as malnutrition.
- Starvation-related malnutrition is due to pure chronic starvation or anorexia nervosa but is also affected by social, environmental, physical, and psychological risk factors.

- During extended starvation, several organ systems modify their metabolism. Liver gluconeogenesis decreases the production of glucose and kidney production of glucose increases. Fat loss also occurs in starvation-related malnutrition which provides a more stable energy source than glucose produced by gluconeogenesis.
- Sarcopenia is the loss of muscle mass, strength and function that occurs in ageing.
- The etiology of age-related sarcopenia is multifactorial. Declines in nutritional intake, malabsorption of nutrients, reduced physical activity levels, progressive and irreversible loss of motor neurons, although normal in ageing, result in loss of muscle mass and function.
- Sarcopenia has a significant impact on the independence of older adults and is also known to increase the risk of depression and type II diabetes.
- Cachexia is a complex syndrome which presents with the loss of body weight, predominately skeletal muscle, as a result of metabolic abnormalities related to disease processes.
- Conditions which predispose to cachexia and disease-related malnutrition are those that present with systemic inflammation including cancer, chronic infection, chronic kidney disease, chronic obstructive pulmonary disease, acquired immune deficiency syndrome, rheumatoid arthritis, chronic heart failure, and liver failure.
- Cachexia also significantly increases the risk of death beyond the rate seen in standard protein-energy malnutrition and is one of the primary causes of death in cancer.

Conclusion

There is ample evidence showing that weight and muscle loss seen in PEM, starvation, sarcopenia, and cachexia are associated with frailty, loss of independence, poor prognosis, and increased mortality. Although these conditions present with similar characteristics, differential diagnosis is important in the clinical setting so that the patient may be linked with the most appropriate treatment and that new methods of management may be developed.

Abstract

Significant weight loss caused by malnutrition seems to be one of the leading symptoms associated with cancer development. Presence of malnutrition in oncologic patients is most frequently a result of insufficient nutrition and overactivation of inflammatory response. It leads to progressive wasting of the body as a consequence of the increased body catabolism and changes in body composition, and even may develop cancer cachexia – a systemic wasting that cannot be completely compensated by conventional nutrition support. In numerous cancer patients, presence of malnutrition is commonly a first indicator and symptom of the tumor development.

The nutrition status of such patients is significantly associated with risk of the disease complication during therapy and may result in extension of patients' hospitalization. Moreover, in some group of cancer individuals, the progressive malnutrition leading to cachexia is a main cause of death and not underlying disease. Based on above facts early malnutrition assessment is required for cancer nutritional support. There are various tools used in nutritional status evaluation in the form of scales, questionnaires or risk assessments, anthropometric examinations, and biochemical tests. Despite that they provide a valuable information about patient's nutrition status, also require arrangement various method of their evaluation. Currently, the particular attention is drawn into imaging tools which could provide as a single method the assessment of a body composition. Among these tools the bioelectrical impedance analysis serves as an objective, reliable, and noninvasive method of malnutrition assessment. Bioelectrical impedance analysis measures body compositions electronically, and parameters obtained during examination refer to body vitality at a cellular level, e.g., fluid distribution in the body, fat mass or fat free mass. Also, other parameters derived from bioelectrical impedance analysis demonstrate high clinical utility in malnutrition assessment in cancer patients.

Appropriate evaluation of body composition in cancer patients may provide diagnostic or prognostic information, which seems more valuable than weight loss or body mass index change. In present study the literature review of bioelectrical impedance analysis usefulness in cancer malnutrition assessment is described.

TBW	Total body water
Xc	Reactance
Z	Impedance

Definition of Malnutrition

Malnutrition due to starvation, disease, or aging can be defined as a "state resulting from lack of uptake or intake of nutrition leading to altered body composition (decreased fat free mass) and body cell mass leading to diminished physical and mental functions and impaired clinical outcome from disease" (Sobotka 2012).

Patients who are identified at risk of malnutrition have two options of the diagnostic criteria which one of them should be fulfilled: the first requires a body mass index (BMI) <18.5 kg/m^2. The alternative way includes weight loss (unintentional) $> 10\%$ indefinite of time, or $>5\%$ over the last 3 months combined with either:

- BMI < 20 kg/m^2 if <70 years of age, or <22 kg/m^2 if ≥ 70 years of age or
- fat free mass index (FFMI) <15 and 17 kg/m^2 in women and men, respectively (Cederholm et al. 2016)

According to the etiology, malnutrition is divided into three main areas:

1. Disease-related malnutrition (DRM) with inflammation
2. Disease-related malnutrition without inflammation (acute disease or injury-related and chronic DRM with inflammation)
3. Malnutrition without disease (socioeconomic-, hunger-, or psychologic-related) (Cederholm et al. 2016).

The second etiology area includes cancer cachexia and other disease-specific cachexia.

Nutrition Assessment Tools

The nutrition assessment methods with various scope of usage have been described below.

Nutrition Interview

The basic way of assessing the malnutrition status is taking precise patient history. It facilitates the determination of the risk of nutrition disorders or the evaluation of the degree of the process severity. The assessment of daily food intake provides key information.

There are various tools used in nutritional status evaluation in the form of scales, questionnaires, or risk assessments. Below, we have listed the ones with the greatest potential for the evaluation of the nutritional status in cancer patients that are recommended by ESPEN:

- MUST scale *(Malnutrition Universal Screening Tool)*
- NRS-2002 (*Nutritional Risk Screening*)
- MNA-SF *(Mini Nutritional Assessment – short form)*
- SGA (*Subjective Global Assessment*)
- PG-SGA (*Patient-Generated Subjective Global Assessment*)

Physical Examination

The patient history is supplemented with physical examination. The most important element of the examination is body weight assessment and the measurement of involuntary body weight loss in time. However, it should be noted that the factor of time is, in this case, dependent on the treatment phase.

In 2015, according to ESPEN consensus the following body weight loss cutoff points have been established:

1. Involuntary body weight loss $>$ 5% within 3 months or
2. Involuntary body weight loss $>$ 10% in undefined time (Cederholm et al. 2015)

Studies confirmed that body weight loss is an important prognostic factor (Jagielska 2011). They demonstrated a correlation between body weight loss and response to treatment and patient survival time (Jagielska 2011).

Anthropometric Examinations

The anthropometric examinations that are the most important and most frequently used in the nutritional status assessment are (http://polspen.pl/assets/files):

- BMI (*body mass index*)
- WHR (*waist to hip ratio*)
- Measurement o skinfolds in appropriate sites, most frequently over the biceps, triceps, under the shoulder blade, and over the hip
- Arm circumference
- Fat tissue percentage using anthropometric formulas

Functional Tests (http://polspen.pl/assets/files)

The most important functional tests are:

- Direct stimulation of muscles (most frequently electric stimulation of adductor pollicis muscle)

- Respiratory resistance measurement
- Hand grip

Biochemical Tests

The most frequently used laboratory examinations evaluating the nutritional status are:

- Albumin level
- Hemoglobin level
- Transferrin level
- Prealbumin level
- Retinol binding protein level
- Fibronectin level
- CRP level
- IL-6 level
- Number of lymphocytes in peripheral blood

Image and Other Tools

The most frequently used imaging examinations evaluating the nutritional status are:

- CT (computed tomography)
- MRI (magnetic resonance imagery)
- Adipometry (ultrasound of adipose tissues)
- BIA (bioelectrical impedance analysis)

Introduction to Bioelectrical Impedance Analysis

Impedance constitutes a measurement parameter of the bioelectrical impedance analysis. Impedance is the total resistance of the body to alternating current. In the cylindrical structure it depends on the cylinder length L and the cross section area A, according to formula $Z = \rho L/A$, where ρ is the specific resistance of a material (Fig. 1).

The cylinder volume is calculated by multiplying the length by the cross section area A:

$$V = A \times L$$

Formula $Z = \rho L/A$ can also be expressed as $A = \rho L/Z$ and introduced to the above formula, which results in the formula:

$$V = \rho L^2/Z$$

It is assumed for the purpose of measurement that human body consists of five cylinders (upper limbs, trunk, lower limbs), which are connected in serious electrically (Fig. 2).

Impedance consists of two elements:

1. **Resistance (R)**, which is the resistance (measured in Ohms) of the whole body water and electrolytes dissolved in it
2. **Reactance (Xc),** which is the capacitive resistance of body cells acting like condensers

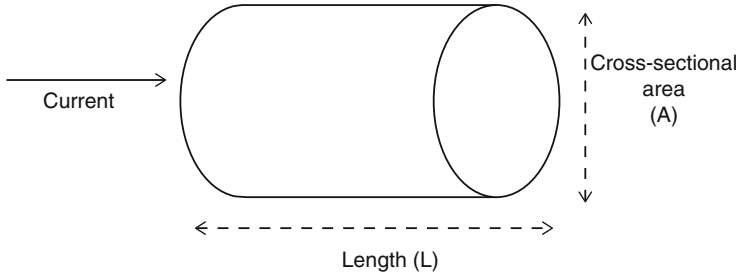

Fig. 1 Cylindrical model for the correlation between impedance and geometry (Source: own preparation based on: (Kyle et al. 2004))

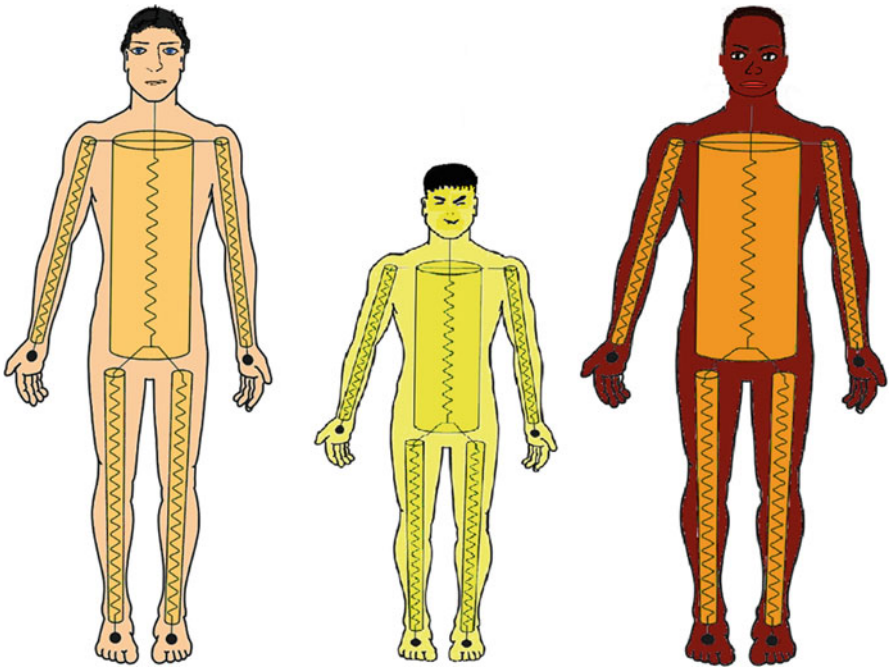

Fig. 2 Human body as a conductor consisting of five cylinders, in three ethnic groups (Source: own preparation based on: (Kushner 1992))

Ad. 1. Resistance (R) (resistivity, electric resistance, active resistance) is the resistance of a conductor towards alternating current, which means that it is inversely proportional to the total amount of water in the organism. Due to significant amount of water and electrolytes, the lean body mass is a good electric current conductor, while the fat tissue is characterized with high resistance.

Resistance is a perfect measure of the amount of body water in healthy people with normal body weight. About 95% of resistance is generated in the limbs and thus it depends on changes of the water content in the extremities. If the measured resistance exceeds normal values, which can occur in case of low water content in limbs (low temperature, high pressure), when using this method, the water content calculation will produce results that are too low, and thus, the fat tissue content will look too high. When blood circulation in the limbs increases or is partly blocked, the resistance values fall and the water and lean body mass content will be too high while the calculated fat tissue mass will be too low.

Ad. 2. Reactance (Xc) (capacitative or passive electric resistance) is the resistance of a capacitator towards alternating current. All cell membranes in the body act as mini-capacitators due to the content of protein-lipid layers. Thus, reactance is the measure of the body cell mass.

The living (live) cells of the body, tissues, organs, and the entire living organisms demonstrate active-capacitative character. Resistance is nonlinear and changes with the frequency of the conducted current (decreases when the frequency increases). Capacitative reactance (capacitance) also demonstrates curvilinear correlation with the frequency (Fig. 3).

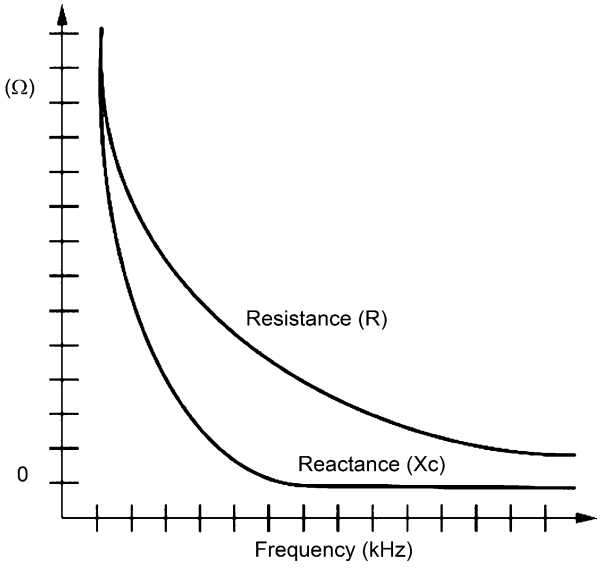

Fig. 3 The correlation between capacitative resistance (Xc) and inductive resistance (R) at defined alternating current frequency (Source: own preparation based on: (Kushner 1992))

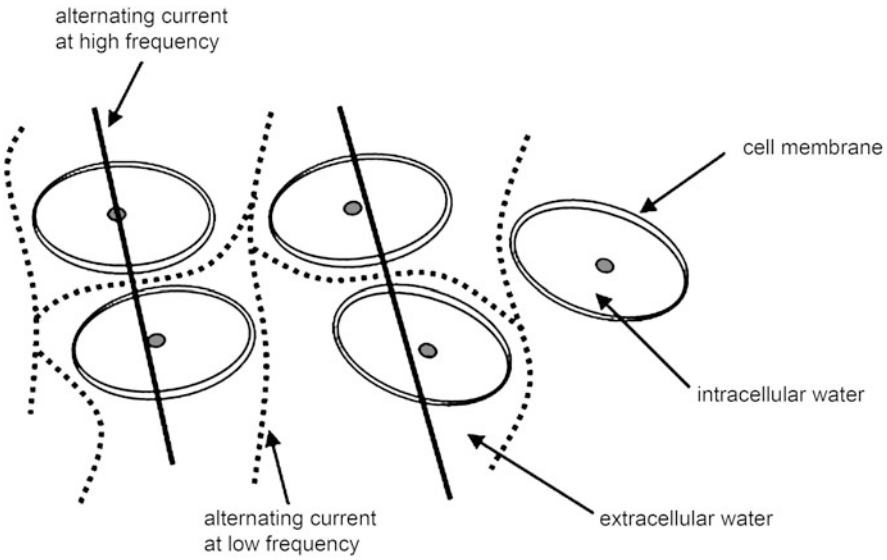

Fig. 4 A graph illustrating the alternating current distribution in relation to the frequency spectrum (Source: own preparation based on: (Cole 1972))

At zero (or low) frequency, electric current does not penetrate the cell membrane, which acts as an insulator and therefore the current only flows through the extracellular fluid which is then responsible for the measurement of the R element of the whole body resistance.

At indefinite (or very high) frequency, the capacitator acts like a perfect (or almost perfect) capacitator and thus the total R – resistance of the organism – reflects the combined resistance of extra- and intracellular fluid (Fig. 4).

Thanks to bioelectrical impedance analysis we obtain direct values (raw data) and indirect values (calculated data) presented below (Table 1). The difference between them results from the fact that the latter (indirect values) do not constitute direct BIA measurement results but can be calculated only after applying appropriate formulas.

The correlation between reactance and resistance is reflected in a parameter obtained using bioelectrical impedance analysis in the form of phase angle. Phase angle is calculated on the basis of resistance and reactance according to phase angle formula = arc tangent Xc/R. Biological significance of the phase angle is not fully understood but it is considered to be an indicator of cellular health. Phase angle value is closely correlated with body cell mass (BCM) (Gonzalez et al. 2013). Higher phase angle value is correlated with better cell function. It is an indicator of cell membrane integrity. Its value is influenced by the difference between the potential on the internal and external side of cell membranes. In case of well-nourished cells, their reactance is high, which implicates high phase angle value. In contrast, cells in bad condition lose membrane integrity, which is reflected by low phase angle value. Thus, it depends on the condition of integral components of cells responsible for biochemical and energetic activity (Selberg and Selberg 2002; De Oliveira et al.

Table 1 Division of parameters obtained from bioelectrical impedance measurements

Raw data	Calculated data
Cm – capacitance of membrane	FFM – fat free mass
Z – impedance	LBM – lean body mass
R – resistance	BCM – body cell mass
Xc – reactance	FM – fat mass; BF – body fat
PA – phase angle	ECM – extracellular mass
	TBW – total body water
	ECW – extracellular water
	ICW – intracellular water

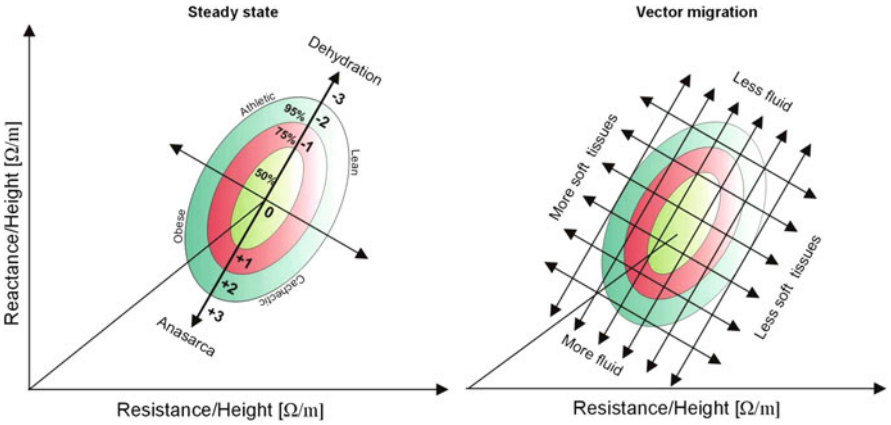

Fig. 5 Bioelectrical impedance vector analysis (BIVA) method (Source: own preparation based on: (Piccoli 2002))

2012). In this aspect, the value of this parameter reflects the efficiency of energy processes and proteolysis, indicating direct relationship with patient health status (De Oliveira et al. 2012).

The resistance and reactance values can be presented as a graphic illustration of human body resistance on the coordinate system (bioelectrical impedance vector analysis) (BIVA acc. to Piccoli) (Piccoli et al. 1994, 2002). In order to do that, the capacitative resistance of body cells (Xc, reactance) is marked on the Y axis, and the water and its electrolyte content resistance (R, resistance) on the X axis. Both values are related to body height (Xc/height and R/height), i.e., standardized for the length of the conductor. Placing the measured values of Xc/height and R/height on the coordinate system allows for determination of an individual vector that looks like an arrow (Fig. 5). This vector picture allows to examine both values (R and Xc) in a patient (Toso et al. 2000, 2003). Because the equation only includes body conductivity characteristics, the analysis is not independent from patient's body weight. The content of fat tissue that acts as electrical insulator is not included in the analysis either.

Due to the fact that the BIA vector position also depends on factors influencing physiology (sex, age, BMI) separate evaluation of pathological changes in the body content (overhydration, dehydration, low BMI, cachexia) may be conducted by comparing the measurement results with tolerance ellipses for the same sex and comparable age group and BMI.

Literature Review of BIA Usefulness in Malnutrition Assessment

BIA is a reliable, noninvasive, and, above all, an objective tool to assess body composition. It can be used both in healthy subjects as well as in various groups of patients (Barbosa-Silva and Barros 2005). It has been widely used in patients affected by kidney disease (hemo- or peritoneal-dialyzed patients), COPD, AIDS, cirrhosis, and heart failure. Recently, most researchers suggest beneficial effect of using BIA to assess body composition (as a tool for screening for malnutrition or cachexia) in different sets of cancer patients (Mulasi et al. 2015; Grundmann et al. 2015). Depending on the type of tumor, weight loss occurs in 30–90% of patients. At the time of diagnosis, in approx. 60% of patients with lung cancer and approx. 80% of patients with cancer of the upper gastrointestinal tract, significant decreases in body weight are recorded. Weight loss is an unfavorable prognostic factor for patients with most types of cancer. Mortality of patients with cachexia syndrome was reported to be as high as 80%. Death usually occurs when weight loss reaches 30–40%. In approx. 20% of patients the direct cause of death is cancer cachexia. Interestingly, signs of malnutrition precede the diagnosis of cancer by several months (Argilés et al. 2013; Dewys et al. 1980; Fearon et al. 2011). Therefore, appropriate body composition evaluation in cancer patients may provide diagnostic or prognostic information, which seems more valuable than weight loss or BMI change.

In cancer patients, BIA parameters are used for an objective evaluation of nutrition status (to distinguish between patients with normal nutrition, malnutrition, and cachexia) and usually compared with subjective scales (SGA, NRS) or as a prognostic factor (assuming that adverse changes in body composition serve as a marker of disease progression).

Phase Angle

The phase angle is used as a general measure of the membrane integrity of the cells. It provides information about the state of a cell and the overall condition of a patient's body. To date, in cancer patients, only few parameters have been evaluated widely, of which PA was assessed most frequently. It was evaluated in solid (HNC, hepatocellular carcinoma (HCC), nonsmall cell lung cancer (NSCLC), pancreatic cancer, breast cancer, colorectal cancer (CRC), and hematological tumors. BIA usefulness as a tool for assessing the nutritional status of cancer patients has been

confirmed in many studies. In the study by Gupta et al. (2008b) in advanced colorectal cancer, PA cutoff of 5.2 was 51.7% sensitive and 79.5% specific whereas a cutoff of 6.0 was 82.8% sensitive and 54.5% specific in detecting malnutrition. Büntzel et al. (2012) showed that in HNC patients PA value of 4.0–5.0 was assessed as high risk of malnutrition development. Moreover they noticed stabilized PA in survivors (4.7 to 5.2) whereas patients who died exhibited a significantly lower phase angle (4.6 to 3.7). Also Małecka-Massalska et al. (2016a) demonstrated that well-nourished HNC patients had a statistically significantly higher PA score (5.25) as compared to those who were malnourished (4.73). A PA cutoff of 4.73 was 80% sensitive and 56.7% specific in detecting malnutrition diagnosed by SGA in these populations. However, Stegel et al. (2016) noted that PA does not allow to distinguish malnourished HNC patients from cachectic ones. Whereas several researchers suggest the possibility of using the PA as a predictive factor for the applied therapy (Schwenk et al. 2000). Burden et al. (2010) in a study concerning colorectal cancer suggest that nutritional screening would be beneficial preoperatively to identify weight-losing patients at an early stage in the care pathway when they initially enter the secondary care system. Małecka-Massalska et al. (2014a) showed that PA measured at 50 kHz was found to be significantly lower in patients after surgery than before treatment (4.22 vs. 4.69 respectively). Moreover, numerous studies confirm that PA could be used as a prognostic factor in different sets of cancer patients. Gupta et al. (2004) showed that advanced colorectal patients with a PA $\leq$ 5.57 had a significantly shorter median survival (8.6 months) compared to those with a PA $>$ 5.57 (40.4 months). In the next study (Gupta et al. 2008a), they demonstrated similar results in breast cancer patients in which PA $\leq$ 5.6 had significantly shorter survival (23.1 months), than those with a PA $>$ 5.6 (49.9 months). The same authors (Gupta et al. 2009) also confirmed above findings in another set of cancer patients (advanced NSCLC). In this study, patients with PA $\leq$ 5.3 showed poor survival (7.6 months) when compared to other patients with PA $>$ 5.3 (12.4 months). These results were confirmed later by other authors (Sánchez-Lara et al. 2012). Lower PA (cutoff 5.8) correlates with worse patient survival (11 months) when compared to higher PA $\geq$ 5.8 (17 months), and this parameter was an independent prognostic factor of NSCLC patient survival. Similar results were obtained by Norman et al. (2010) in several solid and hematological tumors. They concluded that standardized PA is an independent predictor for impaired functional and nutritional status and a better indicator of 6-months' mortality than are malnutrition and disease severity in cancer. In the study of Władysiuk et al. (2016) performed in patients with advanced HNC, lower PA value ($<$4.733) was associated with significantly higher risk of overall survival (OS) shortening (19.6 vs. 40 months respectively). Such results were also demonstrated in hepatocellular carcinoma patients. In this study, Schütte et al. (2015) found that PA values (cutoff 4.8) affect patient survival. Lower PA ($<$4.8) was associated with shorter OS (298 days) when compared with higher PA value ($\geq$4.8) (399 days). Similar results were also obtained by Lee et al. (2014) in a set of terminal patients (advanced stages of solid and hematologic cancers) previously treated with surgery, CTH and RTH. In this case, PA presents positive correlation with patient survival. Lower PA score was

related with poor disease prognosis; survival was shorter than 25 days when PA was <4.4 and longer than 50 days when PA was above >4.4. Moreover, a PA analysis can be used to determine nutritional risk in cancer patients undergoing RTH. In a study by Souza et al. (2015) conducted in pre-radiotherapy patients (with advanced stages of solid and hematologic cancers), lower PA (cutoff 5.2) was established as a criterion for identifying patients with higher risk of malnutrition. Also Castanho et al. (2013), in their study in non–small cell lung cancer (NSCLC) advanced patients (stage IB-IIIB), concluded that PA may be used as an assessment tool for evaluation of needs for nutritional treatment in those patients because it informs about disease severity. They demonstrated that PA is closely related with tumor mass volume, which may provide important information about early nutritional intervention requirements in NSCLC patients. In another study (Richter et al. 2012) conducted in pancreatic cancer, the authors show that parenteral nutrition (supported with sufficient level of calories) started in appropriate moment led to improvement of nutritional status of patients. Moreover, Jager-Wittenaar et al. (2014) showed that PA and other BIA parameters are appropriate for FFM evaluation and can be used as a part of a comprehensive malnutrition evaluation in HNC patients.

Capacitance of Membrane

To date, only one paper is available describing a raw data derived parameter, other than PA, useful in evaluation of nutritional status of cancer patients. In a study by Małecka-Massalska et al. (2016b) conducted in advanced (stage III and IV) HNC patients, higher Cm values in well-nourished patients, compared to malnourished ones, were observed (1.41 vs. 1.01 respectively). Cutoff value of 0.743 (established by ROC analysis) was characterized by very high specificity (98%) and medium-low sensitivity (37%) in the detection of malnutrition. Moreover, in patients with Cm values below cutoff, shorter OS was noted when compared to other patients (12.1 and 43.4 months, respectively).

Calculated Parameters

Raw data are used for estimation of numerous calculated parameters including: total body water (TBW), intracellular body water (ICW), extracellular body water (ECW), body cell mass (BCM) and, thus, body fat mass (FM), fat-free body mass (FFM), lean body mass (LBM), extracellular mass (ECM), ECM/BCM index, body fat (BF), and other. These parameters, also characterizing nutritional status of a patient, usually play supporting role in malnutrition assessment (Piccoli et al. 1997; Schwenk et al. 1998).

In a study by Małecka-Massalska et al. (2014b) conducted in patients with HNC (in operable stages), the well-nourished patients had significantly lower ECM/BCM ratio (1.11 vs. 1.28) when compared to malnourished patients. Cutoff value established at 1.194 (according to ROC analysis) was 76% sensitive and

63% specific in detection of malnutrition condition. In another study (Castanho et al. 2013), ECM/BCM ratio was evaluated as malnutrition indicator of NSCLC (stage IB-IIIB) patients. The values >1.22 were assessed as high risk indicator of malnutrition development in studied subjects. Moreover, authors considered that the ECM/BCM ratio is a valuable marker of patients' nutritional status and also could be used as a potential marker of hypermetabolic tumors. Regarding patients' survival, the study participants with the highest ECM/BCM ratio (>1.5) had shorter survival time compared to patients with lower value of this parameter. In recent German study (Schütte et al. 2015), the positive correlation of BCM with body weight, BMI, and MUAC (circumference of thigh and mid-upper arm circumference) as well as negative correlation of this parameter with age was found in HCC patients. Moreover, authors reported that differences in BCM percentage among studied subjects had no impact on patients' survival probability. Interestingly, study results demonstrated a significant correlation between BIA screening (BCM, ECW%TBW, PA) and NRS (The Nutritional Risk Score) in malnutrition assessment of HCC patients, whereas such correlation was not observed between BIA and MNA (Mini Nutritional Assessment) screening tool. Trabelsi et al. (2006) considered that also parameters such as FMI (fat mass index) and FFMI (free-fat mass index) can provide reliable assessment of malnutrition in patients suffering from various cancers. According to study results, BIA analysis of FMI and FFMI can be more objective screening tool for malnutrition detection than BMI because some patients demonstrate relative high BMI despite the presence of malnutrition. The high utility of BIA for reliable assessment of FFM was also proved in group of HNC patients (Jager-Wittenaar et al. 2014). In a study by Lopes et al. (2013), both anthropometric and BIA methods were used to assess malnutrition status of CRC patients in two periods, before and after surgery. Parameters including FFM, TBW, and BFM demonstrated high utility to measure changes of body composition in patients who underwent surgery. Considering this, the mentioned parameters are especially important to estimate nutritional status of surgically treated CRC patients as well as to detect early symptoms of developing malnutrition, which could facilitate personalized nutritional intervention in future. Usefulness of FFM, BCM, and TBW was also evaluated in malnutrition screening of preoperative CRC patients (Burden et al. 2010). Measurements of body composition using BIA demonstrated that malnourished CRC patients showed less FFM in contrast to not malnourished subjects. The significant differences in FFM between patients who had lost <10% of their body weight and those who had lost >10% of their body weight were reported. These patients could potentially benefit from BIA nutritional screening, because it allows identification of weight-losing patients at an early stage. The significant correlation between FFM and BMI was found in patients with various types of advanced cancer (Slaviero et al. 2003). Furthermore, MNA and weight change demonstrated no significant relationships with results of BMI and FFM in study population. It may suggest that analysis of FFM could improve assessment of malnutrition performed by only MNA and BMI measurement (Gupta et al. 2006; Muramatsu et al. 2015) (Table 2).

Table 2 Overview of research using BIA parameters in the assessment of malnutrition in cancer patients

Study (country)	Year	Cancer (stage)	Study design	Study group (M-male, F-female)	Age (years ±SD)	Malnutrition assessment	BIA parameters
Władysiuk et al. (Poland)	2016	Head and neck cancer (stage III and IV)	Prospective	75 patients (M = 67, F = 8) therapy naive	Mean: 56.9 ± 8.2	PG-SGA, BIA	PA (Mean: 5.04 ± 0.88)
Małecka-Massalska et al. (Poland)	2016b	Head and neck cancer (stage III and IV)	Prospective	75 patients (M = 67, F = 8) therapy naive	Mean: 56.9 ± 8.2	PG-SGA, BIA	Cm (Mean: 1.75 ± 0.55)
Małecka-Massalska et al. (Poland)	2016a	Head and neck cancer (stage III and IV)	Prospective	75 patients (M = 67, F = 8) therapy naive	Mean: 56.9 ± 8.2	PG-SGA, BIA	PA (Median: 5.04 ± 0.88)
Stegel et al. (Slovakia)	2016	Head and neck cancer	Prospective	55 patients analyzed pre- and post-RCTH	Unknown	SGA	PA (before and after treatment)
Schütte et al. (Germany)	2015	Hepatocellular carcinoma (HCC)	Prospective	51 patients (M = 44, F = 7)	Mean: 66.2 ± 9.82	Anthropometric, BIA	PA (Mean: 4.77 ± 0.89), TBW, ECW, ICW, FM, BCM
Souza et al. (Brazil)	2015	Solid and hematologic tumors	Prospective	93 patients (M = 67, F = 26) pre-RTHC	Median: 62 ± 12.74	Anthropometric, PG-SGA, BIA	PA (Median: 5.95 ± 1.0)
Muramatsu et al. (Japan)	2015	Pancreatobiliary tract and urothelial cancer	Retrospective	37 patients (M = 23, F = 14) treated with gemcitabine-based CTH	Mean: 68.3	BIA	BFR, SMR, BMI, basal metabolism

Małecka-Massalska et al. (Poland)	2014a	Head and neck cancer (operable stages)	Prospective	31 patients (M = 28, F = 3) analyzed pre- and post-surgically	Mean: 57.9 ± 8	SGA, BIA	PA (Mean: 4.69 ± 0.71)
Małecka-Massalska et al. (Poland)	2014b	Head and neck cancer (operable stages)	Prospective	75 patients (M = 67, F = 8) preoperative	Mean: 56.9 ± 8.2	SGA, BIA	ECM/BCM
Jager-Wittenaar et al. (Netherlands)	2014	Head and neck cancer	Prospective	24 patients (M = 20, F = 4) analyzed pre- and twice post-therapy	Mean: 60.4 ± 8.3	BMI, BIA	PA, ECW/ICW, FFM
Lee et al. (South Korea)	2014	Terminal cancers – solid and hematologic (advanced stages)	Prospective (preliminary)	28 patients (M = 13, F = 15) previously treated with surgery or CTH and RTH	Range from 30 to >70	Unknown	PA (Median: 4.50)
Castanho et al. (Brazil)	2013	Nonsmall cell lung cancer (NSCLC) (stage IB-IIIB)	Cross-sectional study	30 male patients, therapy naive	Mean: 65.6 ± 9.3	Anthropometric, BIA	PA (Mean: 5.66 ± 0.90) ECM/BCM (1.28 ± 0.14)
Lopes et al. (Portugal)	2013	Colorectal cancer (operable stages)	Prospective	50 patients (M = 33, F = 17) analyzed pre- and post-surgically	Mean: 66 ± 12	Anthropometric, BIA, PG-SGA	BFM, FFM, TBW, SLM
Büntzel et al. (Germany)	2012	Head and neck cancer	Retrospective	66 patients (M = 50, F = 16) adjunctive or primary RTH	Mean: 67.7	BIA	PA

(*continued*)

Table 2 (continued)

Study (country)	Year	Cancer (stage)	Study design	Study group (M-male, F-female)	Age (years ±SD)	Malnutrition assessment	BIA parameters
Richter et al. (Germany)	2012	Pancreatic cancer	Retrospective	17 patients (M = 11, F = 6) parenteral nutrition support, CTH	Mean: 64 Median: 66	SGA	PA, BCM, ECM, ECM/BCM
Sánchez-Lara et al. (Mexico)	2012	NSCLC (stage IIIB and IV)	Prospective	119 patients (M = 64, F = 55) treated with paclitaxel-based CTH	Mean: 60.5 ± 12.5	SGA	PA (Mean: 5.8 ± 1.8)
Norman et al. (Germany)	2010	Solid and hematologic tumors	Prospective	399 patients (M = 208, F = 191) therapy naive	Mean: 63.0 ± 11.8	SGA	PA (Mean: 4.59 ± 1.12)
Burden et al. (United Kingdom)	2010	Colorectal cancer (operable stages)	Prospective	87 patients (M = 54, F = 33) preoperative	Mean: 64.5	SGA, MUST	Fat (kg, %), FFM (%), DLW (kg), BCM, TBW (%)
Gupta et al. (USA)	2009	NSCLC (stage IIIB and IV)	Retrospective	165 patients (M = 93, F = 72) newly diagnosed and treated – not specified	Median: 56 ± 9.1	BIA	PA (Median: 5.3)
Gupta et al. (USA)	2008a	Breast cancer (stage I–IV)	Retrospective	259 female patients newly diagnosed and treated – not specified	Median: 49	SGA	PA (Median: 5.6)

Gupta et al. (USA)	2008b	Colorectal cancer (stage III and IV)	Retrospective	73 patients (M = 38; F = 35)	Mean: 56 ± 11.4	SGA	PA (Mean: 5.7 ± 1.3)
Trabelsi et al. (Tunisia)	2006	Different cancers	Retrospective	83 patients (M = 18, F = 65) surgically treated	Unknown	BMI	FFMI, FMI
Gupta et al. (USA)	2006	Colorectal cancer (stage III and IV)	Retrospective	58 patients (M = 35, F = 23) newly diagnosed and previously treated – surgery and CTH	Mean: 58 ± 10.6	SGA	PA (Mean: 5.7 ± 1.4)
Gupta et al. (USA)	2004	Colorectal cancer (stage IV)	Retrospective	52 patients (M = 30, F = 22) newly diagnosed and previously treated	Mean: 55.8 ± 10.8	SGA	PA (Mean: 5.6 ± 1.5), LBM, FM, BCM
Slaviero et al. (Australia)	2003	Lung, breast, and prostate cancer (locally advanced and/or metastatic)	Retrospective	73 patients (M = 40, F = 33) treated with palliative CTH	Mean: 61 Median: 63	Mini Nutritional Assessment	TBW, FFM, FFM (%), FM

Dictionary of Terms

- **Body cell mass (BCM)** – In contrast to extracellular mass (ECM), it reflects all the metabolically active tissues of the body, such as organ, muscle, and blood cells. Body cell mass also includes water inside the living cells, called intracellular water (ICW).
- **Bioelectrical impedance (BIA)** – Imaging examination evaluating the nutritional status by electrical measurement of body composition. BIA is a reliable, noninvasive, and an objective tool to assess body composition which can be used both in healthy subjects and in various group of patients, e.g., cancer, chronic diseases.
- **Cachexia** – Marked state of weight loss and malnutrition usually associated with a chronic disease or cancer that cannot be compensated by nutritional support.
- **Extracellular mass (ECM)** – Reflects all the metabolically inactive tissues of the body, such as blood plasma or bone minerals. Extracellular mass also includes extracellular water (ECW).
- **Extracellular water (ECW)** – Reflects the total amount of body water contained outside cells, together with intracellular water (ICW) is a component of total body water (TBW).
- **Intracellular water (ICW)** – Reflects the total amount of body water contained within cells, together with extracellular water (ECW) is a component of total body water (TBW).
- **Fat free mass (FFM)** – (Lean or nonfat components) BIA calculated parameter that refers total amount of all body components except fat.
- **Fat free mass index (FFMI)** – Is an indicator of body condition alternative to BMI and is used to calculate amount of muscle mass with following formula: value from the percentage ratio of body fat percentage, the height in meters, and weight in kg.
- **Malnutrition** – State characterized by faulty nutrition because of inadequate uptake or intake of nutrients leading to altered body composition resulting in diminished physical and mental functions and impaired clinical outcome from disease.
- **Nutritional status** – Reflects the index of nutrients intake, digestion, and absorption influenced by a diet as well as ability of assimilated nutrients level to maintain normal metabolic integrity.
- **Phase angle (PA)** – Is a BIA parameter calculated on the basis of resistance and reactance according to following formula = arc tangent Xc/R. Phase angle is usually used as a general measure of the membrane integrity of the cells.
- **Reactance (Xc)** – (Resistance of a capacitator towards alternating current) raw parameter obtained from BIA measurement. Resistance is the capacitive resistance of body cells acting like condensers.
- **Resistance (R)** – (Resistance of a conductor towards alternating current) raw parameter obtained from BIA measurement. Resistance is the resistance (measured in Ohms) of the whole body water and electrolytes dissolved in it.

- **Total body water (TBW)** – Parameter reflecting water contained in lean body mass. Total body water consists of two compartments: extracellular water (ECW) and intracellular water (ICW). Total body water is calculated parameter of BIA referring basic hydration status of the body.

Summary Points

- Weight loss occurs in 30–90% of cancer patients depending on the type of tumor.
- Bioelectrical impedance analysis is one of the objective methods for the nutrition assessment.
- Parameters obtained by bioelectrical impedance analysis are two types: direct (impedance, resistance, reactance, capacitance of membrane, phase angle) and indirect (fat free mass, lean body mass, body cell mass, fat mass, extracellular mass, total body water, extracellular water, intracellular water). The difference between them results that the latter (indirect values) do not constitute direct bioelectrical impedance measurement results but can be calculated only after applying appropriate formulas.
- Either direct or indirect parameters are used in the nutrition assessment.
- Impedance measured by bioelectrical impedance analysis is a sum of resistance and reactance.
- Resistance is inversely proportional to the total amount of water in the organism, and reactance is the measure of the body cell mass.
- The correlation ratio reactance and resistance is reflected in a parameter named phase angle. Phase angle is calculated according to the formula: phase angle = arc tangent reactance/resistance.
- Phase angle is considered to be an indicator of cellular health and cell membrane integrity. The value is closely correlated with body cell mass. Higher phase angle value is correlated with better cell function.
- Phase angle utility in nutrition assessment among cancer patients is well established.
- Certain phase angle cutoff was assessed in different types of cancer as predictive in detecting malnutrition. Numerous studies confirm usefulness of phase angle as a prognostic factor in different sets of cancer patients.

Abstract

Rheumatoid arthritis is a systemic inflammatory disease that destroys articular cartilage and bone and leads to joint damage. Cachexia is common in rheumatoid arthritis patients and is called rheumatoid cachexia, characterized by a reduction in muscle mass with body fat gain and stable or slightly increased body weight. Loss of muscle mass in rheumatoid cachexia leads to weakness, loss of independence, and increased risk of death. Muscle atrophy seems to be secondary to an increase in muscle proteolysis, but not to a decrease in myogenesis. A variety of factors are involved in the pathogenesis of rheumatoid cachexia, including excessive cytokine production, physical inactivity, hormone deficit modifications, and glucocorticoid treatment. In this chapter, we summarize the mediators

involved in the increase in fat mass and skeletal muscle wasting observed in rheumatoid arthritis patients.

Keywords
Rheumatoid arthritis · Cachexia · Inflammation · Anorexia · Skeletal muscle · Muscle wasting · Proteolysis · Ubiquitin-proteasome system · Autophagy · Cytokines · TNFα · NF-kB · COX-2 · IGF-I · Glucocorticoid

List of Abbreviations

AgRP	Agouti-related peptide
Akt	Protein kinase b
Atrogin-1	Muscle atrophy F-box or MAFbx
BMI	Body mass index
COX-2	Cyclooxigenase-2
FFM	Fat-free mass
IGF-I	Insulin-like growth factor-I
IGFBPs	IGF binding proteins
IL	Interleukin
LC3b	Microtubule-associated protein light chain 3
MuRF1	Muscle ring finger 1
NF-kB	Nuclear factor kappa B
NPY	Neuropeptide Y
RA	Rheumatoid arthritis
TNFα	Tumor necrosis factor α

Introduction

Rheumatoid arthritis (RA) is the most frequent form of inflammatory arthritis. RA is an autoimmune disease characterized by autoantibody production and chronic and systemic inflammation that can affect many tissues, mainly synovial tissue (Fig. 1). These clinical features cause joint destruction and functional disability with a substantial economic burden on patients, their families, and society in terms of cost and lost productivity. Joint destruction from synovitis primary affects small diarthrodial joints symmetrically (wrists, fingers, feet, knees, and ankles).

Although the etiology remains unknown, several genes and environmental factors (mainly tobacco smoke), hormones, infections, and gut macrobiota act together to cause pathological events (Fig. 2). The disease can occur at any age, but it is most common within the fourth and sixth decade of life, and its incidence increases with age. The prevalence of RA in the world population is approximately 0.5–1%, with a frequency in women three times higher than in men (Scott et al. 2010). Ovarian steroids seem to play a protective role, since RA often develops at times when sex steroid hormone levels are changing, such as in the postpartum and perimenopausal period. Furthermore, oral contraceptive and postmenopausal estrogen therapy reduce the risk of RA (D'Elia et al. 2003). It is also more likely to occur in urban versus rural

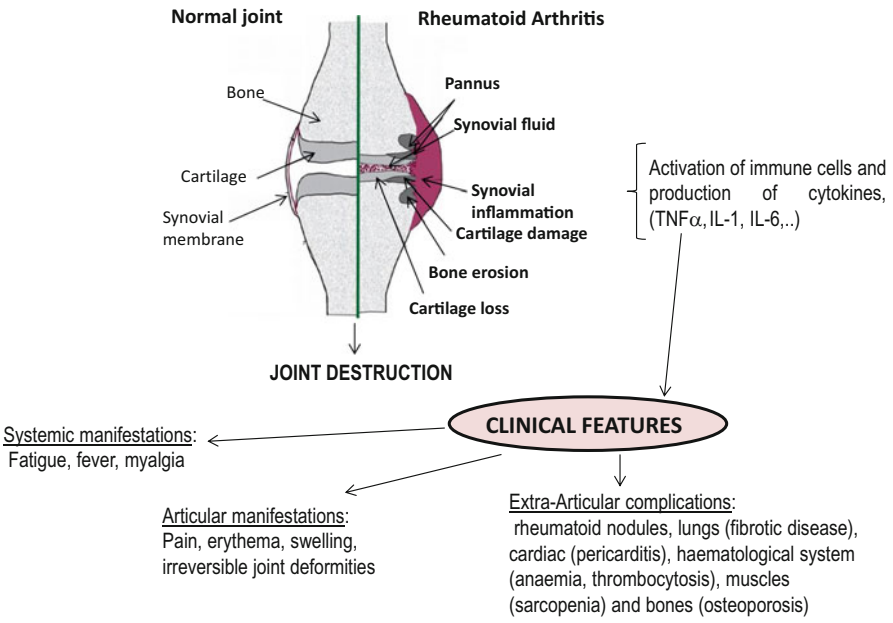

Fig. 1 Schematic view of a normal and an affected joint by rheumatoid arthritis (RA). RA increases inflammation and cellular activity in affected joint. The pathobiology of RA involves immune cells and the complex interaction of many pro-inflammatory cytokines, including TNFα and IL-6. These cytokines cause local and systemic symptoms associated with this disease. *IL* interleukin, *TNFα* tumor necrosis α

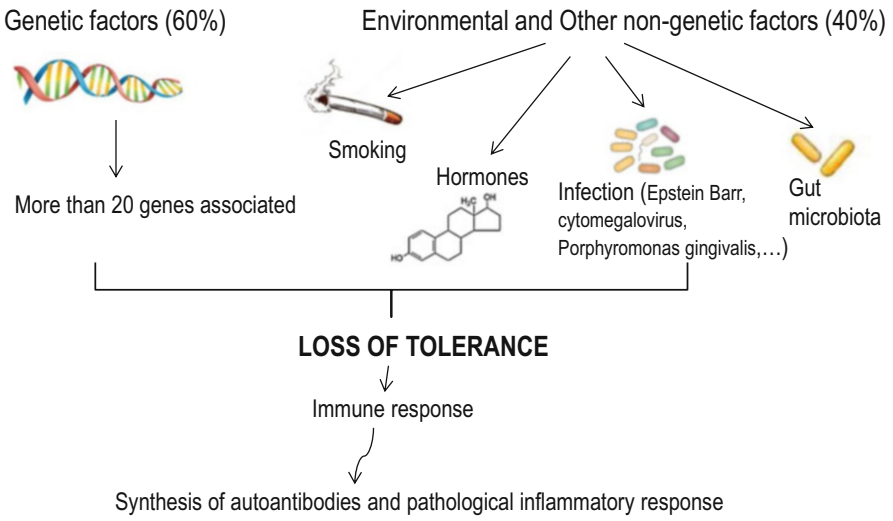

Fig. 2 Etiology of rheumatoid arthritis (RA). Causes of RA remain yet unknown, but there seems to be a combination of genetic and environmental factors

populations. The geographic distribution of RA is worldwide, with the highest prevalence found in specific tribes of Native Americans and Alaska Natives (>1.2%), and the lowest prevalence described in countries such as South Africa, Pakistan, China, Nigeria, Indonesia, the Philippines, and Argentina.

That rate of mortality is two to three times higher in the population with RA versus the population without RA of similar age and sex. Life expectancy of patients with RA decreases by 20 years, which can vary depending on the therapy. This reduction is associated with an increased prevalence of several comorbidities. Comorbidities most frequently seen in RA include cardiovascular disease (mainly coronary disease), osteoporosis, lung disease, malignancies, and neuropsychiatric disease. The average patient with RA has two or more comorbid disorders (Dougados et al. 2014).

Rheumatoid Cachexia

The term "cachexia" originates from the Greek terms *kakos* and *hexis*, which mean "bad condition." It generally connotes a state of advanced malnutrition and wasting, with a decrease in body cell mass and muscle atrophy. To date, accurate criteria used to define cachexia by different research groups vary. The prevalence of cachexia depends on the clinical criteria considered for the diagnosis and the measurement method used. A group of scientists and clinicians reached a consensus on the clinical definition of cachexia: *a complex metabolic syndrome associated with underlying illness and characterized by loss of muscle with or without loss of fat mass. The prominent clinical feature of cachexia is weight loss in adults (corrected for fluid retention) or growth failure in children (excluding endocrine disorders). Cachexia is distinct from starvation, age-related loss of muscle mass, primary depression, malabsorption, and hyperthyroidism and is associated with increased morbidity.*" (Evans et al. 2008). Using this definition, the number of people in Europe, USA, and Japan with cachexia and severe forms of RA was 190,000, a prevalence estimated at approximately 0.8% of the population (von Haehling et al. 2016).

The first description of altered body composition in RA patients was reported in 1873 (Paget 1873). Roubenoff et al. (1994) introduced the term "rheumatoid cachexia" to describe the special body composition that often characterizes patients with RA. Cachexia associated with illnesses such as cancer and heart failure is characterized by severe muscle and fat loss. However, in RA patients with cachexia, the decrease in fat-free mass, predominantly skeletal mass, is often associated with an increase in fat mass. In this case, body mass index (BMI) values are within the normal range. This condition has also been termed "rheumatoid cachexia" or "rheumatoid cachectic obesity." Stavropoulos-Kalinoglou et al. (2011) reported that RA patients have a decreased BMI, which is approximately 2 kg/m^2 lower than that of the general population for a given body fat content. Therefore, for the general population where individuals with a BMI of >30 kg/m^2 are classified as obese and those with a BMI of 25–30 kg/m^2 are characterized as overweight, it was proposed that in patients with RA, these values be reduced for overweight and obesity to 23 and to 28 kg/m^2,

respectively. Patients with RA have 13–14% less body cell mass than their age-, sex-, race-, and BMI-matched controls (Walsmith and Roubenoff 2002). If a loss greater than 40% of baseline body cell mass is associated with death, the 13–14% decrease observed in RA patients, although not directly fatal, severely compromises muscle strength, balance, and functional mobility and reduces quality of life. In addition, rheumatoid cachexia has been reported to worsen disease outcomes and to increase the prevalence of metabolic syndrome and hypertension, which may contribute to the increased mortality in RA. This is because the main store of body protein is the muscle, and depletion of body protein weakens adaptation to metabolic stress and the capacity of patients to overcome secondary infection and concomitant illness.

In RA patients, several studies have shown deficits in muscle cross-sectional area, muscle density, and muscle strength compared with controls. These deficits seem to be significantly greater among those patients with less adiposity and greater inflammatory disease (Baker et al. 2015a, b). Decreased muscle density, measured by peripheral quantitative computed tomography, indicates intramuscular fat infiltration strongly associated with limitation in physical performance and disability. In the general population, obesity is related to the major complications also found in RA patients: cardiovascular mortality and disability. However, there is no conclusive evidence about the relationship between high BMI values and cardiovascular risk in RA patients. There is evidence that patients with low BMI (<18.5) have the highest cardiovascular risk, while obese patients may be partially protected (Escalante et al. 2005). This finding is the opposite of the pattern found in the general population, in which obesity is clearly linked to an increase in cardiovascular mortality. In contrast, other authors have reported strong positive associations between obesity and worse RA disease outcomes, adverse cardiovascular risk factors, and a higher prevalence of comorbidities (Ajeganova et al. 2013). This controversy may be the result of the potentially important confounders in RA patients (i.e., disease activity, antirheumatic and/or cardiovascular disease medication, and smoking). Nevertheless, low BMI in RA is associated with the highest rates of erosive disease and disability, whereas an increased BMI protects the joints (Kaufmann et al. 2003). The protective effect of high BMI seems to be present in overweight or obese RA patients before the diagnosis of RA. This effect continues during the first few years of RA, with a greater reduction in radiographic joint damage in obese than in normal-weight RA patients (van der Helm-van Mil et al. 2008). Serum adiponectin in RA seems to be the link between high adiposity and less progressive and erosive disease. Taking into account that this hormone has a negative effect on the bone metabolism promoting bone resorption (Wang et al. 2014), and that obesity decreases adiponectin, decreased adiponectin levels in RA patients with high BMI may explain the less erosive course of the disease (Giles et al. 2011). In summary, even if BMI poorly reflects body composition, low BMI in RA indicates severe cachexia. RA patients with intermediate BMI probably have good disease control, but they can be cachectic. Obese RA patients may have a decreased risk of joint damage progression, whereas there is no clear association with the risk of cardiovascular death (Challal et al. 2016).

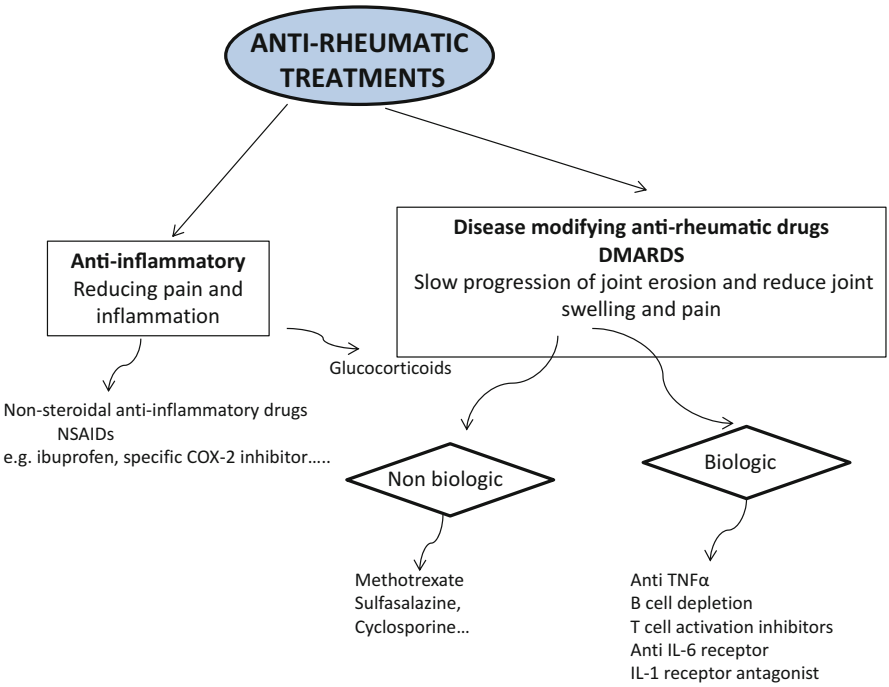

Fig. 3 Antirheumatic therapies in rheumatoid arthritis (RA). Two classes of drugs are used to treat RA. The first class of drugs, anti-inflammatory drugs, simply alleviate pain and swelling. The second, disease-modifying antirheumatic drugs (DMARDs) are able slow disease and prevent joint deformity. The treatment of RA usually involves the use of combination therapy

There are sex differences in body composition phenotypes of RA. Men with RA tend to have greater muscle wasting than women with RA. In addition, men with RA have higher fat mass. These data could indicate that disease-related body composition alterations overall are greater in men than in women with RA (Baker et al. 2015a). Furthermore, there are also sex differences in treatment responses, with men responding better in early RA (Jawaheer et al. 2012).

Antirheumatic Treatments

When studying rheumatoid cachexia, antirheumatic treatments can interfere with the effects of RA on food intake and cachexia. Obviously, systemic inflammation is decreased by antirheumatic treatments, and many of the side effects of inflammation can be modified by these treatments. Among the most common RA treatments (see Fig. 3), methotrexate has been reported to decrease whole-body proteolysis in RA patients (Rall et al. 1996). In addition to muscle proteolysis, treatment with methotrexate decreases anorexia and body weight loss in an experimental model of RA (Jurcovicova et al. 2009). Similarly, inhibition of COX-2 by administering a

nonsteroidal anti-inflammatory agent (NSAID) increases food intake and body weight gain, whereas it decreases skeletal muscle atrophy in arthritic rats (Granado et al. 2007). Anti-TNFα, the *second-line* of medical treatment for RA, has important actions on food intake as well as on fat and skeletal muscle. TNFα appears to play an important role in reducing adipose tissue mass. Accordingly, an increase in fat mass after 2 years of treatment with an anti-TNFα antibody has been reported in RA patients (Engvall et al. 2010). Glucocorticoids, on the contrary to the aforementioned, have an inhibitory effect on muscle mass, and chronic elevation of their levels induces muscle atrophy, both indirectly and directly on a muscular level (Bodine and Furlow 2015). Therefore, glucocorticoid therapy can be an important factor in rheumatoid cachexia, since it modifies body composition, increasing fat mass and decreasing skeletal muscle mass. In summary, antirheumatic treatments not only decrease inflammation but can also both increase and decrease muscle proteolysis and increase food intake and fat mass. Therefore, some of the modifications in body composition found in RA patients, such as an increase in fat mass, can be due to the antirheumatic treatments rather than to the disease itself.

Mechanisms of Rheumatoid Cachexia

The exact pathophysiological mechanisms of rheumatoid cachexia are not fully elucidated. The etiology is probably multifactorial and it is likely that the severity of cachexia in RA patients will depend on a combination of intensity, duration, and activity of inflammatory disease. A variety of factors are involved in the pathogenesis of RA cachexia, including malnutrition, excessive cytokine production, physical inactivity, and hormones.

Malnutrition and Food Intake

Systemic inflammation is associated with anorexia, low nutrient intake, and accelerated loss of skeletal muscle mass. However, RA is not associated with anorexia and is refractory to dietary intervention alone. There is great disparity between studies on the prevalence of malnutrition in RA patients, ranging from 26% to 71% (Elkan et al. 2009). However, in most studies, RA patients were treated with methotrexate, nonsteroid anti-inflammatory drugs, TNFα, and prednisolone, and all these antirheumatic treatments have been demonstrated to increase appetite.

In rats with adjuvant-induced arthritis, when arthritis is developing, body weight loss and muscle wasting are associated with a decrease in food intake. However, body weight loss and muscle atrophy are not only due to anorexia, since body and skeletal muscle weight loss in arthritic animals is higher than in pair-fed animals. Furthermore, pair-fed animals lose fat mass (Martín et al. 2008), but skeletal muscle is similar to that of controls with free access to food (Castillero et al. 2009). Experimental arthritis increases COX-2 levels in the hypothalamus (Gómez-SanMiguel et al. 2013), whereas administration of a COX-2 inhibitor, which

decreases prostaglandin levels, increases food intake in arthritic animals, even to levels higher than those observed in control animals (Granado et al. 2007). These data are agreement with those showing that increased release of prostaglandins, by COX-2 induction, plays an important role in inflammation-induced anorexia (Johnson et al. 2002).

When the external signs of the illness have reached their maximum value, arthritic rats have not anorexia, but their skeletal muscle wasting continues. Therefore, as reported in RA patients (Roubenoff et al. 1994), muscle atrophy in rodents with experimental arthritis seems to be mainly due to inflammation rather than to anorexia. Similarly, monkeys with collagen-induced arthritis have a decrease in body weight together with a decrease in food intake only during the early phase of the illness, and cachexia in these monkeys was not the consequence of a decrease in caloric intake (Horai et al. 2013). All these data suggest that the decrease in fat-free mass observed in RA patients during a flare is not only due to a decrease in food intake, but rather to an increase in resting energy expenditure. Although in some studies absolute resting energy expenditure in RA patients is not different to that of controls, after adjustment (for body cell mass or free-fat mass) resting energy expenditure was increased in RA patients (Roubenoff et al. 1994; Binymin et al. 2011).

Muscle Wasting

In RA patients with rheumatoid cachexia, muscle wasting is associated with a decrease in muscle cross-sectional area and strength (Beenakker et al. 2010). Arthritis-induced skeletal muscle atrophy is predominantly found in type II muscle fibers in RA patients (Edström and Nordemar 1974) and in experimental animals (Castillero et al. 2011; Horai et al. 2013). The decrease in muscle mass can be secondary to an increase in muscle proteolysis and/or a decrease in protein biosynthesis and muscle formation. Gibson et al. (1991) reported that RA-induced muscle atrophy was secondary to an increase in muscle proteolysis, whereas muscle protein synthesis in patients with RA (that had never received corticosteroids) was similar to controls. It has recently been reported that muscles of RA patients are able to increase protein synthesis after several different types of stimuli, such as acute resistant physical exercise and protein intake, in a way similar to that of controls (Mikkelsen et al. 2015).

A decrease in muscle remodeling and regeneration has not been reported in RA patients or in experimental models of arthritis. On the contrary, it is known that inflammation in skeletal muscle triggers satellite cell proliferation and muscle regeneration. Wróblewski and Nordemar (1975) reported that satellite cells in muscles are more common in RA patients and are regarded as an index of muscle regeneration. In addition, RA does not affect in vitro regenerative potential of human satellite cells compared to controls (Duijnisveld et al. 2011). Local macrophage-derived IGF-I (insulin-like growth factor-I) has been reported as a key factor in inflammation resolution and during muscle regeneration (Tonkin et al. 2015). These data are in agreement with those showing that there is an increase in both IGF-I and IGFBP-5 in skeletal muscle, together with the myogenic marker MyoD in

experimental arthritis (Castillero et al. 2009). All these data indicate that muscle atrophy in RA is primarily due to an increase in the rate of muscle protein breakdown rather than to a decrease in muscle formation.

Skeletal Muscle Proteolysis

Muscle wasting can occur through different proteolytic systems: autophagy, calcium-activated proteases, such as calpains and caspases, and the ubiquitin-proteasome system. Most of the muscle atrophy reported in experimental models of inflammatory diseases seems to be due to activation of the ATP-dependent ubiquitin-proteasome proteolytic pathway.

The ubiquitin–proteasome pathway mediates the degradation of the most abundant contractile proteins. The degradation of proteins occurs in the proteasome, which is a complex consisting of one or three large enzymes. Proteins destined for degradation by proteasome should be labeled with ubiquitin monomers. Conjugation of ubiquitin to proteins occurs in a series of steps involving three distinct enzymatic components: an E1 ubiquitin-activating enzyme, an E2 ubiquitin-conjugating enzyme, and an E3 ubiquitin ligating enzyme. The key enzymes in this process are two E3 ubiquitin ligases, muscle ring finger 1 (MuRF-1) and muscle atrophy F-box (MAFbx) or atrogin-1, which confer substrate specificity. In muscle wasting induced by different illnesses, MuRF1 and atrogin-1 are upregulated (Lecker et al. 2004). Therefore, these E3 ubiquitin-ligating enzymes are called atrogenes and serve as muscle atrophy markers. Arthritis in experimental animals decreases muscle protein content and increases the expression of both atrogenes atrogin-1 and MuRF1 in skeletal, but not in cardiac, muscle (Granado et al. 2005; Teixeira et al. 2013). The ubiquitin-proteasome pathway has not been analyzed in the skeletal muscle of RA patients without antirheumatic treatments. Mikkelsen et al. (2015) were unable to find differences in atrogin-1 and MuRF1 expression between RA patients and controls. However, their RA patients were treated with methotrexate and, as mentioned above, methotrexate has been reported to decrease proteolysis. At a cellular level, atrogene expression can be upregulated by activation of the two pathways: nuclear factor kappa B (NF-κB) and p38/MAP kinase. Between these two pathways, our group has reported NF-kB activation in skeletal muscle of arthritic rats (Gómez-SanMiguel et al. 2016), whereas the possible role of the second pathway in arthritis-induced muscle atrophy has not yet been studied. NF-kB is an important transcription factor that mediates many effects of the inflammatory response, including the expression of the two atrogenes: atrogin-1 and MuRF1 (Fig. 3).

Autophagy is another proteolytic system that is involved in the pathogenesis of muscle wasting under different catabolic conditions. An increase in autophagic activity in the atrophic muscle has been observed in experimental models of cancer and sepsis, as well as in cancer patients with cachexia (Aversa et al. 2016). Although studies in RA patients assessing the role of autophagy in rheumatoid cachexia are still lacking, it can play a role in muscle wasting, since autophagy plays a key role in the pathogenesis of rheumatoid arthritis. It is increased in the synovial tissues of

patients with active RA and the autophagy markers such as LC3II are correlated with the disease activity and severity (Zhu et al. 2017). Arthritis-induced by adjuvant injection in rats increases the autophagy marker genes such as LC3b, as well as the conversion of LC3b I to LC3b II by lipidation in skeletal muscle. Furthermore, treatments that decrease muscle wasting downregulate atrogene and autophagy in this experimental model of rheumatoid arthritis (Gómez-SanMiguel et al. 2016). All these data suggest that, as it has been reported in sepsis, arthritis-induced muscle proteolysis is mainly due to an increase in the activity of ubiquitin-proteasome pathways and autophagy.

Mediators of Muscle Proteolysis

Muscle proteolysis and wasting in RA can be the result of inflammation, low physical activity, decreased secretion of IGF-I, and glucocorticoid therapy.

Inflammation. In rheumatoid cachexia, relative excess of pro-inflammatory cytokines seems to be the central feature. The pro-inflammatory cytokine tumor necrosis factor-α (TNFα) and interleukin 1ß (IL-1ß) not only have a central role in the pathogenesis of joint inflammation and destruction in RA (Fig. 1), but also exert a powerful influence on whole-body protein and energy metabolism (Fig. 4). TNFα and IL-1β levels are increased in RA patients during flares, but their levels are undetectable during the quiescent phases of disease (Morley et al. 2006). These cytokines, together with IL-6, and IFN-γ are also known as sarcoactive "muscle-active" cytokines and have been proposed as inducers of muscle wasting (Rall et al. 1996). Anti-TNFα biologic agents are still the therapy of choice for rheumatoid arthritis. It has been postulated that TNFα can contribute to muscle wasting directly, increasing skeletal muscle proteolysis (Zhao et al. 2015), and indirectly decreasing anabolic hormones and growth factors that regulate muscle mass, such as IGF-I (Granado et al. 2006a). Therefore, it is logical to think that blocking TNFα would attenuate cachexia in RA patients. However, only 5 out of 14 studies with anti-TNFα treatment reported significant increases in BMI and/or body weight (Peluso and Palmery 2016). Most studies show that anti-TNFα treatments reduce disease activity and increase body weight, but this increase is mainly due to an increase in fat mass in RA patients (Engvall et al. 2010). Similarly, TNFα blockade in arthritic rats increases food intake, serum IGF-I, body weight, and fat mass, but is unable to prevent muscle proteolysis and atrophy (Granado et al. 2006a, b).

IGF-I deficiency. Circulating IGF-I plays an important role in the control of skeletal muscle mass; it decreases proteolysis and increases protein synthesis and myogenesis (Fig. 5). Rheumatoid arthritis is associated with a decrease in circulating IGF-I or its bioavailability (Engvall et al. 2008). Similarly, experimental arthritis also decreases circulating and liver IGF-I (Castillero et al. 2009). In addition, a dysfunction of IGF binding proteins (IGF-BPs) in serum and skeletal muscle has been reported in humans and experimental animals with arthritis (Engvall et al. 2008; Castillero et al. 2009). Decreased circulating IGF-I levels in

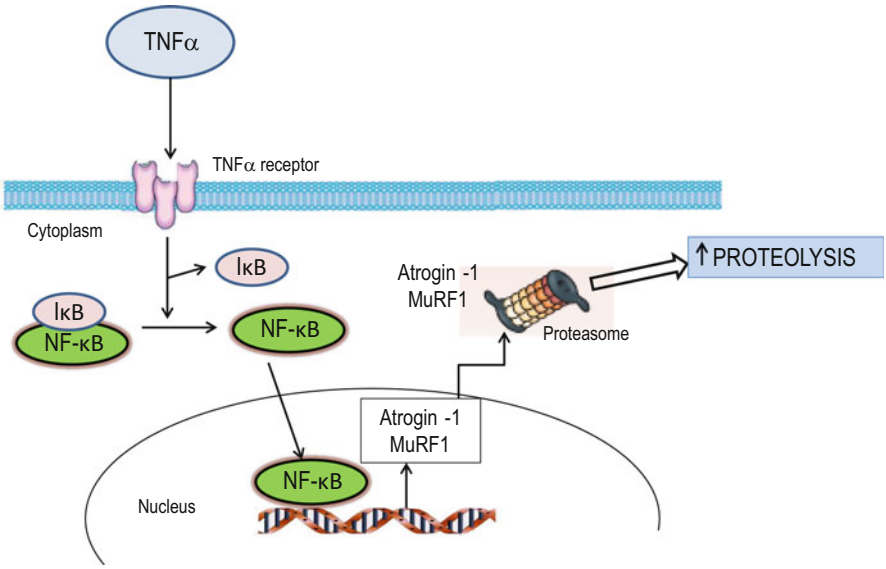

Fig. 4 TNFα receptor signaling pathway. Signaling initiates with the binding of TNFα to its receptor. TNFα induces proteolysis via activation of the NF-κB pathway. NFκB is in the inactive state when it is sequestered in cytoplasm by a family of inhibitory proteins called IκB. In response to TNFα, IκB is degraded. This leads to nuclear translocation of NFκB and activation of NFκB-mediated gene transcription, resulting in an increased transcription of atrogin-1 and MURF1, which are involved in the proteolysis of myofibrillar proteins via the proteasome system. *IkB* I-kappa-B-beta, *MURF1* muscle RING finger-containing protein 1, *NFκB* nuclear factor kappa B, *TNFα* tumor necrosis factor α

RA are correlated with both disease severity (activity, joint destruction, and disability) and with muscle atrophy (Baker et al. 2015b). Taking into account that circulating, but not muscle IGF-I, is decreased in arthritis and that systemic administration of IGF-I ameliorates arthritis-induced skeletal muscle atrophy (López-Menduiña et al. 2010), the decrease in circulating IGF-I during inflammation can be one of the causes of muscle wasting.

Low physical activity. It has been postulated that muscle wasting and the reduction in circulating IGF-I observed in RA patients is more related to their sedentary lifestyle than to inflammation (Lemmey et al. 2001). However, patients with quadriceps atrophy caused by forced leg immobilization, after tibial fracture, have a decrease in the rate of muscle protein synthesis (Gibson et al. 1987), whereas as mentioned above, muscle protein biosynthesis was unaffected by RA. Recently, Teixeira et al. (2013) demonstrated in mice that arthritis and immobilization activate skeletal muscle atrophy, but the pathways activated in the two experimental models were different. In addition, arthritis, as in other inflammatory diseases, mainly induces atrophy of the type II myofibers (Edström and Nordemar 1974; Castillero et al. 2011). On the contrary, disuse-induced muscle atrophy mainly affects type I

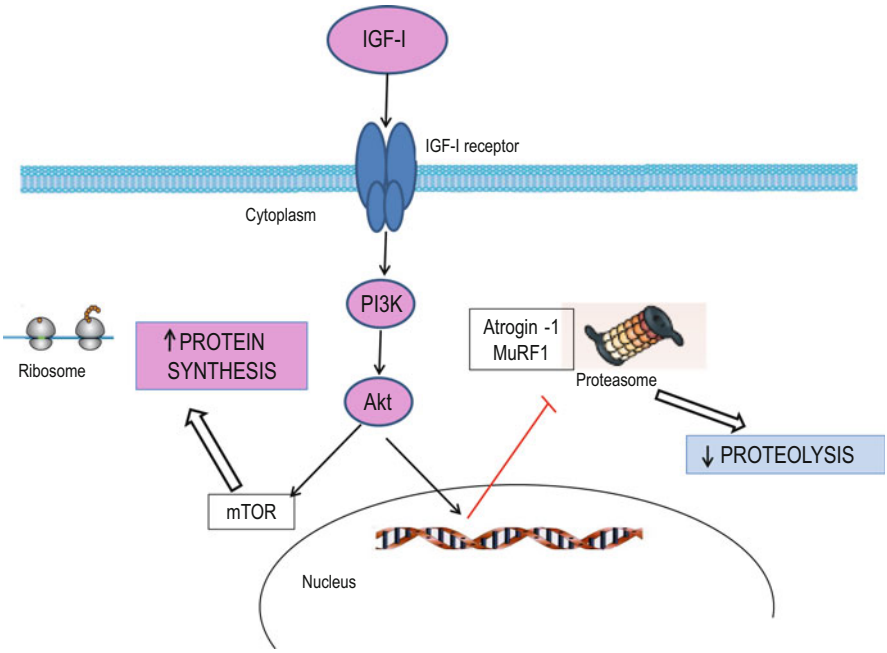

Fig. 5 Schematic illustration of IGF-I signaling pathway. Lines (in *red*) ending with a perpendicular segment represent inhibitory pathways. The binding of IGF-I to IGF-I receptor activates PI3K, which induces Akt activation. When activated, Akt stimulates protein synthesis through mTOR. Akt also inhibits protein degradation by activating the expression of MuRF1 and atrogin1. *Akt* protein kinase B, *IGF-I* insulin-like growth factor-1, *mTOR* mammalian target of rapamycin, *MURF1* muscle RING finger-containing protein 1, *PI3K* phosphatidylinositol-3 kinase

myofibers (Wang and Pessin 2013). Therefore, we can assume that muscle atrophy in arthritis is not mainly due to decreased mobility.

Glucocorticoid therapy. When used in excess, glucocorticoids have a catabolic effect on skeletal muscle that is opposite to that of IGF-I and results in muscle atrophy (Fig. 6). Endogenous glucocorticoids often increase in acute inflammatory diseases, but RA patients have normal or decreased cortisol levels compared to healthy controls (Eijsbouts et al. 2005). Nevertheless, exogenous glucocorticoids are widely used to treat inflammation in RA. In spite of the stimulatory effect of glucocorticoids on food intake in humans, chronic elevation of their levels induces muscle atrophy and weakness (Bodine and Furlow 2015). In women with juvenile idiopathic arthritis, glucocorticoid treatment has a negative effect on muscle and bone mass, whereas it has a positive effect on fat mass (Brabnikova Maresova et al. 2014). Glucocorticoid treatment decreases muscle protein biosynthesis in RA patients (Gibson et al. 1991), and when glucocorticoids are chronically elevated, they also increase muscle proteolysis (Bodine and Furlow 2015). In addition to their effects on muscle cells, glucocorticoids inhibit plasma concentrations of IGF-I, an anabolic hormone that increases muscle mass.

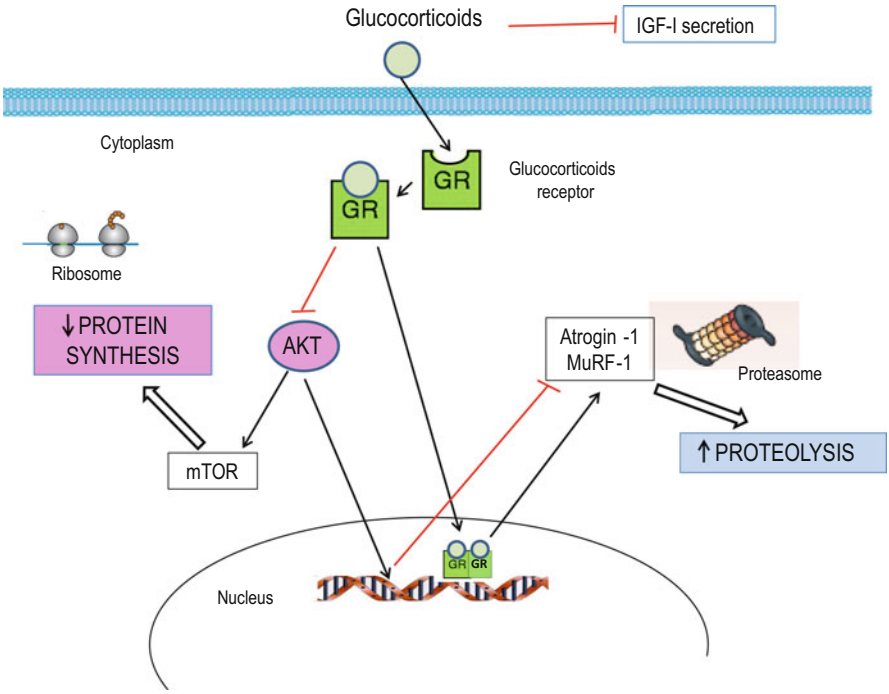

Fig. 6 Mechanism of action of glucocorticoids. Lines (in *red*) ending with a perpendicular segment represent inhibitory pathways. Glucocorticoids interact with cytosolic glucocorticoid receptor. The majority of the effects occur via glucocorticoid receptor dimerization, nuclear translocation to nucleus, and transcription activation. Nuclear GR increases MuRF1 and atrogin-1 expression, which induces proteolysis by the proteasome system. A reduction in protein synthesis occurs via cytosolic ligand bound GR monomers that inhibit Akt activation and mTOR system. *Akt* protein kinase B, *GR* glucocorticoid receptor, *IGF-I* insulin-like growth factor-1, *mTOR* mammalian target of rapamycin, *MURF1* muscle RING finger-containing protein 1, *PI3K* phosphatidylinositol-3 kinase

Policies and Protocols

Rheumatoid arthritis is a systemic inflammatory disease that often induces skeletal muscle proteolysis and atrophy. This chapter points out the importance of rheumatoid cachexia found in rheumatoid arthritis patients as a consequence of the state of chronic inflammation. The decrease in skeletal muscle mass in these patients increases their morbidity and mortality and contributes to the decline in their quality of life. Skeletal muscle health is an important contributor to overall health and wellbeing, and muscle wasting limits mobility and exacerbates the impact of other long-term conditions leading to premature death. Rheumatoid cachexia is often associated with no modifications in body weight, since the decrease in skeletal

muscles mass is associated with an increase in fat mass. This altered body composition is associated with the development of several comorbidities, primarily cardiovascular disease, and obesity that have a negative impact on functional ability, pain, and global health in the patients.

Body composition is generally not assessed in rheumatoid arthritis patients. Therefore, specific policies aimed to detect rheumatoid cachexia. Assessing both disease activity and body composition, by measuring both muscle mass and fat mass, should be considered in order to prevent the development of rheumatoid cachexia and improving outcomes in rheumatoid arthritis.

Dictionary of Terms

- **Atrogenes** – Enzymes that conjugate ubiquitin to muscle proteins. There are two ubiquitin ligases specifically involved in myofibrillar protein degradation: mouse atrophy gene-1 (atrogin-1) also described as rat muscle atrophy F-box (MAFbx) and rat muscle RING finger 1 (MuRF1). The polyubiquitin-tagged protein is recognized by the proteasome and is degraded to small peptides.
- **Body mass index (BMI)** – Weight divided by height squared.
- **Ubiquitin-proteasome proteolytic system** – It is a complex multicatalytic enzyme responsible for intracellular protein degradation. This system consists of three sequential processes: recognition of the protein for degradation, addition of several copies of the small protein ubiquitin onto proteins to mark them, and proteolysis of the protein inside the proteasome system.
- **Resting energy expenditure** – Represents the energy expended at rest, although not necessarily basal conditions, by a fasted individual in a thermo-neutral environment. There are many individual factors that contribute to a variation in this parameter: age, gender, body size, body composition, muscle mass, ethnicity, hormonal status, and genetic and environmental influences.
- **Rheumatoid cachexia** – A decrease in skeletal muscle mass that can be associated with an increase in fat mass. In this condition, there is no body weight loss and body mass index is within the normal values.

Summary points

- Skeletal muscle atrophy has been reported in two-thirds of people with rheumatoid arthritis, where muscle type II is more affected than type I.
- Rheumatoid arthritis patients can have normal body mass index values, since their muscle mass is decreased and their fat mass is increased.
- Muscle skeletal wasting in rheumatoid arthritis patients seems to be secondary to an increase in muscle proteolysis rather to a decrease in muscle generation.
- The proteolytic pathways ubiquitin-proteasome and autophagy have been found elevated in experimental models of rheumatoid arthritis.

- Systemic inflammation and insulin-like growth factor-1 deficiency contribute to skeletal muscle atrophy in rheumatoid arthritis patients.
- Chronic elevation of glucocorticoid levels by glucocorticoid therapy can increase the loss of muscle mass and function in rheumatoid arthritis RA patients.

Malnutrition in Older Adults in the United States

45

Angela M. Fraser

Contents

Abstract

The scientific literature clearly establishes the relationship between good nutrition and healthy aging. Unfortunately though, a large number of older Americans are at risk for poor nutrition not only because of the aging process but because of poverty, rurality, and/or lack of access to good quality food. Poor nutrition can easily translate into malnutrition, a leading cause of morbidity and mortality among older Americans. Malnutrition is not an inevitable side effect of aging, it can be prevented or at least managed. Medical conditions and lifestyle, social and psychological factors all play a role in increasing one's risk for malnutrition. Prevention of or treatment for malnutrition must be improved to reverse its deleterious effects among older Americans. Despite the availability of evidence that demonstrates the benefits of good nutrition for healing and recovery, there is no consensus for implementing optimal nutrition care with gaps associated with

nutrition screening, assessment, intervention, monitoring, and overall care for malnourished and at-risk hospitalized older adults. Moreover, the US government spends $51.3 billion each year to prevent malnutrition in community-dwelling older adults. In 1965, the US Congress passed the Older Americans Act (OAA), which aims to provide support (including nutrition) services for older Americans. Title III of the OAA (of the seven titles) specifically addresses the delivery of nutrition services, including nutrition education, to older adults. To date, few evidence-based nutrition education programs target this population making it clear that thoroughly tested curricula are needed, especially programs tailored to the culture and context of the older adult and their environment.

Malnutrition in Older Adults in the United States

The United States is rapidly becoming an "older" nation. In 2014, 42 million Americans (1 in 7) were age 65 or older. By 2030, this number is projected to increase to 72 million (or 1 in 5) (Federal Interagency Forum on Aging-Related Statistics 2016). In addition to the US population growing older, Americans in general are becoming less healthy. Compared to 16 other developed countries, the United States ranks last in terms of the health status of its population (Institute of Medicine 2013).

Historically, the most common causes of death among Americans were infectious disease or acute illness (Centers for Disease Control and Prevention 2009). Today, the most common causes of death are chronic diseases – heart disease, diabetes, cancer, and stroke – of which many are associated with poor nutrition (Kochanek et al. 2016). One recent study of older Americans illustrates the magnitude of the situation. Nearly all study respondents (92%) reported having at least one chronic

disease and 77% at least two (National Council on Aging 2015a). The high rates of obesity among older Americans, as well as the general population, are further compromising the health of Americans. Obesity is a well-recognized risk factor for many chronic diseases, including diabetes, heart diseases, and some cancers. In 2011–2014, about 35% of older Americans were obese, compared to 22% in 1988–1994 (Federal Interagency Forum on Aging-Related Statistics 2016).

The scientific literature clearly establishes that good nutrition is the foundation of healthy aging as many chronic diseases are treated by consumption of a healthful diet. Unfortunately though, a large number of older Americans are at risk for poor nutrition not only because of the aging process but because of poverty, rurality, and/or lack of access to good quality food. These three conditions alone or in combination can impact one's nutritional status and hence one's overall health and ability to live independently longer. Helping older Americans to live independently is vital because aside from personal reasons it costs less than institutionalized care. Older adults who maintain a good nutritional status could have decreased Medicare expenditures. Medicare, a social health insurance program available to Americans who are age 65 or older and to the disabled, is used by 55 million people and constitutes about 15% of all federal spending in the United States (Centers for Medicare and Medicaid Services 2015). Moreover, and most importantly, almost 90% of older Americans want to live in their home and community as long as possible, according to a report by the AARP Public Policy Institute and the National Conference of State Legislatures (Farber et al. 2011). The bottom line is that it costs a lot less for someone to age in their home than to be admitted into a long-term care facility (Clark 2013).

Malnutrition

Poor nutrition can easily translate into malnutrition, a leading cause of morbidity and mortality among older Americans, if it is not identified quickly then properly managed. Malnutrition is defined as the inadequate intake of nutrients, particularly protein, which contributes to the development of acute and chronic disease conditions. Malnutrition and weight loss can also contribute to sarcopenia, the age-associated loss of skeletal muscle mass and function, which directly effects recovery, mobility, and the ability to live independently. Lastly, malnourished older adults also have reduced homeostatic reserves limiting their ability to recover from an acute illness or injury making them more vulnerable to medical complications and an increased likelihood of admission to a long-term care facility (Starr et al. 2015).

Published evidence suggests that 20–50% of all US hospital patients are at risk for or are malnourished at the time of hospital admission (Barker et al. 2011) and up to 20% of malnourished patients and 38% of well-nourished patients experience nutritional decline during a single hospital stay (Braunschweig et al. 2000). It is estimated that as many as 65% of older Americans may be malnourished upon hospital admission (Sullivan et al. 1995). To further exacerbate this problem,

hospitalized patients are more vulnerable to nutritional decline because of dietary restrictions, treatments, and medical conditions, as well as, poor appetite and gastrointestinal problems they may experience as an outcome of hospitalization. In one study, Sullivan et al. (1999) noted that 20% of hospitalized older patients had an average nutrient intake of less than 50% of their calculated maintenance energy requirements. In addition, patients (across all age groups) who were malnourished while hospitalized had a greater risk of complications, readmissions, and length of stay, which is estimated to increase healthcare costs by 300% (Correia and Waitzberg 2003). Nutritional status is another important factor in "posthospital syndrome," which can result from the stress of hospitalization (Krumholz 2013).

In addition, disease-associated malnutrition has also been identified as a prevalent condition, particularly among older Americans (Goates et al. 2016). Malnutrition not only intensifies the effect of existing disease conditions but can also lead to increased incidents of infection, including flu, pneumonia, and foodborne disease. To illustrate, older adults are ten times more likely than the general population to develop complications or die from foodborne disease presumably because of their age and nutritional status (Buzby 2002).

Because there are no national prevalence rates for malnutrition among older Americans, much of what is known is derived from research studies conducted in healthcare settings (Mogensen and DiMaria-Ghalili 2015). Current estimates of the prevalence of adult malnutrition range from 15% to 60% depending on the patient population and criteria used to identify its occurrence. According to the National Resource Center on Nutrition, Physical Activity and Aging, it is believed that between 35% and 50% of older residents in long-term care facilities are malnourished. To illustrate the magnitude (and cost) of this problem, in 2014, about 67,000 paid, regulated long-term care providers served about nine million people in the United States. Excluding Medicare spending on home health and skilled nursing facilities, total long-term care services spending was US$241.7 billion in 2011. Less is even known about the rate of malnutrition in community-dwelling older Americans. DiMaria-Ghalili et al. (2013) estimated the prevalence of malnutrition using a probability sample of 3209 community-dwelling older adults (aged 60 years and older) to be 56.3% at risk of malnutrition and 5.9% malnourished. However, these statistics need to be used with caution as the sample was limited to one geographic region in the United States.

Risk Factors for Malnutrition

Malnutrition is not an inevitable side effect of aging, it can be prevented or at the very least managed. Medical conditions and life-style/social, and psychological factors all play a role in increasing one's risk for malnutrition (Table 1). Medical conditions, of which there are many, can lead to decreased appetite or difficulty eating (Shils and Shike 2006). In 2014, 22% of older Americans reported having a disability, such as limitation in vision, hearing, mobility, communication, cognition, and self-care, with women more likely to report a disability than men (24% vs. 19%)

Table 1 Risk factors for malnutrition

Medical conditions
• Poor appetite
• Poor dentition, other oral problems and dysphagia
• Loss of taste and smell
• Respiratory disorders
• Gastrointestinal disorders
• Endocrine disorders
• Infections
• Physical disability
• Drug interactions
Lifestyle and social factors
• Lack of knowledge about food, cooking, and nutrition
• Isolation/loneliness
• Poverty
• Inability to shop or prepare food
Psychological factors
• Confusion
• Dementia
• Depression
• Bereavement
• Anxiety

(Federal Interagency Forum on Aging-Related Statistics 2016). All of these disabilities can directly affect one's ability to care for oneself as well as shop for groceries, prepare meals, and feed oneself – all essential to maintaining good nutritional status (Getty et al. 2016). Long-term health illnesses, such as dementia and stroke, can also affect one's ability to prepare and eat healthy meals as well as directly impact one's appetite (National Institute on Aging 2015).

Dental problems can also affect the taste of food and make chewing nearly impossible (Moynihan 1995). Older Americans with the worst oral health are, not surprisingly, those who are economically disadvantaged, lack insurance, and are members of racial/ethnic minorities. Many older Americans do not have dental insurance because they often lose dental benefits when they retire and Medicare does not cover dental costs. The situation may be worse for older women, who generally have lower incomes and may never have had dental insurance. About 25% of adults age 60 or older no longer have any natural teeth. Missing teeth can affect what one eats as individuals without teeth tend to prefer soft, easily chewed foods. Moreover, because dentures are not as efficient for chewing food as natural teeth, denture wearers also may eat soft foods and avoid fresh fruits and vegetables known to be essential to good health. In addition, older Americans continue to experience dental decay having new tooth decay at higher rates than children. Severity of periodontal disease increases with age – about 23% of 65- to 74-year-olds are classified as having severe disease with men more likely than women to have

more severe disease. At all ages, people at the lowest socioeconomic level are reported to experience the most severe periodontal disease.

Dry mouth, a side effect of some prescription drugs, and diseases like Parkinson's can interfere with swallowing, hence decrease food consumption (Turner and Ship 2007). Moreover, most older Americans take both prescription and over-the-counter drugs (Centers for Disease Control and Prevention 2006) with residents of long-term care facilities – about 5% of all older Americans – taking an average of eight drugs each day. Over 400 commonly used medications can be the cause of a dry mouth. In addition, painful conditions that affect the facial nerves are more common among the elderly and can be debilitating. These conditions can affect mood, sleep, and oral-motor functions, such as chewing and swallowing. Neurological diseases, such as Parkinson's disease, Alzheimer's disease, Huntington's disease, and stroke also negatively impact oral sensory and motor functions (Centers for Disease Control and Prevention 2006). In addition, some prescription drugs commonly prescribed for older adults can suppress the appetite or affect the way food tastes, causing nausea and vomiting. This particular problem is often compounded because many older Americans take multiple medications.

Taste and smell also diminish as one ages making it difficult to distinguish off-flavors related to spoiled (and potentially unsafe) foods or to even enjoy the taste of food resulting in less food consumed (Boyce and Shone 2006). Additionally, older adults are more likely than any other group to have dietary restrictions, including limits on sodium, fat, protein, and sugars, which can result in bland and unappealing food choices so much so that older adults stop eating (Zeanandin et al. 2012). Lastly, vision also weakens as one ages. The ability to distinguish between colors decreases as one ages, especially between blues and greens, making food preparation and detecting spoiled food more difficult.

In addition to medical conditions, life-style/social and psychological factors also increase the risk for malnutrition among older Americans (Shils and Shike 2006). In 1966, 29% of older Americans lived below the poverty threshold but by 2014, this number decreased to over 4.5 million (or 10% of the total population). However, this figure might not accurately capture the extent of poverty among older Americans. The US Census Bureau uses monetary income thresholds that vary by family size and composition to determine who is living in poverty (U.S. Census Bureau 2016). However, in 2011, the US Census Bureau released a Supplemental Poverty Measure (SPM), which takes into account regional variations in cost of living as well as noncash benefits received, such as food assistance programs (Supplemental Nutrition Assistance Program, National School Lunch Program, Women, Infants, and Children Program), rent subsidies, and energy assistance (Short 2015) and non-discretionary expenditures. The SPM indicates that 14% of older Americans (not 10% as determined using the standard poverty measure) are living in poverty. This difference is mainly attributed to out-of-pocket expenses, such as increased healthcare and prescription drug costs. As health care, prescription drug, and utility costs increase, many older Americans cut back on their food budget hence leading to decrease food consumption (DiMaria-Ghalili 2014). As a share of total expenditures, in 2014 healthcare costs increased with age (Health Care Cost Institute 2015).

Across all age groups, healthcare expenditures were reported to be substantially higher for those who are age 85 or older compared to those in the younger age groups. This is important to note as by 2030, it is predicted that the fastest growing age group in the United States will be those who are age 85 or older, exceeding 8.9 million people (United States Census Bureau 2014). For example, the share of healthcare expenditures for those who are age 75 or older was 16% or more than double that for those who are younger (ages 45–54) (7%) (Federal Interagency Forum on Aging-Related Statistics 2016). This problem is amplified among those who are classified as poor/near poor. Moreover, these expenditures are expected to continue to increase. From 1977 to 2013 the percentage of household income older Americans allocated to out-of-pocket spending for healthcare services increased from 12% to 17% (Federal Interagency Forum on Aging-Related Statistics 2016).

Many older Americans, particularly those who live in rural areas and some urban neighborhoods do not have access to grocery stories that have a variety of good quality food. Instead those living in these areas must rely upon small convenience-type stores that typically sell highly processed foods, high fat and carbohydrate snacks, and few fresh foods (Inagami et al. 2006). These food deserts, a term defined by the US Department of Agriculture, are often found in impoverished urban areas and rural areas (Fig. 1).

For older Americans who live far from a supermarket or grocery store, not having access to a private vehicle makes it difficult to shop so they must rely on public or alternative means of transportation, which is often not available in rural areas in the United States. However, even when grocery stores are nearby, older Americans might not drive. One study suggests that more than 600,000 people age 70 or older stop driving each year and become dependent on others to meet their transportation needs (Foley et al. 2002). Poor vision, memory impairment, and an inability to care for oneself were common reasons cited by older Americans for why they stopped driving.

Another risk factor for malnutrition is a solitary life. Many older adults (29%; 13.3 million) live alone with almost half of women age 75+ (46%) living alone. The possible negative effects of living alone can be worsened as the proportion of leisure time older Americans spend socializing and communicating – visiting friends or attending or hosting social events – declines with age. The time spent socializing and communicating was about 11% for those ages 55–64 and 9% for those age 75 and over (Federal Interagency Forum on Aging-Related Statistics 2016). Social contact can also have a positive effect on eating well and can increase morale and well-being, factors that can contribute to lack of appetite (Higgs and Thomas 2016).

Although frequently unrecognized and untreated in older Americans, depression affects an estimated six million older Americans, with change in food intake a common symptom (National Alliance on Mental Illness 2009). Depression has been found to predict poor quality of life (Goldney et al. 2000), cognitive decline (Comijs et al. 2001), functional decline (Bruce et al. 1994; Penninx et al. 1998), mortality (Barefoot and Schroll 1996; Blazer et al. 2001), and resource use (Beekman et al. 2002). The proportion of older Americans is higher in rural areas than in urban areas, with these numbers expected to increase in the next decade

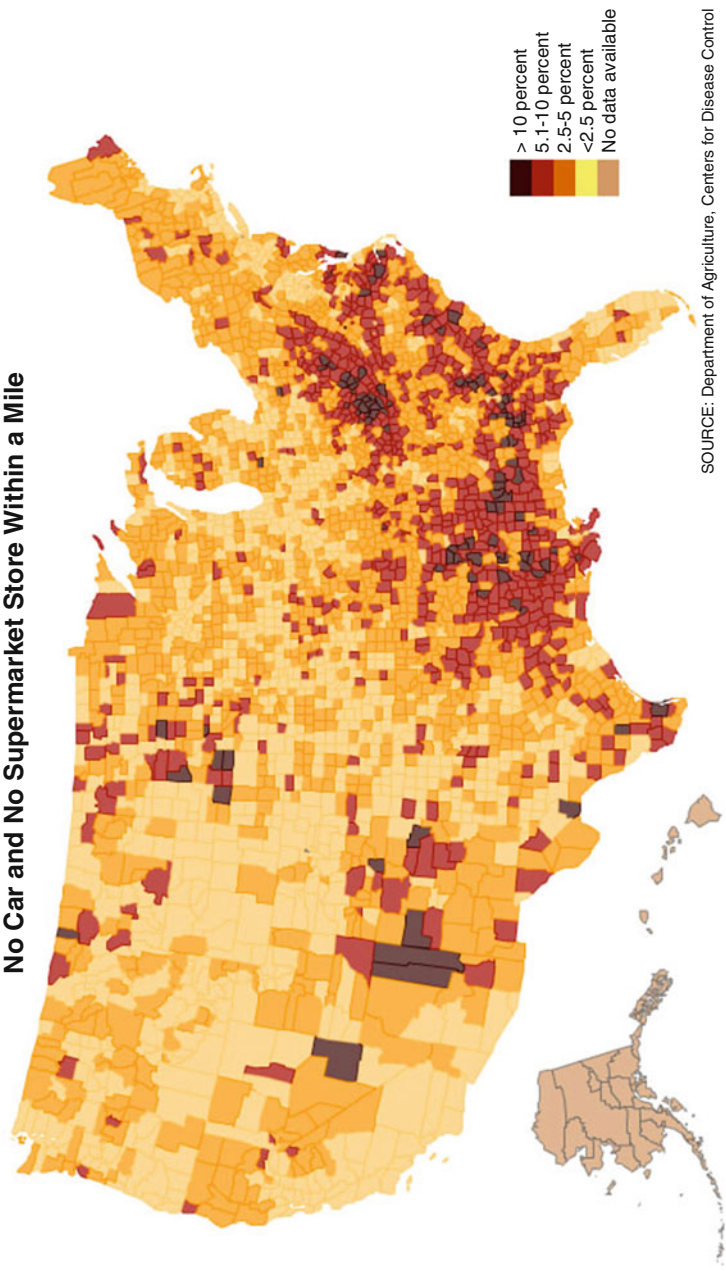

Fig. 1 : Food deserts in the United States

(Baernholdt et al. 2012). The potential negative effects of rural life on depression include long distances to social activities and services that could limit opportunities for social interaction and engagement. One study of community-dwelling older adults according to geographic location showed lower scores on social functioning in rural areas than urban areas suggesting that rural older adults may be socially isolated (Baernholdt et al. 2012).

Food insecurity defined as *"the inability to acquire or consume an adequate quality or sufficient quantity of food appropriate for one's health in socially acceptable ways, or the uncertainty that one will be able to do so"* (Wolfe et al. 2003) also contributes to malnutrition. The overall rate of food insecurity among Americans as a whole remains above 18% – higher than the 2007 – with those at greatest risk – the poor/near poor, minorities, the unemployed and disabled, and those residing in the southeastern United States. Even when one has food, the quality of that food may not meet one's nutritional needs, sometimes called overnutrition, which is another form of malnutrition. Whites have the lowest rate of food insecurity (15%) followed by Hispanics (30.4%) and Black (32.4%). Currently married and never married respondents have the lowest rates of food insecurity, whereas the widowed, divorced and separated have the highest. Older Americans who reported food insufficiency were more likely to have lower mean intakes of several nutrients; lower intake of the vegetable and meat groups; lower dietary variety; lower mean serum levels of certain nutrients; higher risk of being underweight, and in poor or fair health.

Screening for Malnutrition

Prevention of or treatment for malnutrition must be improved to reverse its effects among older Americans. However, a review of nationally representative data on cost and utilization indicated that, in 2010, only 3.2% of patients had a diagnosis of malnutrition, suggesting malnutrition may be under-recognized and underdiagnosed in hospitals (Corkins et al. 2014). Despite the availability of high-quality evidence that demonstrates the benefits of nutrition for healing and recovery, there is no consensus among healthcare professionals for implementing optimal nutrition care with gaps associated with nutrition screening, assessment, intervention, monitoring, and overall care for malnourished and at-risk hospitalized older adults. Nutrition screening can trigger a nutrition assessment for patients found to be at risk. The nutrition assessment is the basis upon which diagnosis, care plans, and treatments are made. For instance, a national survey of hospital-based health professionals in the United States showed that 36.7% reported they conduct nutrition screening at admission, 50.8% did so within 24 h, and only 69% documented the findings in the patient's medical record (Patel et al. 2014). In addition, no national benchmarking of malnutrition in acute-care hospitals exists in the United States because malnutrition screening and assessment are not standardized as to date there is no universal definition of malnutrition. In 2012, the Academy of Nutrition and Dietetics and the American Society for Parenteral and Enteral Nutrition collaborated to develop clear characteristics to define three broad categories of malnutrition

Table 2 Summary of malnutrition characteristics established by the Academy of Nutrition and Dietetics and the American Society for Parenteral and Enteral Nutrition in 2012

Type of malnutrition	Acute illness or injury		Chronic illness		Social and environmental circumstances	
Degree of malnutrition	Nonsevere (moderate) malnutrition	Severe malnutrition	Nonsevere (moderate) malnutrition	Severe malnutrition	Nonsevere (moderate) malnutrition	Severe malnutrition
Energy intake	<75% of estimated need for >7 days	≤50% of estimated needs for ≥5 days	<75% of estimated need for ≥1 month	<75% of estimated need for ≥1 month	<75% of estimated need for ≥3 months	≤50% of estimated needs for ≥1 month
Weight loss	1% to 2% in 1 week	>2% in 1 week	5% in 1 month	>5% in 1 month	5% in 1 month	>5% in 1 month
	5% in 1 month	>5% in 1 month	7.5% in 3 months	>7.5% in 3 months	7.5% in 3 months	>7.5% in 3 months
	7.5% in 3 months	>7.5% in 3 months	10% in 6 months	>10% in 6 months	10% in 6 months	>10% in 6 months
			20% in 1 year	>20% in 1 year	20% in 1 year	>20% in 1 year
Body fat wasting	Mild	Moderate	Mild	Severe	Mild	Severe
Muscle wasting	Mild	Moderate	Mild	Severe	Mild	Severe
Presence of edema	Mild	Moderate to severe	Mild	Severe	Mild	Severe
Grip strength	Not applicable	Measurably reduced	Not applicable	Measurably reduced	Not applicable	Measurably reduced

(White et al. 2012). These characteristics include the etiology of malnutrition, recognizing the influence of illness and inflammation on nutritional status. These types of malnutrition have subcategories of moderate (or nonsevere) or severe malnutrition, depending on specific parameters and described in Table 2.

Addressing malnutrition is also aligned with the Triple Aim and National Quality Strategy priorities (Agency for Healthcare Research and Quality 2017). Clinical consensus recommendations highlight the need for early identification and nutrition care in managing malnutrition in healthcare settings (Tappenden et al. 2013). Two studies showed that implementation of optimal nutrition care from admission to discharge improved identification of high-risk patients and decreased time to nutrition consult, length of hospital stay, and 30-day readmission rate (Brugler et al. 1999; Somanchi et al. 2011).

The Joint Commission, a US-based nonprofit tax-exempt organization that accredits more than 21,000 health care organizations and programs in the United States, requires nutrition screening upon hospital admission. But, even if a patient is determined to be at risk for malnutrition or is malnourished, this might not be properly coded in the medical record. Another problem is that screening is routinely not performed at discharge. A nationally representative sample of US hospital discharges from the 2010 Healthcare Cost and Utilization Project reported that

Table 3 Determine checklist of risk factors for malnutrition

Disease
• Chronic diseases impairing appetite or ability to eat
• Mood and cognitive disorders
Eating poorly
• Inadequate food or poor food quality/caloric intake
• Skipping meals; drinking too much alcohol
Tooth loss or mouth pain
• Missing or rotting teeth
• Missing or poorly fitting dentures
Economic hardship
• Inadequate income to buy food
Reduced social contact
• Single, widowed
• No family or community supports
Multiple medicines
• Causing nausea, taste alterations, constipation, or anorexia
• Includes dietary supplements, over-the-counter medications, and herbal products
Involuntary weight loss or gain
• Due to undiagnosed medical conditions such as cancer, malabsorption syndromes, metabolism-altering states
Needs
• Assistance with self-care
• Problems with transportation for shopping
• Problems with ambulation or cooking
Elder years
• Older than age 80

only 3.2% of patients were diagnosed with malnutrition even though other studies suggest a much higher prevalence of malnutrition (Corkins et al. 2014). Many studies report a direct relationship between the degree of malnutrition and increased length of hospital stay, treatment costs, and readmission to hospital rates. In 2010, 38.7% of hospital discharges and 44.8% of days of hospital care were attributed to older adults (Centers for Disease Control and Prevention 2012).

The Academy of Nutrition and Dietetics has identified clinical quality measures that could result in early detection and prevention of malnutrition. These electronic clinical quality measures (eCQMs) could improve patient outcomes and reduce cost. The four eCQMs focus on malnutrition care in patients' ages 65+ years in the hospital setting (Table 3). They include: (1) completion of a malnutrition screening within 24 hours of admission; (2) completion of a nutrition assessment for patients identified as at-risk for malnutrition within 24 hours of a malnutrition screening; (3) nutrition care plan for patients identified as malnourished after a completed nutrition assessment; and (4) appropriate documentation of a malnutrition diagnosis. The eMeasures are just one component of a broader initiative called Malnutrition

Quality Improvement Initiative, which aims to advance evidence-based, high-quality, and patient-driven care for hospitalized older adults who are malnourished or at-risk for malnutrition (Academy of Nutrition and Dietetics 2016).

Older adults may also become more vulnerable to becoming malnourished during recovery, especially if they have a weakened state, are unable to take care of themselves and live alone. Nutrition screening must be administered after an older patient has been discharged from the hospital or a skilled care or rehabilitation facility. It must also become part of routine geriatric assessments. The mini nutritional assessment (MNA) tool, developed specifically for older adults, has two validated forms available in 27 languages. The short form (MNA-SF) consists of seven items that assess changes in food intake, weight, mobility status, current disease or psychological stress, presence of neuropsychological problems, and body mass index. The long form MNA consists of 18 items – all 7 items on the MNA-SF and anthropometric measurements (Nestle Nutrition Institution 2009).

Preventing Malnutrition

The US government spends approximately $51.3 billion each year to prevent malnutrition in community-dwelling older adults as cost of treating it and the treatment of associated chronic diseases is high. In 1965, the US Congress passed the Older Americans Act (OAA), which aims to provide support (including nutrition) services for older adults. The legislative intent of OAA is to make community-based services available to older adults who may be at risk of losing their independence with a focus on those in social or economic need or who are classified as low-income minorities (National Committee to Preserve Social Security and Medicare 2016). Title III of the Older Americans Act (of the seven titles) specifically addresses the delivery of nutrition services to older adults through regional Area Agencies on Aging (AAAs). OAA nutrition programs, provided through the US Department of Health and Human Services, include congregate meals, which are meals served at senior centers and in other group settings, and home-delivered meals to more than 2.4 million older adults each year. The Administration on Aging (AoA) Elderly Nutrition Program (ENP), which is charged with executing the OAA, provides grants to states to support nutrition services to older Americans throughout the United States.

The goal of the ENP is to improve the nutritional status of older Americans and to offer them opportunities to socialize and create a social network. The meals and other nutrition services provided through ENP are provided in a variety of group settings, such as senior centers, faith-based settings, schools, as well as delivered to the homes of those who are home bound. Meals served under the ENP must provide at least one-third of the recommended dietary allowances established by the Food and Nutrition Board of the Institute of Medicine of the National Academy of Sciences, as well as the Dietary Guidelines for Americans (Administration on Aging 2014). In practice, participants typically receive more – approximately 40–50% of required nutrients. The ENP also provides a range of

related services through the aging network's estimated 4000 nutrition service providers, such as nutrition screening, assessment, education, and counseling. In fact, one older American can be fed a home-delivered meal for an entire year for about the cost of 1 day in a hospital (Meals on Wheels America 2015). In addition to providing nutrition and nutrition-related services, the ENP provides an important link to other needed supportive in-home and community-based services, such as home health aide services, transportation, physical activity programs, and even home repair and home modification programs. Participants must be age 60 or older. While there is no income means test for participation, services target older Americans who have the greatest economic or social need, with attention given to low-income racial/ethnic minorities and those who live in rural areas. In addition, others may also receive service – a spouse of any age; disabled persons under age 60 who reside in housing facilities occupied primarily by the elderly where congregate meals are served; disabled persons who reside at home and accompany older persons to meals; and nutrition service volunteers. As Native Americans tend to have lower life expectancies and higher rates of illness at younger ages than the general US population, Tribal Organizations, funded under Title VI, Grants for Native Americans, can set the age at which older people can participate in ENP.

Nutrition programs funded by the Older Americans Act are also required to provide nutrition counseling to identify persons at high risk for malnutrition. The Nutrition Screening Initiative was developed to address the prevalence of malnutrition among older adults. This initiative was spearheaded by the American Academy of Family Physicians and the American Dietetic Association to promote the integration of nutrition screening and intervention into healthcare for older adults. The DETERMINE Your Nutritional Status instrument, designed by the American Academy of Family Physicians, the National Council on the Aging, and others as part of the National Screening Initiative, aims to assess the risk for poor nutritional status or malnutrition among older Americans (Berdanier et al. 2013). The DETERMINE checklist has also been used to measure an individual's change in level of nutritional risk over time. Individuals at high nutritional risk are defined as individuals who score six or higher (Table 3). The checklist is based on the following symptoms of poor nutrition – chronic disease, eating poorly, tooth loss/mouth pain, economic hardship, reduced social contact, multiple medicines, involuntary weight loss/gain, need for assistance in self-care, and age 80 or older. The checklist must be completed annually and recorded for all older adults who receive congregate meals, home delivered meals, or nutrition counseling.

Choices for Independence is an integrated set of strategies and tactics designed to strengthen the Older Americans Act, particularly as it relates to preventing malnutrition among older Americans (U.S. Department of Health and Human Services 2007). This national initiative focuses on the development of health promotion interventions targeting older adults so they can live independently longer. Choices are supported by scientific evidence that shows that improving quality of life and decreasing health care costs can be achieved through low-cost health promotion programs that target older adults (Wacker and Roberto 2008).

Other programs offered through the US Department of Agriculture also serve older adults. The Supplemental Nutrition Assistance Program (SNAP) serves over four million older adults each year, with only 42% of eligible older adults enroll in SNAP due to participation barriers (National Council on Aging 2015b). The Commodity Supplemental Food Program provides 600,000 older adults each year with healthy food boxes to supplement their diets (United States Department of Agriculture 2015). The USDA also administers the Senior Farmers' Market Nutrition Program (800,000 participating older adults) and the Child and Adult Care Food Program (120,000 participating older adults). The Senior Farmers Market Nutrition Program awards grants to all 50 states, the District of Columbia, US territories (American Samoa, Guam, the Northern Mariana Islands, Puerto Rico, and the US Virgin Islands), and the 566 federally recognized Indian tribal governments to provide low-income seniors with coupons that can be exchanged for eligible foods (fruits, vegetables, honey, and fresh-cut herbs) at farmers' markets, roadside stands, and community-supported agriculture programs (National Conference of State Legislatures 2016).

Nutrition Education

If older Americans do not know how to practice good nutrition, their risk for nutrition- related health problems will continue to increase underscoring the need for effective nutrition education. People aged 50 or older were first recognized as a specific population group needing special consideration in the 2005 Dietary Guidelines for Americans (U.S. Department of Health and Human Services 2005). Per the OAA, one service each site that provides meals must provide nutrition education once per month. Unfortunately, delivery of these classes is occurring in a haphazard manner across the United States without consideration for the appropriateness of the information presented and the effectiveness of the delivery strategy, making behavior change unlikely.

To date, there are few evidence-based programs targeting this population making it clear that thoroughly tested curricula are needed, especially those that are tailored to the culture and context of the older adult and their environment (Partnership for Livable Communities, 2010). Older Americans who attend congregate meal sites experience a higher rate of food insecurity (29.1%) than those who do not (Duerr 2006) so for this reason alone may be at risk for malnutrition. Older adults living in rural America are also at higher risk for food insecurity (Pheley et al. 2002), which is contrary to the assumption that these older adults may still be gardening or receiving farm produce. Food choices and food preparation practices are a culturally based phenomenon that relies heavily on ritual and context (Aselage and Amella 2010; Fjellstrom 2004). To assist in the elimination of health disparities, one goal of *Healthy People 2020*, culturally, contextually, and environmentally appropriate education interventions targeting older adults must be created (Centers for Disease Control and Prevention 2011).

Little evidence is available to show the effect of OAA-required nutrition education on older adults. One systematic literature review to determine the effect of nutrition education interventions for community-dwelling older adults yielded only three randomized control trials of interventions provided as part of the OAA Nutrition Program (Bandayrel and Wong 2011).Because each study examined the effect of a unique and specific nutrition education intervention and sample sizes differed greatly (with 44, 104, and 703 participants, respectively), results were difficult to compare (Kupka-Schutt and Mitchell 1992; Mayeda and Anderson 1993; Mitchell et al. 2006). Only one study (with the largest sample size) yielded significant, positive change in dietary behaviors, specifically in use of dietary supplements (Mitchell et al. 2006).

Conclusions

As the US population continues to grow older, more attention must be given to addressing the nutritional needs of older Americans. Malnutrition is a problem but the magnitude of the problem is unknown because of the lack of data. To effectively address this problem, we need to collect national-level data on the prevalence of malnutrition among older Americas in both healthcare settings (i.e., hospitals and long-term care facilities) as well as in community-dwelling older Americans. These data will allow for informed interventions to be directed in high need areas. But, to collect such data there is a need for universal accepted procedures for screening for malnutrition not only upon hospital admission but during other healthcare visits. Preventing malnutrition, which is grounded in good nutrition, is essential to helping older Americans live independently.

Procedures

Malnutrition is not an inevitable side effect of aging, it can be prevented or at least managed if properly diagnosed. As of 2017, the extent of malnutrition among older Americans is unknown because of the lack of national-level data. To prevent malnutrition, at a minimum we need to:

- Establish a universal, measurable definition of malnutrition that is accepted and used across the healthcare spectrum.
- Develop universal procedures to screen for malnutrition not only upon hospital admission but during other healthcare visits.
- Collect national-level data on the prevalence of malnutrition among older Americans in both healthcare settings (i.e., hospitals and long-term care facilities) and among community-dwelling older adults.

National-level data will help inform the development and delivery of nutrition interventions for use by the government, educators, and healthcare professionals.

Moreover, such a data set could also result in the more efficient use of the US$51.3 billion the US government spends each year to prevent malnutrition in community-dwelling older adults as these data can be used to direct the delivery of nutrition interventions to high-need areas.

Dictionary of Terms

- ***Alzheimer's disease*** – A degenerative brain disease of unknown cause that is the most common form of dementia, that usually starts in late middle age or in old age, that results in progressive memory loss, impaired thinking, disorientation, and changes in personality and mood.
- ***Cognitive decline*** – Decreased memory and thinking skills.
- ***Dementia*** – A progressive condition (such as Alzheimer's disease) marked by the development of memory impairment, loss of the ability to understand or express speech, and the inability to plan and initiate complex behavior.
- ***Functional decline*** – The decrease in physical and/or cognitive functioning resulting in one not being able to engage in activities of daily living, such as bathing, cooking meals, and shopping for food.
- ***Homeostatic reserves*** – The redundancy of the body's ability to overcome acute and chronic health insults.
- ***Huntington's disease*** – A hereditary brain disorder that is a progressive, neurodegenerative condition marked by depression, irritability, mood swings, deficits in memory and concentration, dementia, difficulty in swallowing, jerky movements, and loss of coordination.
- ***Parkinson's disease*** – A chronic progressive neurological disease chiefly of later life that is marked especially by tremor of resting muscles, rigidity, slowness of movement, impaired balance, and a shuffling gait.
- ***Periodontal disease*** – Any disease affecting the supporting structures of the teeth.
- ***Pneumonia*** – An acute disease that is marked by inflammation of lung tissue that is characterized by fever, chills, cough, difficulty in breathing, fatigue, chest pain, and reduced lung expansion, and is typically caused by an infectious agent (such as a bacterium, virus, or fungus).
- ***Sarcopenia*** – The reduction in skeletal muscle mass due to aging.

Summary Points

- The United States is rapidly becoming an "older" and less healthy nation.
- Malnutrition is a leading cause of morbidity and mortality among older Americans primarily because of poverty, rurality, and/or lack of access to good quality food.
- Medical conditions (chronic diseases and those associated with growing older) and lifestyle, social, and psychological factors all play a role in increasing one's risk for malnutrition.

- A review of nationally representative data suggest that malnutrition may be under-recognized and underdiagnosed in hospitals.
- To date, there is no consensus among healthcare professionals for implementing optimal nutrition care for malnourished and at-risk hospitalized older adults.
- Malnutrition screening and assessment are also not standardized as to date there is no universal definition of malnutrition.
- In 1965, the US Congress passed the Older Americans Act, which provides support for nutrition services to community-dwelling older adults through the Elderly Nutrition Program.
- The US government spends US$51.3 billion each year on the Elderly Nutrition Program.
- The meals and other nutrition services provided through the Elderly Nutrition Program are provided in a variety of group settings, such as senior centers, faith-based settings, schools, as well as delivered to the homes of those who are home bound.
- Each participating site must provide nutrition education once per month, with current delivery occurring in a haphazard manner across the United States.
- To date, few evidence-based nutrition education programs target older adults making it clear that thoroughly tested curricula are needed, especially programs tailored to the culture and context of the older adult and their environment.

Nutritional Status in Malnourished Older Diabetics

46

Alejandro Sanz-París and Beatriz Lardiés-Sánchez

Contents

Abstract

Diabetes mellitus is especially prevalent in the elderly. It has a different presentation, management, and complication rate in this population. Diabetes in the older people increases the risk of suboptimal nutrition, being malnutrition highly prevalent in elderly diabetic patients. Malnutrition should be screened for in these patients and, when present, should prompt a revision in diet and drug therapy. In malnourished diabetic patients, diabetes-specific enteral nutritional formulas have been specially developed as effective alternatives for providing nutrients, improving glycemic control, and reducing the incidence of complications.

Introduction

Diabetes mellitus is one of the most prevalent endocrine disorders in the general population, being especially prevalent in the elderly. Around 20% of the western society population over 65 years of age have diabetes, and several studies have shown that abnormal glucose tolerance is present in more than 60% of adults older than 60 years of age, as a result of decreased insulin sensitivity and impairment of pancreatic beta-cell function with age (Sanz-París et al. 2013). Diabetes is associated with an increased risk of suffering malnutrition and other geriatric syndromes and chronic health conditions, placing an important burden on healthcare systems.

Malnutrition is also more common and increasing in older population; currently 16% of those >65 years and 2% of those >85 years are classified as malnourished. The aging process involves a deterioration in some functions that can result in reduced appetite, difficulty in chewing, inflammation of the gums, and a poor quality diet, which can negatively impact nutritional status (WHO 2015). Studies in developed countries found that up to 15% of community-dwelling and home-bound elderly, 23–62% of hospitalized patients, and up to 85% of nursing home residents suffer from malnutrition (Ahmed and Haboubi 2010).

Diabetes in the elderly increases the risk of suboptimal nutrition, being malnutrition highly prevalent in elderly diabetic patients. Malnutrition should be screened for in these patients and, when present, should prompt a revision in diet and drug therapy. In particular, the possibility of reducing unnecessary drug therapy should be considered (Vischer et al. 2010).

Diabetes in Elderly People

There is increasing evidence suggesting that type 2 diabetes mellitus has a different presentation, management (including dietary therapy), and complication rate in older population.

There are several factors affecting glucose metabolism with age: genetic and ethnic influence, resistance to insulin-mediated glucose uptake, progressive reduction of insulin secretion from the pancreas, changes in body composition (relative increase adipose tissue in relation to muscle mass), changes in food intake, impaired mobility and physical activity, psychological factors (such as stress, isolation), use of medications that impair insulin sensitivity, and finally lifestyle modifications (efforts at weight loss and physical activity), which lead to improved insulin sensitivity (Rizvi 2009) (see Fig. 1).

Diabetes in the elderly increases the risk of suboptimal nutrition, hospitalizations, nursing home admissions, and physical disability that substantially impairs quality of life. Diabetes is linked to higher mortality, reduced functional status, and increased risk of institutionalization in elderly frail population (see Table 1). Older people with diabetes is a heterogeneous population that includes people residing independently in communities, in assisted care facilities, or in nursing homes. These patients usually present common geriatric syndromes such as cognitive impairment,

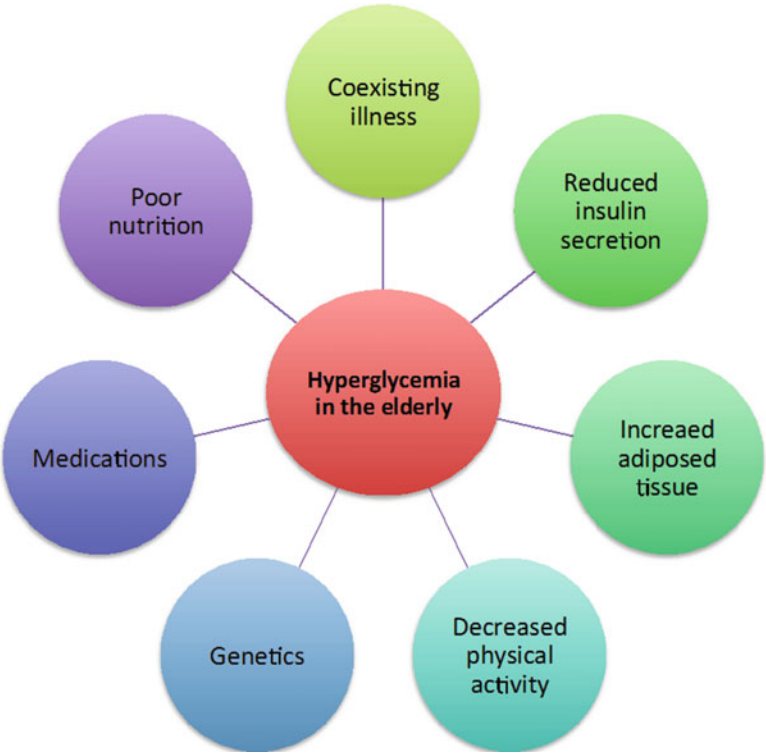

Fig. 1 Pathogenesis of diabetes mellitus in the elderly

Hospitalizations
Higher mortality
Reduced functional status
Increased risk of institutionalization
Impaired quality of life

depression, urinary incontinence, and falls, and there is a high risk for polypharmacy. This implies that management of diabetes in older adults should be individualized, taking into account all these variables (Kirkman et al. 2012).

Older adults with diabetes are at risk of the same microvascular and macrovascular complications as those at younger ages, although absolute cardiovascular risk is much greater at a more advanced age (Kennedy 2016). Moreover, they are more likely to have coexistent chronic conditions like hypertension, dyslipidemia, and cardiovascular disease that may impact their nutritional requirements (Leon-Sanz et al. 2015).

The overall goals for glycemic control, as well as risk factor management, should be individualized considering several factors such as individual's overall health, level of patient engagement, risk for hyperglycemia and other adverse reactions, duration of diabetes, comorbidities, vascular complications, and life expectancy, since the risk of complications is duration-dependent (Kennedy 2016). Amelioration of symptoms is foremost, although reducing morbidity from complications is a worthy long-term goal. Older adults who are functional, are cognitively intact, and have significant life expectancy should receive diabetes care using goals developed for younger adults (Kirkman et al. 2012).

Factors that affect the patients' quality of life and their ability to manage their condition should be assessed. The importance of diet, blood glucose monitoring, and adherence to prescribed medications are important aspects of care for the frail elderly with diabetes.

The vulnerability to hypoglycemia is substantially increased in older adults. Thus, avoidance of hypoglycemia is an important consideration in establishing goals and choosing therapeutic agents in the elderly.

On the other hand, older patients with diabetes should receive individualized counseling regarding lifestyle modification, including a medical nutrition evaluation. The nutrition prescription is tailored based upon medical, lifestyle, and personal factors. Appropriate diet, loss of excess weight, and regular aerobic and resistance exercise continue to be beneficial in the majority of this population. Individualization of advice in these areas is important, with due consideration given to comorbidities, family, and social support (Kennedy 2016).

Malnutrition in Older Adults

Nutrition is an important element of health in the older population and affects the aging process (Ahmed and Haboubi 2010). Older people are at an increased risk of inadequate diet and malnutrition, which is defined as a state with a deficiency, excess, or imbalance of energy, protein, and other nutrients that causes adverse effects on body form, function, and clinical outcome (Stratton et al. 2003). A poor nutritional status is associated with a decline in functional status, decreased bone mass, impaired muscle function, immune dysfunction, anemia, reduced cognitive function, poor wound healing, delay in recovering from surgery, and higher hospital readmission rates and mortality (Ahmed and Haboubi 2010; Lim et al. 2012) (see Fig. 2).

The prevalence of malnutrition in the elderly is increasing and its etiology is multifactorial (Chapman 2006). Aging is associated with a decline in number of physiological functions that can affect nutritional status. Older people often have reduced appetite and energy expenditure, coupled with a decline in biological and physiological functions such as reduced lean body mass, changes in cytokine and hormonal level, and changes in fluid electrolyte regulation, delayed gastric emptying, and diminished senses of smell and taste (Ramos Martínez et al. 2004). Healthy older people are less hungry and are fuller before meals, consume smaller meals, eat

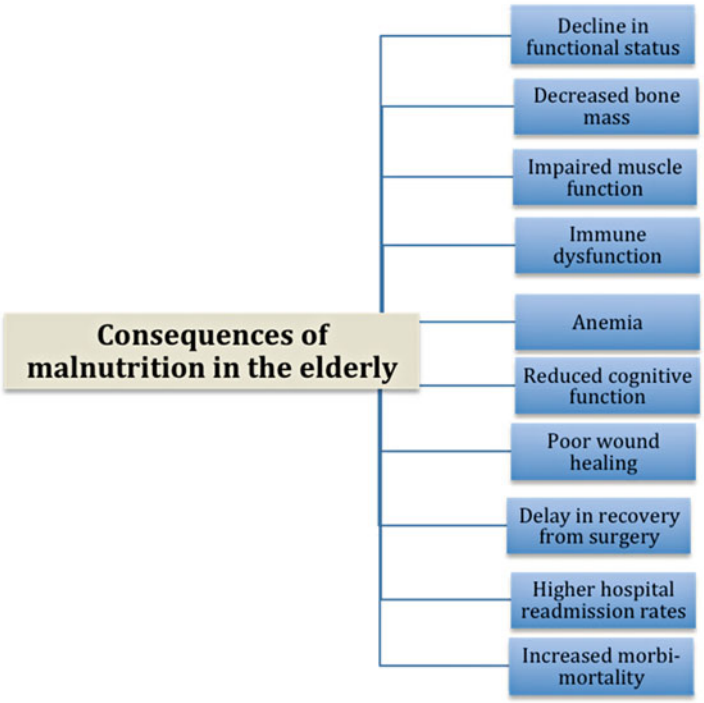

Fig. 2 Consequences of malnutrition in the elderly

more slowly, have fewer snacks between meals, and become satiated after meals more rapidly after eating a standard meal than younger people. Moreover, several factors such as physical conditions (e.g., poor dentition, dysphagia, altered taste and smell, swallowing difficulties), psychosocial conditions (low income, limited knowledge of diet and cooking skills, alcohol or drug abuse, poverty, isolation, inability to shop, functional impairments leading to difficulties in preparing or consuming food), and medical conditions (e.g., infection, stroke, drugs, anorexia, palatability, dietary restrictions, eating disorders, altered bowel conditions, cancer, dementia, depression, diabetes, etc.) all play a role in the complex etiology of malnutrition in older people (Kirkman et al. 2012). Moreover, basal metabolic rate decline with age and higher prevalence of obesity is difficult to reconcile with sharply lowered energy intakes (Drewnowski and Warren-Mears 2001) (see Fig. 3).

Assessment of Nutritional Status in Older Adults

Nutritional assessment is important to identify and treat patients at risk. Several tools have been used for the evaluation of nutritional status in the elderly. To quantify nutritional intake, different methods can be used. Twenty-four hour recall is

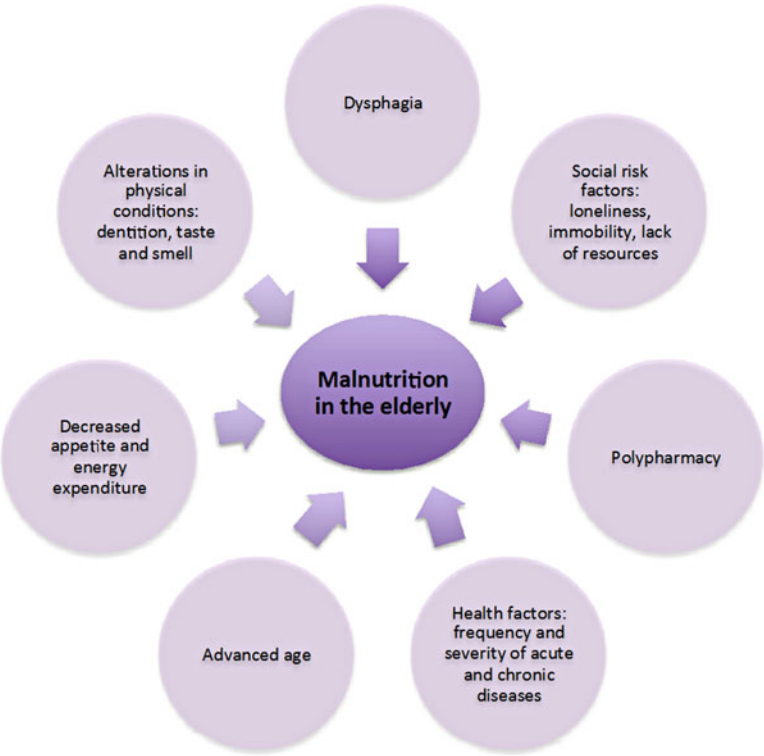

Fig. 3 Risk factors of malnutrition in the elderly

commonly used and is based on an interview in which the patients recall all food consumed in the previous 24 h, and also food records for 7 days for all food and drink consumed can be used. A food frequency multiquestion questionnaire can also be used to explore dietary intake over a period of time (Pirlich and Lochs 2001).

Screening of malnutrition is vital in identifying and monitoring patients, and it should assess body mass index (BMI) and percentage of unintentional weight loss (which is one of the best predictors of worst clinical outcome) and should also consider the time over which nutrient intake has been unintentionally reduced and/or the likelihood of future impaired nutrient intake. Structured screening tools may identify nutrition-related issues that warrant evidence-based interventions (Cena et al. 2008).

The European Society for Clinical Nutrition and Metabolism (ESPEN) recommends the use of the Mini Nutritional Assessment (MNA) tool, specifically designed for older adults, because the predictive validity has been evaluated by demonstrating its association with adverse health outcome in fragile elderly patients. This tool also takes into account relevant physical and social aspects, besides the dietary habits. It has been evaluated in acute care facilities showing an inverse relationship between its final score and mortality. Moreover it is simple to perform and may help

determine whether referral to a registered dietitian for medical nutrition therapy is needed. The MNA test includes 18 items in four sections: anthropometric assessment (four questions concerning weight, height, and body circumferences), global evaluation (six questions concerning lifestyle, medication, and mobility), dietetic assessment (six questions concerning number of meals, food and fluid intakes, and autonomy of feeding), and subjective assessment (two questions concerning self-perceptions of health and nutrition). The score obtained (maximum, 30) classifies the elderly in three categories: malnourished (<17), at risk of malnutrition (17–23.5), and well nourished (>24) (Guigoz 2006).

The Malnutrition Universal Screening Tool (MUST) may also be used (Donini et al. 2016). The MUST score is calculated using three steps: body mass index (BMI), percentage weight loss in the past 6 months, and disease effect. Each resulting score has its own set of recommended interventions. Higher scores represent a greater risk of malnutrition.

As the population ages, it is more important than ever that the implications of malnutrition are recognized and addressed (Willis 2017).

Nutritional Status and Malnutrition in Elderly Diabetic Patients

Disease-related malnutrition is common in diabetic patients. Older adults with diabetes appear to be at risk of nutritional impairment compared with nondiabetic people (Hamdy et al. 2014), and in fact previous studies have shown that diabetic patients are at a higher risk of malnutrition than nondiabetic patients (Alvarez-Hernandez et al. 2012). Residents with diabetes may have numerous underlying risk factors for poor nutritional status including multiple medications affecting gastrointestinal function and appetite, medical comorbidities, disabilities affecting the ability to eat and drink safely, low mood, and poor cognition.

Diabetes mellitus is characterized by hypermetabolism. Metabolic and nutritional factors play a role in the development of DM and complicate its course. These patients have a high metabolic rate, especially in patients with DM and renal failure. Despite a high metabolic rate, patients with type 2 DM are prone to be obese (currently the main cause of this type of diabetes). Even though type 2 DM patients are obese, they have reduced lean body weight, compared with nondiabetic obese individuals, and an exaggeration of the normal loss of muscle mass with age (Park et al. 2007).

Patients with type 2 DM suffer mainly from macronutrient overnutrition (an important etiological factor in causing the disease), and those with type 1 DM tend to be undernourished at the time of diagnosis. In fact, a common presentation of patients with type 1 diabetes is weight loss, included marked loss of lean mass. Micronutrient deficiencies are frequent in both type 1 and type 2 DM.

Type 2 diabetes mellitus usually occurs in the context of obesity and is associated with insulin resistance, so it is expected to find diabetic elderly patients, though suffering some level of malnutrition, with higher body mass index than those without diabetes.

Elderly people with diabetes share nutritional problems of older people with chronic diseases, but they have also specific nutritional deficiencies which are specific of this disease. An increased prevalence of malnutrition has been described especially in patients with nephropathy and diabetic foot ulcers (Turnbull and Sinclair 2002).

Current treatment recommendations are based on lifestyle modifications and incremental drug therapy. However, this approach could lead to inappropriate priorities upon aging, when diabetes may be compounded by malnutrition and reduced insulin resistance. The overlap of malnutrition and glucose intolerance in older people is common but frequently overlooked. The prevalence increases with frailty, physical infirmity, and institutionalization.

In hospitalized elderly diabetic patients, nutritional assessment is of outmost importance not only because it is the first step to correct malnutrition but also because it can prompt a reduction of unnecessary anti-glycemic therapy, thus preventing hypoglycemic episodes.

In the study of Liu et al. (2017), the aims were to explore the prevalence of malnutrition among elderly diabetic patients admitted to the hospital and to explore the relationships between malnutrition and geriatric syndromes, diabetic complications, and clinical outcomes. Of 302 participants, the prevalence of malnutrition, risk of malnutrition, and normal nutrition was 18.5%, 33.1%, and 48.3%, respectively. Moreover, diabetic microvascular complications and activities of daily living dependence were independently associated with malnutrition. Malnourished patients had longer hospital stays and higher mortality rates than patients either at risk of malnutrition or with a normal nutritional status. Multivariate analysis also showed that malnutrition was independently associated with an increased risk of death.

Recently, in a multicenter study (Sanz-París 2016a), the prevalence of malnutrition according to the new ESPEN definition in elder hospitalized diabetic patients was assessed. In the study was evaluated whether this new diagnosis of malnutrition predicted clinical outcomes in these patients. 1014 hospitalized diabetic patients ($\geq$65 years) from 35 hospitals were screened being at risk of malnutrition using the short version of the MNA. The new ESPEN definition, with MNA-SF as initial screening, identified 68 malnourished geriatric individuals with diabetes (6.73% of the cohort). Additionally, malnutrition lengthened the hospital stay, increased 2.7 times the odds of dying in the hospital, and decreased to one third the odds of being discharged home.

In the study of Solóirzano-Pineda et al. (2012), the incidence of malnutrition was assessed in diabetic and nondiabetic patients in a surgery department, assessing the nutritional status by means of VSG, CONUT, and MNA. The conclusion was that the incidence of malnutrition in surgical diabetic patients is twofold higher than in nondiabetic patients.

Malnutrition is widely prevalent in patients with chronic kidney disease. In the study of Khan (Khan et al. 2009), the primary objective was to assess the utility of subjective global assessment (SGA) as an indicator of malnutrition in patients with diabetic nephropathy, in combination with anthropometric and biochemical parameters. The SGA method was performed to evaluate nutritional status in 40 patients

Table 2 Points to carry out in elderly diabetic patients

Screen for malnutrition using a validated screening tool
Agree glycemic targets and blood glucose monitoring
Identify those patients at risk of hypoglycemia and formulate clear care plans to minimize risk
If risk of malnutrition is identified, give first-line dietary advice including enriching food
Ensure everyone involved has a clear understanding of the goals and targets of dietary intervention
If episode of risk of malnutrition resolves, reinforce previous dietary recommendations

with diabetic nephropathy. Malnutrition was identified in 63% of patients, mild to moderate in 48%, and severe in 15%. The study confirmed that a high degree of malnutrition was prevalent in patients with diabetic nephropathy, as shown by anthropometric and biochemical variables.

Moreover, in diabetic patients, metabolic disturbances of poorly controlled DM may account for the higher resting energy expenditure observed in the chronic renal failure diabetes group (Aversani et al. 2001).

Malnutrition can present a significant clinical and public health problem among older diabetic patients, implying an increased risk of morbidity, hospitalization, and mortality. Therefore, early detection and intervention is important (Mann et al. 2004).

Identifying patients at risk via screening is the first step to providing effective intervention, followed by appropriate management strategies that are implemented once undernutrition or the risk of undernutrition has been identified (Flanagan et al. 2012), (Casimiro et al. 2001). Overly restrictive eating patterns, either self-imposed or provider-directed, may contribute additional risk for older adults with diabetes (see Table 2).

A few studies have evaluated the prevalence of malnutrition in hospitalized elderly diabetic patients by means of the Mini Nutritional Assessment (MNA®) tool. The study of Leon-Sanz et al. (2015) is the first study that evaluates the prevalence of malnutrition and its costs in adult hospitalized patients with diabetes using the NRS®-2002 screening tool. In this study, a third of diabetic patients admitted at Spanish hospitals are malnourished, and these patients have longer hospitalizations and higher costs than those at no nutritional risk. This study also suggests that nutrition support is a cost-effective strategy in malnourished patients as it helps reduce the length of hospital stay and the incidence of complications.

People with diabetes are already at risk of poor healing and poor health outcomes because of the complications of the disease. Despite the increased risk in this vulnerable group, malnutrition often remains unrecognized and untreated.

Dietary intervention may be required for varying lengths of time, depending on the underlying contributing factors and the patient's individual requirements.

In patients with diabetes and malnutrition, immediate measures to consider include glycemic control and, in older patients with type 2 diabetes, a review of diabetes medication. Rapid weight loss, as 5–10% body weight, may require an immediate reduction of diabetes medication to prevent hypoglycemia. Moreover,

many diabetic individuals complain of dry mouth (xerostomia), a condition that can affect oral health, nutritional status, and diet selection and edentulous.

On the other hand, older people with diabetes are more susceptible to develop problems with fluid and electrolyte balance due to physiological renal impairment and changes in thirst perception (Drewnowski and Warren-Mears 2001).

Nutrition is an integral part of diabetes care for all ages, but there are additional considerations for older adults and several points to take into account. There is much literature published about the role of dietary therapy in the management of people with diabetes, but most studies focus on the middle-aged patients, and current diet and lifestyle recommendations mainly focus on young and middle-aged diabetic patients. Diabetic patients develop malnutrition and lose lean body weight rapidly when stressed by intercurrent illness. Nutritional support should not be delayed in these patients.

Diabetic patients are at risk of both malnutrition and hospital readmissions, often requiring nutritional support (Elia et al. 2005). Reduced intake due to medical, social, and physiological factors should be addressed (Ahmed and Haboubi 2010). VIDA study is the first Spanish multicenter study describing nutritional status of a large sample of elderly inpatients with diabetes mellitus. 21.22% of the 1098 patients were malnourished. This result depends on age and sex and can increase mortality rate (Gómez-Candela et al. 2016).

Older people in isolation should have social services assistance and "meals on wheels" to help improve food intake. When nutrition needs are not being met with usual intake, oral nutrition support in older malnourished diabetic patients includes any of the following advice to improve nutritional intake: fortified food with protein, carbohydrate, and/or fat, plus minerals and vitamins, snacks, altered meal patterns, and the provision of dietary advice. Additional interventions may include encouraging smaller more frequent meals, fortifying usual foods, changing food texture, or adding liquid nutrition supplements (either regular or diabetes-specific formulas) between meals. Oral supplements or enteral feeding should be considered in patients at high risk or in patients unable to meet daily requirements. Supplements have been shown to improve clinical and functional outcomes and reduce mortality rate. See Table 3.

Postprandial hyperglycemia significantly contributes to overall glycemic control in type 2 diabetes patients. Epidemiological studies have shown a strong and independent relationship between postprandial blood glucose excursions and cardiovascular comorbidities in type 2 diabetes patients. Diets with a low glycemic load are recommended in controlling postprandial plasma glucose levels. The amount of carbohydrate eaten is important to control blood glucose levels. All varieties are fine but those that are more slowly absorbed (lower glycemic index) will not affect blood glucose levels as much.

For diabetic patients in need of nutritional support, diabetes-specific enteral nutritional formulas have been specially developed as effective alternatives for nutritional treatment in diabetic subjects, which aim to result in lower (postprandial) glucose levels than standard formulas (McMahon et al. 2013). Traditionally, these formulas contained less carbohydrates (35–40%) and typically more fat with a large

Table 3 Key points to take into consideration with regard to nutrition in the elderly patient with diabetes

The prevalence of diabetes increases with age and is likely to coexist with other chronic health conditions
Appetite changes, palatability, dietary restrictions, and psychosocial issues become increasingly important factors in the elderly
Nutritional support should be guided by glycemic control, long-term risk of vascular complications, and the patient's preferences and quality of life
Awareness of nutritional guidelines and tailoring them to the elderly diabetic patient is a prudent approach

contribution from monounsaturated fatty acids, generally more than 60% of total fat content (Elia et al. 2005). However, nutritional guidelines for diabetic patients published by the Diabetes Nutrition Study Group of the European Association for the Study of Diabetes recommend that the fat content of a diet should not exceed 35%, and carbohydrate intake should range between 45% and 60%. They have shown to improve glycemic control and reduce the incidence of complications (Gosmanov and Umpierrez 2012). They are an effective alternative for providing nutrients and maintaining glycemic control due to their content of slowly digested and absorbed carbohydrates and monounsaturated fats (Sanz-Paris 2016b; Alish et al. 2010; Ojo and Brooke 2014; Lansink et al. 2011; Vaisman et al. 2009) (see Table 4).

Enteral feeding is indicated if a patient is severely malnourished or if food cannot be taken orally due to medical illness, e.g., stroke. Patients with difficulty swallowing, e.g., stroke patients, need speech and language therapy and possibly percutaneous endoscopic gastrostomy (PEG) feeding in the long term. In the short term, a nasogastric tube can be used.

On the other hand, reduced intake and unbalanced diet predispose older people to vitamin and mineral deficiencies. In patients with proven deficiencies of micronutrients, supplementation should be given. The major function of vitamin D is to maintain calcium and phosphorus homeostasis and promote bone mineralization. Vitamin D deficiency leads to reduced bone density and increased risk of falls and cardiovascular disease. Dietary requirements on older people are higher due to decreased exposure to sunlight, thinning of the skin, and reduced skin production. Calcium and vitamin D supplementation have been shown to reduce the incidence of hip fractures (Ahmed and Haboubi 2010).

In a review of vitamin D and diabetes (Song et al. 2013), it was suggested that vitamin D and calcium may play a role in the development of type 2 DM by influencing inflammation and the destruction of pancreatic beta cells. Low calcium and vitamin D intake are indeed associated with development of DM. Vitamin D appears to increase the insulin response to glucose stimulation while not influencing basal insulinemia. Low vitamin D levels were associated with more severe insulin resistance, development of albuminuria, cardiovascular disease, and higher HbA1c levels.

Table 4 Advantages and disadvantages of diabetes-specific formulas in diabetic patients

Advantages	Disadvantages
Designed specifically for patients with DM and/or hyperglycemia They contain less carbohydrates, more fiber, and more fat than standard solutions, while the protein content and micronutrient composition are similar It results in lower glycemic, lower HbA1c, and lower glycemic variability They reduce the requirements of regular insulin An increase in fiber content helps glycemic control, improves insulin sensitivity, and decreases the glycemic index	The high content of fat and fiber delay more gastric emptying, which may be negative in patients with diabetic gastroparesis or delayed gastric emptying (due to neuropathy, medical treatment, or hemodynamic compromise) No clear reduction in complications or mortality

Policies or Protocols

Medical nutrition therapy is the process by which the nutrition prescription is tailored for people with diabetes based upon medical, lifestyle, and personal factors and is an integral component of diabetes management and diabetes self-management education. It has proven to be beneficial in older adults with diabetes. Unique challenges with aging, such as altered taste perception, coexisting illnesses and dietary restrictions, compromised dentition, altered gastrointestinal function, impaired food shopping, preparation capabilities, and memory decline leading to skipped meals, should be considered before developing meal plans. In general, it is best to avoid complex dietary and treatment regimen in this elderly population.

Nutritional management requires a holistic approach, and underlying causes such as chronic illness, depression, medication, and social isolation must be treated. Recommendations should take into account the patient's culture, preferences, and personal goals and abilities.

Nutrition education should be individually tailored and should incorporate patience, kindness, humor, understanding, and above all a respect for the differences that make each older person an individual.

The elderly diabetic population stands to benefit enormously from streamlining and optimizing diet planning in order to enhance longevity, minimize complications, and improve quality of life. There is a paucity of definitive, long-term studies examining the part that nutrition plays in the overall health and metabolism of older people. In order to meet these challenges, it is imperative to understand the role of dietary factors in the genesis and progression of glucose intolerance and diabetes in the older individual and implement evidence-based recommendations tailored to the specific circumstances (Abatecola and Paolisso 2009; Canadian Diabetes Association Clinical Practice Guidelines Expert Committee et al. 2013; Miller et al. 2004).

On the other hand, though energy needs decline with age, macronutrient needs are similar throughout adulthood. Meeting micronutrient needs with lower caloric intake is

challenging; therefore, older adults with diabetes are at high risk for deficiencies (Kirkman et al. 2012).

The main goal should be to help to improve oral food intake. Optimal nutrition promotes both functional health status and mental well-being. Dietary diversity and variety promote enjoyment and satisfaction with the diet, and modifying the dining environment in care homes has been shown to improve dietary intake.

The issue of attainment and maintenance of an optimal body weight in elderly diabetic persons may not be as straightforward as in other age groups, and the risk-benefit ratio may be different as well.

Although increased prevalence of overweight and obesity in the elderly contributes to insulin resistance and hyperglycemia, older inhabitants of long-term care facilities who suffer from diabetes tend to be underweight. Both may signify inadequate nutritional status and lead to increased morbidity and mortality. The attendant problems of appetite changes, palatability of food, dietary restrictions, loneliness, and depression may affect the type and quantity of food consumed by elderly persons. Although glucose control and health concerns are important factors in diet modification in the older population, other considerations include quality of life and individual preferences. Customizing of nutritional guidelines to the needs of the older diabetic patient makes sense.

Dictionary of Terms

- **Malnutrition** – lack of proper nutrition, caused by not having enough to eat and by inadequate or unbalanced intake of nutrients or their impaired assimilation or utilization.
- **Nutritional screening** – is a rapid, simple, and general procedure to identify subjects who may be at nutritional risk or potentially at risk and who may benefit from appropriate nutritional interventions.
- **Diabetes mellitus** – a chronic disease associated with abnormally high levels of the sugar glucose in the blood.
- **Hypoglycemia** – is when blood sugar decreases to below normal levels. In people with diabetes, levels below 3.9 mmol/L (70 mg/dL) are diagnostic.
- **Percutaneous endoscopic gastrostomy (PEG)** – is a procedure that allows nutritional support for patients who cannot take food orally. It involves placement of a tube through the abdominal wall and into the stomach through which nutritional liquids can be infused.

Summary Points

- Diabetes mellitus is one of the most prevalent endocrine disorders in the general population, being especially prevalent in the elderly.
- Diabetes in older people increases the risk of suboptimal nutrition, hospitalizations, nursing home admissions, and physical disability that substantially impairs quality of life.

- A poor nutritional status is associated with a decline in functional status, decreased bone mass, impaired muscle function, immune dysfunction, delay in recovering from surgery, and higher mortality.
- Malnutrition is highly prevalent in elderly diabetic patients, so it should be screened for in this population.
- Elderly people with diabetes share nutritional problems of older people with chronic diseases, but they have also specific nutritional deficiencies which are specific of this disease.
- Nutritional support should be guided by glycemic control, long-term risk of vascular complications, patient's preference, and quality of life.
- In malnourished diabetic patients, diabetes-specific enteral nutritional formulas have shown to improve glycemic control and reduce the incidence of complications.

Abstract

Malnutrition poses a serious and long-lasting impact on developmental, economic, social, and medical background for communities on a global scale. Tuberculosis on the other hand is ranked among the top ten causes of mortality worldwide. The two are prominently coexistent with evidence suggesting TB leading to malnutrition and vice versa giving rise to a vicious cycle benefiting each

other. Various modulations in immune responses complicate this bi-directional relationship. In this chapter, we have aimed to bring together the vast data on malnutrition and tuberculosis, about what affects what and how, for a better understanding of this relationship. The chapter also talks about micronutrient malnutrition as an integral part of malnutrition. Micronutrient malnutrition too, just like protein malnutrition, negatively affects the state of tuberculosis in TB patients. The various studies done can give an idea on using these data in targeting tuberculosis by overcoming the nutritional deficiencies that worsen the state of tuberculosis in both children and adults.

Keywords

Tuberculosis · Latent tuberculosis infection · Macrophages · Phagocytosis · Malnutrition · Cell-mediated immunity · Protein-energy malnutrition · Kwashiorkor · Secondary immune deficiencies · Anthropometric defects · Severe acute malnutrition · BCG vaccination · Micronutrient malnutrition · Nutritional supplement

List of Abbreviations

Ab	Antibody
Ag	Antigen
BCG	Bacillus Calmette-Guérin
CMI	Cell-mediated immunity
CYP27B1	Cytochrome P450, family 27, subfamily B, polypeptide 1
DN/DCs	Dendritic cells
GALT	Gut-associated lymphoid tissue
IFN	Interferon
IL	Interleukin
Mtb	*Mycobacterium tuberculosis*
NK	Natural killer cells
PPD	Purified protein derivative
ROS/RNS	Reactive oxygen species/reactive nitrogen species
SAM	Severe acute malnutrition
TB	Tuberculosis
TGF	Transforming growth factor
TNF	Tumor necrosis factor
VDR	Vitamin D receptor

Introduction

Nutrition is the most vital element for a healthy growth and development. Various studies have stated the role of malnutrition in developing an immune-deficient state in an individual, thereby making the host susceptible to various opportunistic infections. The relationship between the two was precisely explained for the first time by Scrimshaw et al. (1959). Scrimshaw et al. (1959, 1968) showed how

malnutrition and infection generate what is known as a "vicious cycle" wherein both the units interact and benefit from one another. They proposed that malnutrition increased susceptibility to infection, which by nature caused a furthermore deterioration of the nutritional status perpetuating a cycle that eventually led to extreme protein-energy malnutrition (PEM) or kwashiorkor, usually fatal. These interactions were observed to be usually synergistic with both malnutrition and infection together causing a more pronounced effect (Scrimshaw 2003).

Nutrition and the Immune System: The Critical Interlink

Host resistance to infections is a combined effect of various components of the immune system such as the CMI by T cells, antibody production by B cells, the complement system, barrier defense such as the skin and mucosa, interferons, etc. For a healthy life, it is very important that all these components work fine. The work published by Scrimshaw et al. (1968) showed that the cyclical interaction between nutrition and infection had a critical yet unknown connection to the host's immune system. How nutrition affected the immune system resulting in an infection-malnutrition cycle was the unanswered question. With developing technologies however, various animal and human analysis studies were able to give an insight to the subject leading to a detailed knowledge on effects of nutrition on the immune system.

Tuberculosis: An Introduction

Tuberculosis (TB), one of the top ten leading causes of mortality caused 1.4 million deaths and resulted in an estimated 10.4 million new cases in 2015 (World Health Organization 2016). About one-third of the world's population might have either active/latent TB which makes the disease a major public health priority (Lawn and Zumla 2011). The causative agent of TB, *Mycobacterium tuberculosis*, resides in humans causing either an asymptomatic, noncontagious, latent infection or an activated TB disease with the former being more prevalent than the latter. In a healthy individual, the first exposure to the bacterium is contained by the immune system resulting in latent infection. An immune deficiency caused by various factors such as HIV infection, diabetes, or undernutrition can also result in a progress from the latent to active form of the disease.

Tuberculosis: Pathogenesis and Immunology

The interactions between bacterial virulence and host resistance are a key factor in the pathogenesis of tuberculosis (Cooper 2009). *M. tuberculosis* is spread by airborne droplet nuclei, transmitted when an infected individual coughs and disperses these droplets, which can then be inhaled into the airways and alveoli of a new host. Experimental models have shown that the early host response to *M. tuberculosis*

infection is characterized by an influx of phagocytic cells including primarily resident alveolar macrophages and recruited neutrophils. Following the establishment of *M. tuberculosis* infection in the airways and lung parenchyma, the bacilli are believed to be phagocytosed by the alveolar macrophages and are taken up by neutrophils and dendritic cells (DCs). Macrophages and neutrophils may constitute a first line of defense by, for example, expression of antimicrobial peptides that may function in the early immune response. After infection of the host with *M. tuberculosis*, macrophages and neutrophils and the context of their activation may influence the subsequent immune response toward potential clearance or containment of the pathogen, resulting in persistent latent infection or the development of active disease (Ernst 2012). Clearance of resident bacteria by alveolar macrophages is dependent on the presence of lymphocytes as well as activation by IFN-γ, released by Th1 cells and other cells of the immune response such as NK cells and $CD8^+$ T cells that migrate to the site of infection in response to chemotactic signals generated by infected macrophages. The efficient interaction between infected macrophages and antigen-specific T cells in the host plays a vital role in the successful elimination of the bacterium. Immunity against tuberculosis is thus predominantly a Th1-type immunity involving the production of pro-inflammatory cytokines, specifically IFN-γ and IL-12. Interferon gamma (IFN-γ) plays an important role in activating macrophages, thus initiating phagocytosis, which aids in phagosome maturation, production of reactive nitrogen intermediates (RNI) and antigen presentation, all having important roles in immune response against TB (O'Garra et al. 2013).

Malnutrition: An Introduction

Malnutrition is a condition caused by an improper diet due to either an inadequate food supply (undernutrition) or too much dietary intake (overnutrition). Undernutrition can be either acute (too thin for their height – wasting) or chronic (too short for their age – stunted). Overnutrition is caused by the intake of excessive unhealthy food and not enough exercise leading to overweight (BMI of 25–30) and/or obesity (BMI > 30). Both under- and overnutrition lead to various health disorders with undernutrition leading to an increased risk to more severe forms of infectious diseases such as measles, malaria, tuberculosis, and pneumonia in comparison to obesity that leads to conditions such as diabetes, hypertension, stroke and other such heart disorders, cancer, etc. Nevertheless, both the forms of malnutrition are to be seriously taken with respect to the growing health issues of them in the developing world. According to the Economic and Social Development Department of the Food and Agriculture Organization of the United Nations (FAO-IFAD-WFP 2015), there were around 795 million undernourished people in 2014, of which about 13% of people were undernourished in the developing world with India having the highest rates especially in child/pediatric malnutrition (30% of children in India are estimated to be malnourished). There is also another form of malnutrition which is caused due to the deficiencies in appropriate micronutrients in a person's diet leading to a poor or improper development in health especially in children and pregnant

women. Micronutrients although needed in micro amounts can lead to severe health conditions if absent in the diet as they play an important role in proper production of enzymes and hormones. To summarize, malnutrition can be caused due to the improper uptake of an improper diet but can be prevented simply by taking the right amount of food with the right nutrients and thereby nullifying, to an extent, the risk to various infections.

Malnutrition and Tuberculosis

Malnutrition, specifically undernutrition, and tuberculosis are both widely spread conditions in the world until the current date. What is worse is the fact that the two are closely interlinked and fortunately or unfortunately share a bi-directional relationship, i.e., tuberculosis may lead to wasting and/or malnutrition, whereas malnutrition has a tendency to predispose the person to tuberculosis (Macallan 1999). Fortunately because treating one might reduce the effects of the other and unfortunately because the worsening of either can negatively influence the other and thereby lead to detrimental effects in unison. Moreover, it is almost impossible to determine whether malnutrition led to TB or vice versa since it is difficult to know the nutritional status of an individual with active TB before the onset of the disease.

Malnutrition → Tuberculosis: Does Malnutrition Play a Role in the Onset of Tuberculosis?

PEM is known to negatively affect CMI which is the major host immune response against tuberculosis thereby acting as an important risk factor (Cegielski and McMurray 2004). A number of researchers have looked at the rate at which malnutrition can become a risk factor in developing tuberculosis both on experimental animals and facts from human case and cohort studies. One systematic review by Lonnroth et al. (2010) compared various studies that related TB with malnutrition and came up with a conclusion that BMI and TB incidence shared a log-linear inverse dose relationship specifically in people between the BMI range of 18.5–30 kg/m^2.

Protein malnutrition in guinea pigs interfered with interactions between the macrophages and T lymphocytes in addition to mycobactericidal/static activity of macrophages (Dai and McMurray 1998). Protein malnutrition-mediated increase in TGF-β (transforming growth factor β) by live Mtb H37Rv-infected macrophages was also observed, showing a role in mediating immunosuppression and immunopathogenesis in tuberculosis. Protein-malnourished guinea pigs showed weak responses to PPD skin tests and an impaired lymphocyte proliferation (Mainali and McMurray 1998). Chronic protein deficiency in BCG-vaccinated guinea pigs caused a decrease in PPD-stimulated IL-2 production required for initiating and amplifying immune responses (McMurray et al. 1989) as well as significant decrease in the IFN-γ and TNF-α production (McMurray et al. 1986). However, on nutrient supplementation to the vaccinated malnourished guinea pigs, the PPD skin reactivity and the

vaccine-mediated control of bacterial loads were reversed to normal and were in fact indistinguishable from the vaccinated animals that have never been protein deficient (McMurray et al. 1986).

PCM in mice revealed a compromised CMI to tuberculosis leading to huge burdens of bacillary loads and a marked increase in the bacterial dissemination along with a poor granulomatous response and T-cell defects, which reversed on re-feeding with the appropriate diet (Chan et al. 1996), similar to guinea pigs. The loss of resistance to TB by the malnourished mice model was due to an IFN-γ defect that causes a diminished nitric oxide (NO) production, typically responsible for containment of infection, thus leading to virulence (Chan et al. 1992). A murine study (Ishikawa et al. 2009) showed how an undernourished mouse is devoid of a particular antibody that is known to normally respond to the TB vaccine antigen introduced. They concluded that undernourishment not only affects the CMI but also humoral immunity. In a more recent study (Hoang et al. 2015), the effects of PEM on the mycobacterial-specific immunity conferred by vaccination was assessed. PEM during the infection in an already vaccinated mouse resulted in a complete blockade of protection given by the vaccine with a loss in the IL-2+ memory CD4 T cells. PEM during the vaccination phase resulted a decrease in the vaccine efficacy characterized by an overall reduction in all T-cell subsets (with the exception of the TNF-α^{+} cells). However, the interesting part was that an improved diet replenishing the required adequate nutrients resulted in the reconstitution of the T-cell response supported by an improved pathogen clearance.

A diet deficient in protein, vitamin, and minerals resulted in an increase in the number of TB cases in Denmark. With the supplementation of the same, the rate of TB incidence drastically reduced. In another study, there was a considerable difference in TB rate in British POW supplemented with a proper diet (1.2%), in comparison to the Russian POW (15–19%). Both the groups shared the same living and working conditions and were exposed to the similar chance of infection, and yet the Russians saw rapid onset and increased severity of TB with poor granuloma formation, thus supporting the idea of a deficit CMI in malnourished individuals. In fact, the nature of dietary eating too seems to play a rather important role in developing a risk; the lifelong vegetarian Indians had a threefold higher risk of TB in comparison to the omnivore Indians and assumed cobalamin deficiency to be the causal agent. In London, a decrease in the frequency of meat/fish consumption was accompanied with an increase in the risk to TB (Strachan et al. 1995). All these studies outlined the concept of immunodeficiency caused by nutrition, i.e., nutritional immunodeficiency. A study in Peru (Pelly et al. 2005) somewhat gives evidence to this concept. The Peruvian data shows how subjects with low protein in the body were less likely to show a positive tuberculin skin test thereby suggesting an insufficient immune response to infection. A study by Anuradha et al. (2016) recently showed that coexistent malnutrition, defined by low BMI levels, in latent TB individuals is associated with diminished circulatory/systemic levels of protective and pro-inflammatory cytokine response (Type 1-IFN-γ and TNF-α; Type 17-IL-22; IL-1 family-IL-1α, IL-1β, and IL-6) and a heightened regulatory cytokine response (IL-10 and TGF-β). To the best of our knowledge, this was the first study to examine the relationship between cytokine responses and BMI in LTBI in humans.

The study confirms the results from animal studies that characterized malnutrition with a decreased IFN-γ and TNF-α response and an increased TGF-β response. The study not only measured the systemic levels but also the TB antigen-stimulated levels and found that a low BMI (LBMI) is associated with diminished levels of TB antigen-stimulated pro-inflammatory cytokines. Also, showing positive and negative correlations to two of the known protective cytokines (TNF-α and IL-1β) and regulatory cytokines (IL-10 and TGF-β), respectively, the study indicated the former as very strong positive predictors and the latter as very strong negative predictors for the effect of nutrition on TB infection.

Hughes et al. (2009) studied the function of DCs in children with severe acute malnutrition (SAM) in Zambia. On tuberculin stimulation, they observed a defect in the numbers of mDCs accompanied by lower spontaneous DC IL-12 production and fewer IFN-γ-producing T cells in the severely malnourished children. Around 17% of the study patients also witnessed a DC maturation failure measured by the downregulation of the HLA-DR instead of upregulation. These DCs called as the "anergic" DCs were associated with low T-cell proliferation and had a strong correlation with the IL-10 generation. However, on replenishing the nutritional supplements, the numbers increased and the maturation defects restored although not guaranteeing their survival, i.e., survival largely depended on the DC numbers in the infants at the time of admission. Thus, malnutrition appears to exhibit many negative effects on the immune system of the host against infection by *Mycobacterium tuberculosis*.

Malnutrition in Tuberculosis: Effect of Tuberculosis on the Nutritional State

Tuberculosis is a disease that is often known to "consume" an individual and thereby gained popularity as a "consumption" disease particularly in the eighteenth and nineteenth century (Macallan 1999). Tuberculosis is known to be the most frequent underlying cause of wasting worldwide, with the mechanism of the same being unknown (Schwenk and Macallan 2000). In fact, the nutrition status of a patient is a principal determinant of both morbidity and mortality from tuberculosis as the disease is known to affect the metabolism of important nutrients such as protein along with some micronutrients such as zinc, selenium, etc. (Kakkar 2014). Even in the coinfection of TB and HIV, a condition most common in the developing world, the major cofactor of wasting is tuberculosis, drawing even more attention to questioning the mechanism by which the disease causes such a condition and is thus often referred to as the "slimming disease" owing to the wasting effects it causes (Lucas et al. 1994). Several studies reported that patients with active pulmonary TB are malnourished, as indicated by reductions in the level of visceral proteins, anthropometric indexes, and micronutrient status (Onwubalili 1988; Saha and Rao 1989). Several studies have shown how tuberculosis leads to nutritional depletion with reduction in the BMI (Onwubalili 1988; Harries et al. 1988) and people with lower BMI have as much as fivefold higher risk to tuberculosis (Tverdal 1986). Apart from BMI, there were visible

reduction in the skinfold thickness and a great reduction in the MUAC (mid-upper arm circumference), a major representative of wasting.

Tuberculosis leads to wasting presumably due to the production of pro-inflammatory cytokines (Matthys and Billiau 1997) since utilization of amino acids and protein synthesis may be inhibited due to the presence of pro-inflammatory cytokines. Although the mechanism of wasting in TB is unknown, factors such as reduction in the appetite, nutrient and micronutrient malabsorption, altered metabolism (Macallan et al. 1998), loss of fat and lean tissues, as well as anorexia (Miller et al. 2000), all represent the major contributing factors for wasting in individuals affected with tuberculosis disease. The association of TB with cachexia or wasting syndrome is further supported by the prevalence of low serum concentrations of leptin, a satiety-regulating hormone, in patients with PEM (Schaible and Kaufmann 2007). Serum albumin concentrations, another marker of PEM, were found to be significantly lower in the untreated pulmonary TB patients when compared to the healthy controls (van Lettow et al. 2003).

Both malnutrition and tuberculosis are individually associated with high mortality rates especially in the developing world. This brings out the question as to how coexistence of malnutrition in tuberculosis affects the mortality rate of such individuals. Research has shown an increased risk of mortality in patients with malnutrition along with tuberculosis, with the risk increasing superlatively with the degree of malnutrition, according to few studies. A study in the Thyolo District in Malawi (Zachariah et al. 2002) showed that the 35% of patients suffering from moderate to severe malnutrition experienced death earlier than the rest, thereby making moderate (BMI = 16.0–16.9 kg/m^2) to severe (BMI < 16.0 kg/m^2) malnutrition an important risk factor for early mortality rates. A review paper by Schaible and Kaufmann (2007) also estimated that malnutrition is responsible for a nearly twofold increase in the risk of death in TB patients. A recent study done in Central India showed the associated risk of mortality with nutritional status of adult patients having pulmonary tuberculosis. They also saw that severe undernutrition at diagnosis was associated with a twofold higher risk of death (Bhargava et al. 2013).

Malnutrition and its association with tuberculosis have been widely studied in adults in comparison to children. Although the known association between the two, very few studies have been done on the same in children. However, extrapolating data from the various studies done on the adults, BCG-vaccinated children and the LTB-infected children throw some insights on malnutrition in children playing a crucial role in increasing the risk of TB (Cegielski and McMurray 2004). In a study by Satyanarayana et al. (1980) wherein they studied the effect of nutrition on tuberculin sensitivity after BCG vaccination, they observed an association of severe malnutrition with a reduced rate of skin test positivity in children. This association suggests an impaired cellular immune function, thereby leading to an increase in the risk of developing active TB disease. In yet another study, transmission of the active disease to children in household contacts with adults having PTB was assessed. It was observed that the children that were severely underweight were at more risk to acquire the active disease (Singh et al. 2005). However, there have been no studies that directly address malnutrition as a risk factor for TB in children.

Micronutrients and How They Play a Role in TB Immunity and Malnutrition

Malnutrition is a composite syndrome of multiple nutrient deficiencies, and single nutrient deficiencies rarely occur. Micronutrients like iron, zinc, and vitamin A are exceptions that can also occur alone but can complicate PEM (Chandra 1997). The above discussion mainly concerned PEM and on how proteins play a rather important role as a macronutrient in providing immunity against tuberculosis and to keep a check on malnutrition. Micronutrients, however, also play a vital role in the same and are important for the "complete diet" of an individual. Micronutrients are trace elements that although required only in small amounts are important for the proper growth and development of an individual and play a role in the key metabolic pathways along with immune cell function. Chandra (1990) gave a detailed outlook on the concepts of how micronutrients affect the immune system and paralyze its functions. They came up with five concepts: (i) immune responses are altered early during the initial reductions in the micronutrient intake; (ii) the degree of immune impairment relies on the person's age, the nutrient that is deficient, the level of its deficiency, its interactions with the other nutrients, and the presence of any other concomitant infections; (iii) the corresponding abnormalities in the immune functions help us to know the risks associated with the micronutrient deficiency; (iv) too much of the nutrient intake can also cause detrimental effects on the immune system; and (v) determining the lower and upper limit along with the minimum intake required for the individual can be determined by tests on immunocompetence.

Micronutrients include vitamins such as vitamins A, B, C, D, E, etc. and minerals such as zinc, iron, copper, selenium, etc. Each has a different role in providing host immunity. The following data has been collected from various review papers (Chandra 1979; Keusch 1990; Bhaskaram 2002; Bourke et al. 2016; Ibrahim et al. 2017) that have efficiently compiled the data on how the presence and absence of various micronutrients (both as a single nutrient deficiency and in combinations) lead to a state of malnutrition that affects the immune responses in the host against infections such as TB.

Iron, an important micronutrient for both innate and adaptive immunity, is known to have a role in various pathways of the immune response. Iron deficiency leading to anemia is a major public health problem, and anemia is common in tuberculosis patients. However, too much iron has detrimental effects to host defense. It impairs the macrophage suppression of invading microorganisms. Moreover, it is also known to be essential for the growth of various pathogens when available in the free form. This makes it tough to determine the effect of iron deficiency in increasing the susceptibility to an infection. There are studies in support of both, viz., studies that show iron deficiency increased the risk to infection and studies that show that iron supplementation increased the susceptibility to infections. When an infection occurs, the reticuloendothelial cells seize iron from the blood and phagocytes by releasing lactoferrin which binds to iron more efficiently than the siderophores of the bacteria thereby depriving the pathogen from iron resulting in an impaired bacterial replication along with an impaired killing of the bacteria by the phagocytes. These

studies demand more research in order to establish optimal levels of iron and on how we can use iron repletion effectively by maximizing the host defense and minimizing the pathogen multiplication.

Zinc, a cofactor for various enzymatic reactions, is an important micronutrient necessary for regulating various immune responses of the body. Its functions include promoting Th1 cell differentiation and cell responses by increasing IL-2, IFN-γ, and IL-12Rβ2 expression levels and the deficiency leading to lymphopenia with reduced CD4/CD8 ratio. It also promotes the activity of the thymic hormone with the deficiency leading to thymic atrophy with a reduced number of circulating T cells and a delayed or reduced PPD sensitivity. Another important function is regulating the release of pro-inflammatory cytokines. The deficiency is accompanied by a reduced number of the Th1 cytokines along with an impaired NK cells and macrophage phagocytosis functions. The decreased phagocytosis thereby affects macrophage-mediated in vitro cellular killing, proved to be restored after zinc supplementation. These functions make zinc deficiency a serious trouble, and unfortunately one-fifth of the world's population is affected by zinc deficiency. Also, around half a million child deaths (under the age of 5 years) each year are due to deficiency of zinc in the nutrition (Krebs et al. 2014), and this often accompanies childhood PEM. Zinc deficiency has profound effects on cellular function, and its presence is necessary for proper childhood growth and sexual maturation. In another study, plasma zinc levels were measured before and after the antituberculosis treatment (ATT), and the levels were shown to improve post-treatment, thus suggesting to be used as a marker for treatment response as well as for disease severity.

Vitamin A deficiency is a global health problem that affects 100 million to 140 million children and is the leading cause of childhood blindness worldwide. The only source of retinol (vitamin A) is through diet; it is absorbed by the enterocytes and stored in the liver. PEM leads to inadequate amino acids necessary for the synthesis of vitamin A transport proteins in the liver, thus complicating the state of vitamin A deficiency. Retinoic acid (RA) plays a role in the proper differentiation of epithelial cells, the lack of which causes pathogenic bacterial and viral invasion easier. It also has key roles in regulating both innate and adaptive immunities. Vitamin A deficiency seems to have an association with a reduction in the ILC3s that in turn led to reduced expression of IL-17 and IL-22 rendering increased susceptibility to acute enteric bacterial infection. The same vitamin A-deficient mice also exhibited an increase in the IL-13-producing ILC2 population with consequent increases in the amount of intestinal mucus, goblet cell hyperplasia, and resistance to intestinal helminths as a result of retinoic acid receptor (RARα)-dependent signaling, thus regulating the balance between the two subsets. Studies on the effect of vitamin A on tuberculosis have not yet been extensively done. The few ones that are done seem to show that the levels of it are lower in tuberculosis infection, but the levels seem to come back to normal even in the absence of supplementation. RA therapy for tuberculosis significantly increased the numbers

of $CD4^+$ and $CD8^+$ T cells, NK cells, and $CD\text{-}163^+$ macrophages in the infected lung tissues in rats with tuberculosis. There was also a significant difference in the severity of tuberculosis histopathology between control and RA-treated rats having tuberculosis thus showing that administration of RA seems to curtail the growth of Mtb in vivo. A combined micronutrient supplementation that includes vitamin A and zinc with other micronutrients might be helpful for TB patients since zinc plays a role in vitamin A metabolism and its deficiency leads to a secondary vitamin A deficiency. A recent study in 2017 on Moroccan patients with tuberculosis confirmed the association of low plasma vitamin A concentration to the TB disease, thus suggesting that vitamin A deficiency could be considered as a risk factor for infection with Mtb, but the role of vitamin A in enhancing immunity against Mtb is to be further assessed. Finally, vitamin A deficiency has been shown to increase the risk of TB ten - fold, making it one of the most important risk factor for active TB (Aibano et al. 2017).

Vitamin D deficiency is estimated to affect one billion people worldwide and is common in children and young adults. Vitamin D synthesis in the skin by means of UV light exposure (present in sunlight) is of critical importance due to the absence of vitamin D in dietary food. Most of the deficiency occurs due to lack of exposure of the skin to sunlight. Serum 25-hydroxyvitamin D [$25(OH)VD_3$] level is used to categorize a person as vitamin D deficient or insufficient, i.e., vitamin D deficient when the serum $25(OH)VD_3$ level is below 25 nmol/l and vitamin D insufficient when the serum $25(OH)VD_3$ level is 50–75 nmol/l. It exhibits roles in both pro-inflammatory antimicrobial effector function and suppression of anti-inflammatory activity. CYP27B1 is a gene that provides instructions for making the enzyme 1-alpha-hydroxylase (1α-hydroxylase), a vitamin D-activating enzyme that converts vitamin D to its active form. Recently several evidences suggest that this expression is under the control of several immune signaling pathways and has a role in exhibiting innate immune responses to bacterial infection. Mtb infection enhances TLR2-mediated induction of CYP27B1 and VDR in monocytes. Various studies showed that TLR4/NFκB and IFN-γ receptor (IFNγR)/STAT1 pathways also induced the expression of CYP27B1 and VDR with the IFN-γ receptor (IFNγR)/STAT1 pathway leading to an antibacterial effect by inducing autophagy as well as generation of the antimicrobial peptides cathelicidin (LL37) and β-defensin-2 that restrict the growth of Mtb in the macrophages in the presence of sufficient vitamin D, thus suggesting importance of vitamin D in rendering protection. 1,25-dihydroxyvitamin D enhanced the Mtb-induced expression of IL-1β that increased antimycobacterial activity via the NLRP3/caspase-1 inflammasome. VDR signaling also enhances the production of cathelicidin (LL37) and β-defensin-2.

Studies that show the effect of vitamin D on tuberculosis infection and treatment have resulted in promising results. A lot of studies are done in adults in the support that individuals with vitamin D deficiency are at an increased risk to get active TB pertaining to the VDR polymorphisms. Moreover, vitamin D deficiency enhanced relapse after ATT in a study done on HIV-TB-coinfected

individuals in both HIV-uninfected and HIV-coinfected patients. In some studies, the sputum smear conversion rates in support of treatment accelerated on vitamin D supplementation and also brought back the serum inflammatory cytokines and chemokines to normal level. In a randomized, placebo-controlled trial on smear-positive PTB patients in London where three doses of 2.5 mg each of vitamin D3 (cholecalciferol) were given as an adjunct with ATT, a significantly improved sputum conversion time was observed specifically in the subjects that had the tt genotype of the TaqI vitamin D receptor polymorphism. Surprisingly, a lower dose (100,000 IU) of oral cholecalciferol at three time points after ATT did not give positive results. Similarly, two doses of 600,000 IU of intramuscular vitamin D3 after ATT gave better results than the placebo. Even with respect to extra-pulmonary TB, adjunctive vitamin D with ATT showed improved results clinically. In 2015, it was shown in two articles that vitamin D levels and the incidence of active tuberculosis disease among contacts of patients with pulmonary tuberculosis are inversely associated. Moreover, the incidence of latent tuberculosis infection (LTBI) in the contacts of patients with PTB is reduced by vitamin D supplementation. All of these studies suggest that the presence or absence of vitamin D leads to immunomodulation however not explaining any direct beneficial effect in any of the clinical trials.

Selenium plays a critical role in mycobacterium clearance reportedly by reducing oxidative stress and enhancing the antioxidant status in the TB-infected individual via selenoproteins.

Cholesterol helps in enhancing the cytotoxicity of human lymphocytes, and its deficiency in TB affects the cellular immunity further, thereby proving to have negative effects. Infections are known to be accompanied by increased energy expenditure, tissue breakdown, and a decrease in the circulating levels of trace elements such as zinc and iron, thereby leading to an increased requirement of both macro- and micronutrients in infectious diseases like tuberculosis (Semba et al. 2010).

Nutrition Supplementation as Adjunctive Antituberculosis Therapy (ATT): Can Nutrition Supplementation Improve or Enhance ATT?

Tuberculosis leads to wasting which comprises of losses both in the fat mass and lean/protein mass, and a nutritional replenishment requires approximately an equal increase in both fat and fat-free/lean tissue masses. Antituberculosis treatment or therapy by itself is seen to increase the weight of the individual on therapy. The nutritional repletion occurs on treatment provided the intake is more than the body needs for energy expenditure required for tissue regeneration. However, studies have shown that this increase is more in the fat mass and not the lean mass suggesting an ongoing anabolic block even during treatment. Hence, for the complete nutritional replenishment, protein intake provided in the everyday diet as a nutritional supplement might be helpful in achieving a balanced increase in both the masses. Also, the

replenishment by treatment is a slow process with one study showing a significantly lesser increase in the MUAC (mid-upper arm circumference) and serum albumin levels even at the end of 1 year of therapy (Onwubalili 1988). Also, the nutritional status was better in the ones having a longer stay in the hospitals owing to the patient care and better food supply in hospitals questioning if the unavailability of proper food resources is limiting the recovery of TB patients undergoing chemotherapy (Kennedy et al. 1996). Vitamins and minerals also can be given as adjuvants in ATT and have proven to enhance the lymphocyte proliferation.

However, a more elaborate understanding of the pathophysiology of wasting is necessary, but an additional nutritional supplementation definitely aids in the recovery from tuberculosis by improving the ability to fight the disease and improving the treatment response, thereby reducing mortality, but the evidence for the same is unfortunately limited. The nutritional requirements may differ for individuals and can be assessed based on the nutritional status at the time of diagnosis by measuring the BMI. A good nutritional status can in fact be a preventative measure against TB and many such infections. Thus, nutritional supplementation is a novel approach recommended to improve TB outcome and also might help in the fast recovery of tuberculosis patients.

Policies and Protocols

Policies

Our chapter attempts to describe the importance of nutrition in developing a robust defense mechanism in the host against a pathogen (in our case *Mycobacterium tuberculosis*). It is important that the patient and his caretaker are both well informed about the effects that nutrition can have in the treatment of the disease to ensure that proper nutrition is provided. Also, along with the drugs for treatment, a proper diet schedule that includes the necessary nutrients (either in the food or as additional supplements) can possibly enhance the treatment. One can also find which nutrient deficiency they have so as to focus on eradicating that particular deficiency for better treatment results. Proper supervised diet and environmental conditions can have major effects on the rate of treatment of an individual.

Protocols

TB: Signs and Symptoms

- Latent TB infection (LTBI) – asymptomatic and noncontagious in nature.
- Active TB disease – long-lasting cough, often with blood or mucus, loss of appetite and thereby loss of weight, fatigue, fever, weakness, night sweats, chills, and chest pain in case of pulmonary TB. In case of extrapulmonary TB, the symptoms reflect respective to the organ infected.

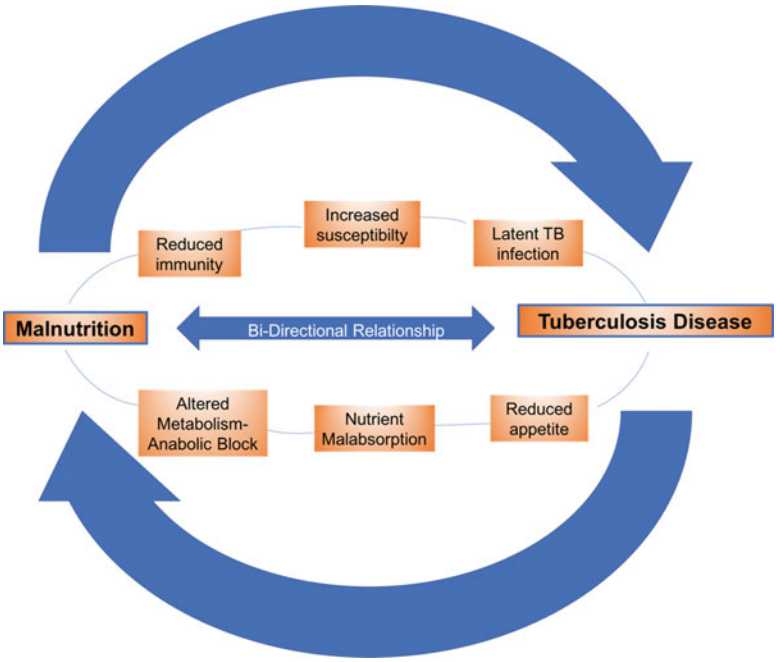

Fig. 1 Tuberculosis-malnutrition: a bi-directional relationship. The figure represents the vicious cycle of malnutrition and tuberculosis where one worsens the state of the other. Given also are the various parameters that result in this cycle

TB: Diagnosis

Various tests are used to diagnose TB in humans. These include PPD skin test (less sensitivity), QuantiFERON-TB Gold In-Tube test and T-SPOT, chest X-ray, sputum smear microscopy (SSM), culture test, and the recently added GeneXpert test. The PPD skin test and QuantiFERON test are used for LTB diagnosis, whereas the chest X-ray, SSM, and culture tests are specific for active pulmonary TB.

Dictionary of Terms

- **Adoptive transfer** – The transfer of cells, usually immune cells, from a healthy individual or patient to another patient. It is gaining popularity as an immunotherapy for certain ailments.
- **All-cause mortality** – The deaths that occur within a specific time period without accounting for the exact cause of the disease.
- **Anthropometric indicators** – Indicators that are used to assess the size, shape, and composition of the human body, to interpret the type and stage of malnutrition.

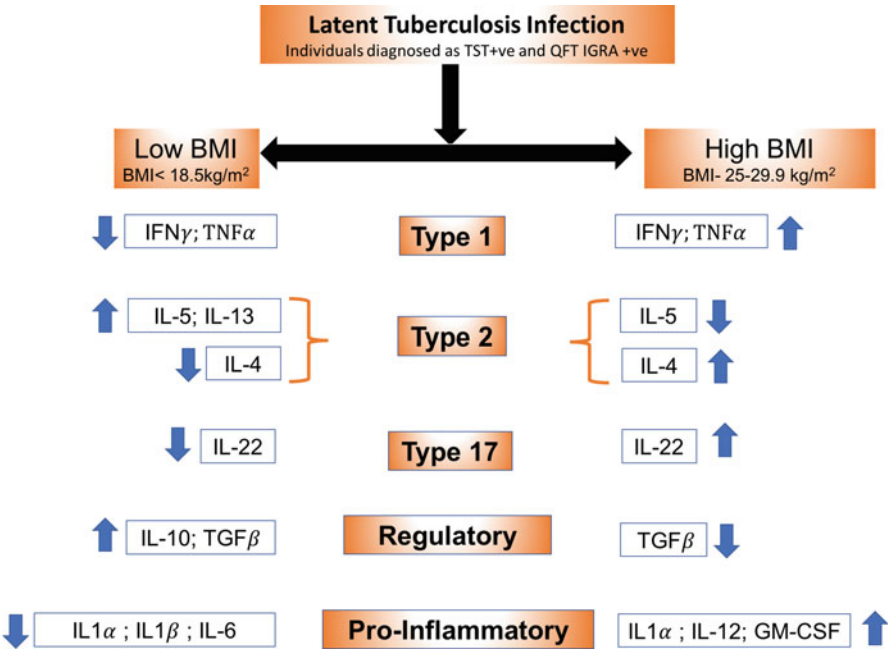

Fig. 2 BMI levels modulate the immune responses in LTBI individuals. The figure shows the upregulation and/or downregulation of the various Type 1, Type 2, Type 17, regulatory, and pro-inflammatory cytokines in LTBI-infected individuals with low and high BMI levels. LTBI, latent tuberculosis infection; BMI, body mass index

- **BMI** – **Body mass index** of an individual is calculated as his weight to square of the height ratio. It basically gives an idea about what is an ideal weight for a person's respective height and assesses malnutrition in adults.
- **MUAC** – Mid-upper arm circumference is one of the anthropometric measurements of the upper arm to assess malnutrition in children with age ranging between 6 and 59 months.

Summary Points

- The chapter aims at looking into the cause-effect relationship shared by malnutrition and tuberculosis.
- Malnutrition and occurrence of infection have long been linked with each other, with one affecting the other.
- Evidences suggest that tuberculosis is no exception.
- Malnutrition predisposes the person to secondary immune deficiencies predisposing them to tuberculosis.
- Tuberculosis itself leads to wasting thereby infamously also known as "slimming disease."

- Coexistence of the two seems to be extremely detrimental.
- Pediatric TB and malnutrition although widely prevalent have not been studied as coexistent infection extensively.
- Our chapter also looks into how micronutrient malnutrition complicates the tuberculosis disease.
- Finally, the chapter also throws light upon nutritional replenishment affecting the antituberculosis therapy (Figs. 1 and 2; Table 1).

Table 1 Studies on effects of nutritional supplementation on tuberculosis treatment. The table lists various studies done globally to witness the effect of micro- and macronutrient supplementation on antituberculosis treatment. The table also shows the respective conclusions obtained along with the journals in which the results were published

S. no.	Author and year	Result	Journal
1	Karyadi et al. (2002)	Vitamin A and zinc supplementation resulted in • An increased TB treatment efficacy after 2 months of the ATT • An earlier sputum smear conversion	Am J Clin Nutr
2	Das et al. (2003)	Iron supplementation accelerated the hematopoiesis in TB patients with mild or moderate anemia during the initial treatment phase	Br J Nutr
3	Range et al. (2006)	Multivitamin/mineral (MVM) with zinc supplementation during the ATT reduced mortality rates in HIV-TB co-infected individuals	Br J Nutr
4	Villamor et al. (2008)	Micronutrient supplementation • Reduced the risk of early TB recurrence in HIV-TB co-infected patients • Increased T cell numbers with reduced complications in the HIV uninfected individuals	J Infect Dis
5	Schon et al. (2011)	Supplementation of a diet rich in arginine showed • No overall clinical effect in TB patients • Increased cure rate in HIV-TB co-infected sub group • Poor clinical outcome in the co-infected sub group having low initial levels of eNO (nitric oxide in exhaled air)	Tuberculosis (Edinb)
6	Isanaka et al. (2012)	Iron overload and deficiency both showed association with poor treatment outcomes and increased mortality in TB patients	PLoS One
7	PrayGod et al. (2012)	Protein energy supplementation given to the individuals co-infected with pulmonary TB & HIV showed no overall changes on the body weight and composition however showed an increase in the handgrip strength	Br J Nutr
8	Jeremiah et al. (2014)	Nutritional supplementation leaded to a higher rifampin exposure in HIV-TB co-infected group reducing the negative effects of HIV on the drug levels during co-infection	Antimicrob Agents Chemother

TB tuberculosis, *ATT* antituberculosis treatment, *HIV* human immunodeficiency virus, *MVM* multivitamin/mineral

V. R. Preedy, V. B. Patel (eds.), *Handbook of Famine, Starvation, and Nutrient Deprivation*, https://doi.org/10.1007/978-3-319-55387-0_104

with nutritional disturbances secondary to the impaired metabolic function of the liver. In fact, the prevalence of malnutrition is believed to be as high as 65–90% in patients with chronic liver disease.

Malnutrition in Chronic HCV may present as protein-calorie malnutrition, manifesting as Sarcopenia or as micronutrient deficiencies. In addition to the signs and symptoms of the underlying liver disease, malnourished patients often present with weight loss, anorexia, nausea, skin and vision changes, as well neurological deficits. In chronic liver disease, nutritional impairment stems from a combination of disturbances in oral intake, absorption of macro- and micronutrients, and regulation of the physiological and biochemical processes of the body.

Subjective Global assessment is often favored as a screening tool for easy identification of malnutrition in HCV patients as it can be used in all settings. More Specialized tools like bioelectric impedance analysis and Dual-energy X-ray absorptiometry are not widely available and only indicated in certain patients such as liver transplant candidates. Additional laboratory investigations such as Serum levels of proteins like albumin may also provide useful clues regarding the nutritional status of HCV patients, but only in the absence of decompensated liver disease.

Management of malnutrition in chronic HCV patients resolves primarily around restoring muscle health. A significant aspect of management is to ensure a balanced diet that contains an adequate amount of calories and limits the amount of fat and simple sugars like fructose that have been implicated in the progression of liver disease.

PEG tube	Percutaneous Endoscopic Gastrostomy tube
SFT	Skin fold thickness
TIPS	Transjugular Intra-hepatic Porto-systemic shunt

Introduction

Hepatitis C is a viral infection of the hepatocytes spanning a spectrum from acute infection to chronic progressive liver disease and decompensated cirrhosis in advanced cases. Acute HCV is usually asymptomatic, very rarely leading to hepatic failure. More commonly though, Hepatitis C presents as gradually progressive chronic liver disease with up to 85% of patients going on to develop cirrhosis over the next 20–30 years (Chen and Morgan 2006) (Fig. 1).

As the primary metabolic organ in the body, liver holds a central role in the regulation of biochemical processes with respect to nutrient intake. Minimal hepatocyte injury in the earlier stages of HCV infection manifests only as subtle nutritional deficits. Only when a significant proportion of hepatocytes have been destroyed, as often seen in chronic liver disease in HCV patients, does the liver function begin to be affected. These alterations in liver function tend to result in poor nutritional intake as well as malabsorption of consumed nutrients and may have significant implications on the body's nutritional status. Studies have indicated the prevalence of malnutrition to be as high as 60–90% among patients suffering from chronic liver disease (Lautz et al. 1992; DiCecco et al. 1989)

Malnutrition in HCV is a serious complication that negatively impacts survival, quality of life, and response to stressors like infections and surgery (Merli et al. 1996). In cirrhotic patients, it manifests not just in the form of Protein-Calorie Malnutrition (PCM) but also Micronutrient deficiencies, particularly in case of an advanced liver disease. Both PCM and micronutrient deficiencies have been linked with a poorer outcome in patients with compensated as well as decompensated

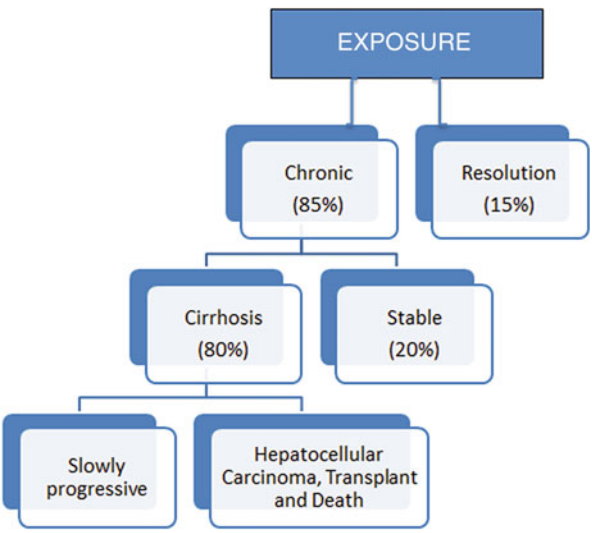

Fig. 1 Natural history of hepatitis C virus infection, depicting the relative frequency of each possible outcome (Cabré and Gassull 2000; Møller et al. 1994, Plauth et al. 1997)

cirrhosis. On the other hand, obesity correlates equally well with a poor prognosis in HCV patients and has been linked to high viral loads and liver damage in patients, particularly the elderly (Petta et al. 2010).

PCM in chronic HCV has been linked to an increase in mortality as well as morbidity by predisposing patients to complications like variceal bleeding and ascites (Cabré and Gassull 2000; Møller et al. 1994; Plauth et al. 1997). It manifests as Sarcopenia or loss of lean muscle mass which is regarded as the most objective feature of malnutrition in patients with chronic liver disease.

Deficiency of micronutrients like vitamins A, C, K, B complexes contributes equally to morbidity by causing skin and vision changes, coagulopathies, and neurological symptoms.

HCV patients commonly co-present with obesity and fatty liver (Menta et al. 2015), which are thought to potentiate the pro-inflammatory state observed in these patients, as evidenced by the higher circulating and hepatic CRP levels in obese patients with HCV (Jonsson et al. 2008). In addition, Visceral adiposity is also thought to enhance HCV-induced whole-body Insulin resistance due primarily to the role of free fatty acids released by visceral adipocytes. Furthermore, studies have demonstrated increased levels of ALT in overweight patients, suggesting an increased risk for liver disease (Ruhl and Everhart 2003).

Chronic liver diseases like hepatitis C that cause cirrhosis are among the most common indications for liver transplantation worldwide (Mazurak et al. 2017). The Model for End-Stage Liver Disease or MELD score used by most liver transplant centers for prioritization of organ allocation, despite its innumerable benefits, is limited by its failure to adequately include nutritional status in the evaluation of patients (Wiesner et al. 2003). For this reason, other tools like the Child-Pugh classification that use objective measures of nutritional status such as the International Normalized Ratio (INR) and Serum Albumin levels are deemed superior to the MELD score, further highlighting the importance of nutritional status as a prognostic indicator in patients with chronic HCV.

Etiology

Malnutrition in chronic liver disease has a multifactorial etiology. Combined disturbances in dietary intake, absorptive capacity, and carbohydrate metabolism, as well as a negative energy balance, predispose patients to nutritional impairment in chronic liver diseases, like HCV (Fig. 2).

Food aversion and intolerance in hepatitis C secondary to signs and symptoms of CLD such as nausea, anorexia, gastritis, and encephalopathy lead to a reduced dietary intake. Additionally, most patients with hepatitis C treated with interferons and direct acting antivirals tend to experience loss of appetite and metallic taste as adverse effects. Deficiencies in vitamin A and zinc lead to an altered sense of taste

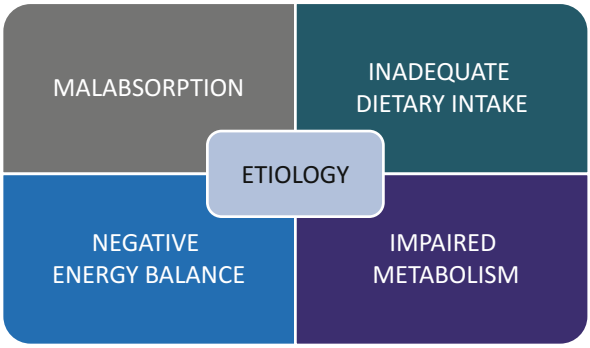

Fig. 2 Etiological factors of malnutrition in HCV and liver disease patients

for food, already low in Sodium, further compounding the problem of reduced oral intake (Madden et al. 1997).

Bile salt deficiency due to reduced entero-hepatic recycling in patients with impaired liver function has been proposed as the primary mechanism of Malabsorption in cirrhotic patients (Vlahcevic et al. 1971; Romiti et al. 1990). Other contributing factors include altered intestinal motility and mucosal injury that may be secondary to portal hypertension or bacterial overgrowth, which in itself impairs absorption of nutrients via small intestinal mucosal surface (Bode 2003, 1980; Dinda et al. 1988; Sarfeh et al. 1986).

In addition to depletion of glycogen stores, hepatocyte injury, in conjunction with insulin resistance, impairs glucose regulatory processes like gluconeogenesis further increasing reliance on alternative energy fuels such as lipids and fats, for the metabolic needs of the body. In addition to the depletion of vital macromolecules, preferential oxidation of lipids further reduces the respiratory quotient in CLD patients relative to those with normal liver function (Merli et al. 1990)

A combination of reduced urea hepatic protein synthesis, impaired intestinal protein absorption, and increased urinary nitrogen excretion predispose cirrhotic patients to sarcopenia and also lead to a lowered ratio of branched-chain amino acids to aromatic acids in the blood.

CLD patients often exhibit an increase in resting energy expenditure, as measured by indirect calorimetry. Hypermetabolism thought to be due to an increase in beta-adrenergic activity has been found to correlate well with a reduction in survival in CLD patients by some studies (Müller et al. 1999). The increased frequency of hypermetabolism in patients with complications like ascites and its negative impact on survival highlight the need to identify and address these complications earlier on in the disease course.

Obesity is often associated with elevated circulating levels of cytokines like leptin released by adipocytes (Schmidt et al. 2015). These adipocytokines with pro-fibrogenic properties are thought to play an important role in inducing a state of low-grade inflammation and hepatic fibrosis due to their pro-fibrogenic properties (Saxena and Anania 2015), as shown in Fig. 3. Free fatty acids secreted by visceral

Fig. 3 Role of obesity in progression of liver cirrhosis in HCV patients

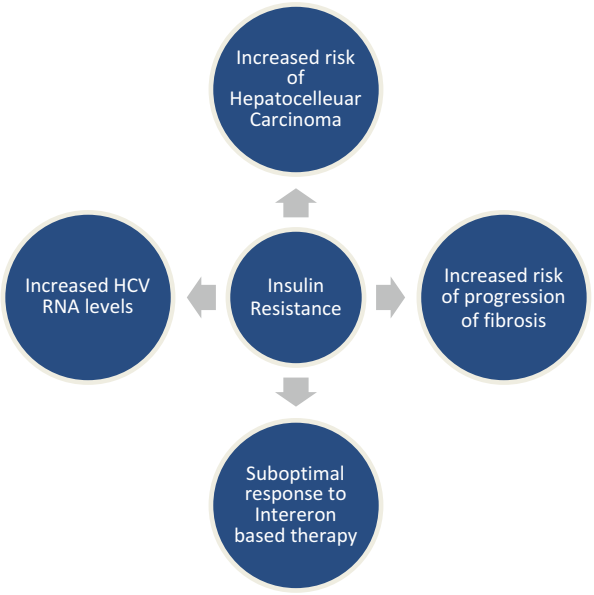

Fig. 4 Impact of insulin resistance in HCV infected patients

adipocytes also impair insulin signaling in the skeletal muscle and liver by activating the lipid-activated protein kinase C family, contributing to insulin resistance in HCV patients (Kawaguchi and Mizuta 2014) (Fig. 4).

Presentation

Nutritional assessment of patients with hepatitis C allows for identification of nutritional risks that may contribute further to morbidity and mortality. Recognition of macro- and micronutrient deficiencies is important as their correction with supplemental nutrition can significantly reduce the risk of infections as well as in-hospital morbidity and improve liver function parameters of such patients. This assessment needs to be much more detailed in patients presenting with decompensated cirrhosis as they are more likely to be at risk for nutrient deprivation. In general, adequate assessment of the nutritional status requires a thorough history, detailed physical examination, and appropriate laboratory investigations.

History

Pertinent findings in patient history may include changes in weight, which can be quantified as the percentage of weight lost involuntarily over the preceding 6 months. Generally, weight loss $> 10\%$ is taken as severe. It is important to note however that a patient with decompensated cirrhosis, presenting with salt and water retention, may not be able to report an accurate history of weight changes.

Dietary intake may be assessed using the 24-h dietary recall to identify incorrect dietary practices commonly observed in patients with CLD, who are often advised to consume a diet low in protein by ill-informed attendants as well as healthcare practitioners.

Other symptoms to inquire about include gastrointestinal disturbances such as diarrhea, vomiting, or constipation that may indicate underlying malabsorption (Quigley 1996).

The severity of the underlying liver disease can be assessed by inquiring about complications like ascites and encephalopathy that may manifest as increasing abdominal girth, respiratory difficulties, and altered mental status or disturbances in sleep wake cycle.

Micronutrient deficiencies may present in advanced cases of liver disease with symptoms like night blindness or photophobia (vitamin A), burning of the mouth or tongue (vitamin B12, folate), easy bruising (vitamin C, K), paresthesias (thiamine, pyridoxine), or even skin lesions (zinc, vitamin A, niacin).

Physical Examination

A general physical examination should be performed on all patients at risk for nutritional deficiencies with particular attention to the presence of peripheral edema and ascites, muscle wasting, and signs of vitamin/mineral deficiencies such as pallor (iron deficiency), hyperkeratosis (vitamin A), dermatitis (vitamin A), bruising (vitamin C, vitamin K), glossitis (vitamin B12, folate, niacin), angular stomatitis (vitamin B12), and reduced lower extremity deep tendon reflexes (vitamins B12, B1).

An accurate assessment of the patient's weight and height needs to be performed and recorded for reference in future as it may facilitate tracking of the patient's physical parameters.

Screening

To date, several nutritional assessment tools have been developed, and although many of these remain in use in various parts of the world, no one tool has been accepted as the Gold standard yet.

To be effective, a screening tool needs to be simple, easy to use, and patient-friendly, and for that reason, subjective global assessment is one of the most

Table 1 Guidelines for subjective global assessment categories

Stage A	Stage B	Stage C
Well nourished	>5% eight loss within a few weeks	Obvious signs of malnutrition[a]
OR		
Recent non fluid weight gain And/Or Improvement in dietary intake or patient reported symptoms	No weight stabilization or weight gain Definite increase in Intake Mild subcutaneous tissue loss	Clear and convincing evidence of weight loss

[a]Severe loss of subcutaneous tissue and/or peripheral edema

commonly employed scales to identify patients suffering from nutritional deprivation.

It combines multiple elements of nutritional assessment to classify the severity of malnutrition from mild to severe. These components include recent weight loss, changes in dietary intake, gastrointestinal symptoms, functional capacity, signs of muscle wasting, and the presence of pre-sacral or pedal edema. On the basis of these assessments, patients are classified as well nourished (grade A), moderately malnourished (grade B), or severely malnourished (grade C)

The SGA is a simple bedside method, proven to be adequate for the purpose of identification of malnutrition among patients with HCV. It is an excellent tool to assess nutritional status that can be applied on the bedside as it uses elements that can all be derived from a focused history and physical examination, rendering expensive, and time-consuming laboratory tests unnecessary (Hasse et al. 1993).

SGA, however, has not been found to be as reliable as handgrip strength, in predicting the complications of cirrhosis, as indicated by some studies (Alvares-da-Silva and Reverbel da Silveira 2005) (Table 1)

Laboratory Evaluation

Several laboratory and radiologic investigations may provide objective evidence of malnutrition in patients with HCV. Of these, specialized investigations like bioelectrical impedance analysis and dual-energy X-ray absorptiometry are not performed routinely but may be indicated in certain cases of an advanced liver disease, cirrhosis, or patients being evaluated for liver transplant.

Serum levels of proteins including albumin, prealbumin, transferrin, and coagulation factors, which are generally regarded as useful indicators of nutritional status in the general population, are not as reliable in patients with decompensated cirrhosis due to hepatic synthetic dysfunction, limiting their use in HCV to patients with acute infection and early cirrhosis. Of these proteins, changes in levels of prealbumin are more reflective of acute changes in nutritional status owing to its relatively short

half-life of two to three days, as compared to albumin which has a half-life of approximately 20 days.

Reduced hepatic synthesis, decreased muscle mass, and increased tubular secretion are all responsible for decreased serum levels of creatinine, another marker of lean muscle mass, in cirrhosis.

Serum levels of fat-soluble vitamins may be normal in HCV patients in the absence of advanced liver disease when fat malabsorption due to impaired enterohepatic recirculation of bile salts leads to deficiencies of these vitamins. Plasma levels of vitamins A, D, and E, as well as INR, may be deranged in such patients.

Levels of water-soluble vitamins such as folate and zinc may also be deranged. Serum vitamin B12 levels may be elevated in chronic HCV and cirrhosis due to hepatic cytolysis and release of stored vitamins and minerals. Patients with a history of concurrent alcohol abuse may also show decreased levels of thiamine. Deficiencies of other B complexes may present with decreased levels of hemoglobin and deranged mean corpuscular volume of RBC's.

Ancillary Tests

Anthropometry

Among anthropometric measures used to identify malnutrition in HCV patients, mid-arm muscle circumference (MAMC) and hand-grip strength have been found to be the best indicators of protein-calorie malnutrition. Based on studies, a mid-arm muscle circumference of <23 cm in combination with a handgrip strength of <30 kg is thought to have a sensitivity of 94% and negative predictive value of 97% for diagnosing PCM (Figueiredo et al. 2000).

Meanwhile, body fat reserves have found to correlate best with skin-fold thickness, which has produced similar results as DEXA scans when used in studies on patients without ascites. For this purpose, the SFT over triceps may easily be measured at the midpoint between the acromion and olecranon using a caliper. A value lower than the 5th centile suggests severe malnutrition.

Miscellaneous Tests

Several other specialized tools for nutritional assessment can be used in certain cases of chronic liver disease, but are not routinely employed primarily due to their cost and limited availability.

Bioelectrical impedance analysis (BIA) uses impedance which measures body water to estimate the fat content of the body. One of the limitations to its use is that even small variations in electrode placement tend to result in relatively large errors in measured impedance.

Dual-energy X-ray absorptiometry (DEXA) scan can be used to accurately measure fat mass in patients with chronic liver disease but is unable to estimate

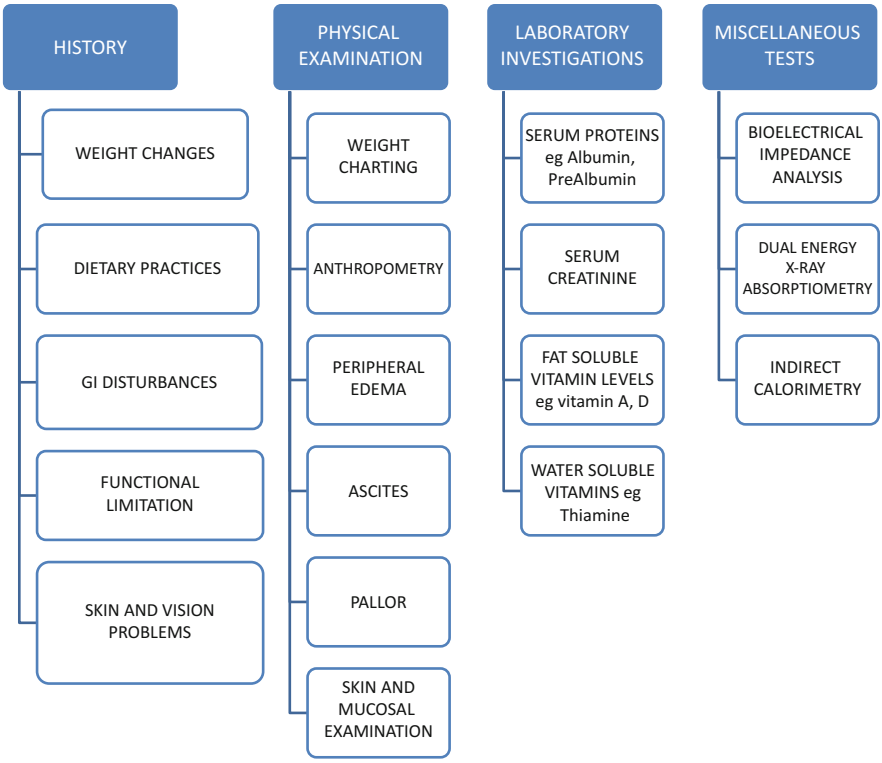

Fig. 5 Clinical, laboratory, and radiological tools for assessment of malnutrition in HCV patients

the lean body mass due to increases in extracellular water in patients with decompensated liver disease (McCullough et al. 1991).

An accurate assessment of the nutritional needs using resting energy expenditure can significantly help in management of patients with chronic HCV as well as cirrhosis secondary to other causes. This can be done either using the Harris Benedict equation (HBE) that relies on factors like weight, age, gender, and height or using Indirect Calorimetry which is considered to be the gold standard assessment (Plevak et al. 1994; Peng et al. 2007). Because it is not widely available though, its use has been limited to patients unable to meet their nutritional requirements despite adequate therapy (Fig. 5).

Management

Ensuring adequate nutrition can significantly improve quality of life in HCV patients. Good nutrition results in improved compliance with pharmacologic therapy and has also been found to hinder disease progression by preventing the development of HCV complications like cirrhosis and hepatic encephalopathy.

In the absence of decompensated cirrhosis or comorbid conditions like diabetes mellitus, HCV patients usually do not require special diets. However, it is imperative that they consume a balanced diet, containing an adequate amount of calories and proteins to fight the infection as well as antioxidants to combat free radicals responsible for hepatocyte damage. In addition, frequent small meals have been found to improve nitrogen and substrate use, diminish fat and protein oxidation, and prevent depletion of glycogen stores.

Major principles in management of malnutrition in chronic HCV revolve around restoring muscle health. In accordance with this, most interventions are focused on providing a diet that is adequate in proteins and calories and integrate physical activity into the patient's lifestyle. Because management of malnutrition in such patients is directed at addressing the underlying etiology, it is important to obtain a good understanding of the nutritional intake patterns and barriers to healthy eating. The best way to achieve that is through a detailed history and physical exam at each clinic visit, as well as counseling sessions with a dietician, who may be able to further draw up an individualized plan for each patient based on his/her need (Tandon et al. 2017). Because a dietitian may not be available in many clinical settings, physicians may need to familiarize themselves with guideline recommendations for both diet and activity.

HCV patients who are unable to meet their caloric requirements due to a diminished nutrient intake and early satiety should be advised to take frequent small volume meals up to 4–6 times/day (Amodio et al. 2013). Patients presenting with refractory ascites with a low MELD score and those suffering from portal hypertensive enteropathy may be offered TIPS in order to improve nutrient absorption. Replacement of trace elements such as zinc, magnesium, and vitamin A may be considered in patients presenting with food aversion due to micronutrient deficiencies, as per their symptoms and serum levels.

Enteral feeding via a feeding tube is only recommended for patients who are unable to consume food orally despite the above interventions, as tolerance is often an important issue with a significant number of patients prematurely removing their feeding tubes themselves. Therefore, an oral route should be preferred as the first line intervention, even in the presence of complications like esophageal varices. Due to the high risk of complications, PEG tube placement is discouraged as well.

Patients with cirrhosis are prone to fluctuating sugar levels and are thus advised to avoid fasting longer than 6 h as it may trigger a hypoglycemic episode and lead to additional complications. Cirrhotic patients are also advised to take small frequent meals throughout the day as well as an evening snack of complex carbohydrates to decrease lipid oxidation and reduce skeletal muscle proteolysis.

It is generally recommended that HCV patients limit fat to 25% of the total calories in their diet. The general recommendation for diet composition is to limit carbohydrates to 50%, mostly in the form of complex sugars, protein to 20%, and total caloric intake to 30–40 kcal/Kg/day of the desirable body weight. It is also recommended that the consumption of processed sugars like fructose be avoided given its association with increases in the severity of liver fibrosis in HCV patients with genotype 1 (Petta et al. 2013). Substances like alcohol that can significantly enhance the rate of disease progression should also be avoided.

Dietary Supplementation

For patients with advanced liver disease presenting with steatorrhea due to bile acid deficiency, fat-soluble vitamins and medium chain triglycerides that do not need bile for absorption may be supplemented in their diet. These are often available as nutritional drinks and can be easily taken even by patients with reduced tolerance to oral intake.

Consuming vegetable-based proteins that contain fewer aromatic amino acids and supplementing the diet with branched chain amino acids should also be considered in patients at risk for hepatic encephalopathy, which is often accompanied by an impaired balance of these amino acids. Some studies have also implicated treatment with interferon and ribavirin in inducing this imbalance in the early stage of therapy, which further suggests the importance of correcting this imbalance early in the course of the disease.

Physical Activity

Moderate physical activity is recommended for all HCV patients and has shown improvements in muscle mass, exercise capacity, and quality of life in general (Román et al. 2014; Zenith et al. 2014; Berzigotti et al. 2017). Exercise will not affect the course of infection, but it can help relieve fatigue, stress, and depression as well as improve appetite and strengthen immunity. HCV patients can also benefit from physical activity due to its effect on obesity. For patients with decompensated cirrhosis, however, physical activity needs to be carefully prescribed and individualized to each patient's exercise tolerance and presence of complications like esophageal varices. Deconditioning and fatigue are major issues for patients with cirrhosis that represent significant barriers to physical activity (Ney et al. 2017). Formal guidelines for physical activity in cirrhosis are not yet available. Therefore, it is important that all patients undergo screening for varices and the required variceal prophylaxis before an exercise regimen is initiated (García Pagan et al. 1996; Bandi et al. 1998) (Fig. 6).

Policies and protocols

Policies

Role of Health Care Providers and Local Government in Ensuring Food Security for All HCV Patients

In this chapter, we have described some screening tools available for the identification of malnutrition as well as its management in HCV patients. Below, we talk about some policies that could be adopted to ensure adequate nutrition for patients with chronic liver disease, and the role of health care providers, as well as the local government in the implementation of these policies.

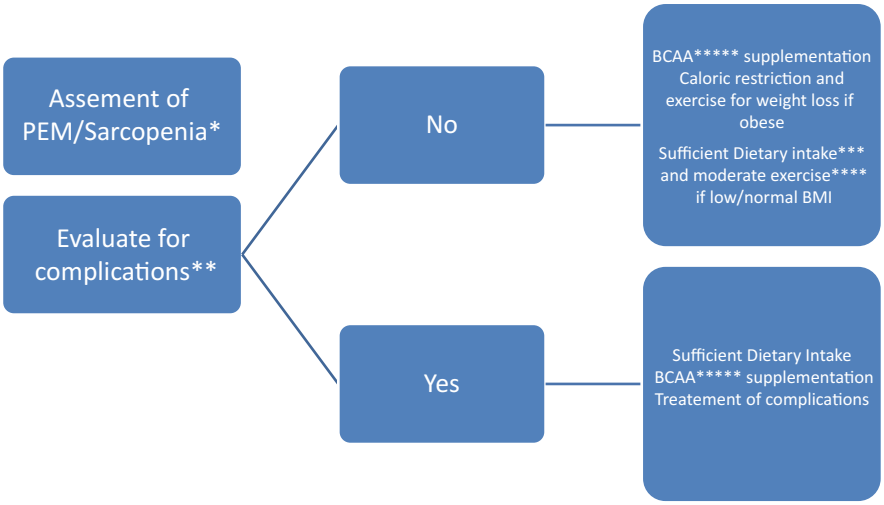

Fig. 6 Overview of management of HCV patients with complicated and decompensate liver disease. (*Based on anthropometry, radiological investigations, and indirect calorimetry, **Complications may include ascites, hepatic encephalopathy, portal hypertension, or hepatopulmonary syndrome, ***Sufficient dietary intake: 30–40 Kcal/kg of body weight per day, ****Walking 5000 or more steps/day or 3 sessions/week of 1 h exercise at an intensity of 60–70% of maximal heart rate, *****BCAA: Branched Chain Amino Acids)

HCV patients can be categorized as those with acute HCV, compensated cirrhosis, and decompensated cirrhosis. We recommend screening all HCV patients with a simple screening tool like SGA to identify patients suffering from nutritional impairment, and limiting the use of more specialized diagnostic measures, such as BIA and DEXA scans, to patients with an advanced form of liver disease, such as those with decompensated liver disease, awaiting liver transplantation.

HCV patients should be offered counseling sessions with a dietician as well as a physical therapist, preferably at each clinical visit so that they may be screened for under-nutrition and managed appropriately, if at risk. In settings where a limitation of resources may present a barrier, physicians should take it upon themselves to familiarize themselves with the dietary needs of HCV patients, as well as the protocols in place, for dietary intervention in malnourished individuals. They should also take advantage of the clinic visits to obtain a dietary history from all patients to ensure an adequate provision of nutrients. It falls to the health divisions of local governments to ensure screening and management of under-nutrition at all healthcare facilities in that area. This can be achieved through regular audits by the concerned authorities as well as appointments of trained professionals by the government at each of these facilities.

In addition to provision of antiviral medication, as is common practice in many third-world countries like Pakistan, local government should take also develop policies to provide aid, in the form of food packets, to HCV patients who may be unable to meet their nutritional needs on their own, due to financial constraints and

the stress of their sickness. For the purpose of identification of such disadvantaged patients, the local government may rely on feedback from healthcare professionals as well as nongovernmental organizations, familiar with the socio-economic circumstances of these patients.

Protocols

ESPEN Guidelines for Screening and Management of HCV Patients with Cirrhosis and Liver Transplant Candidates

Use SGA to identify malnutrition in patients with cirrhosis and bio-electric impedance analysis to quantify undernutrition in such patients.

As per ESPEN guidelines, ensure energy intake of 35–40 kcal/kg/day, protein intake of 1.2–1.5 g/kg/day. For patients unable to meet these caloric requirements with normal daily food intake, supplementary nutrition may be provided, preferably via the enteral route. Tube feeding is only indicated in patients who are unable to maintain or tolerate oral intake. PEG tube is associated with adverse outcomes and should not be used until other options have been exhausted (Plauth et al. 2006).

For nutritional supplementation, whole protein formulas are generally recommended. In patients presenting with cirrhosis complicated with ascites, concentrated high energy formulas should generally be preferred. BCAA-enriched formulas have been found to improve outcomes in patients with encephalopathy and should, therefore, be supplemented in the diet of cirrhotic patients with concomitant encephalopathy (Plauth et al. 2006).

HCV is the most indication for liver transplantation as patients frequently progress to decompensated cirrhosis. For liver transplant candidates, in addition to the usual protocol for Cirrhotic patients, it is recommended that normal food/enteral nutrition be initiated within 12–24 h following liver transplantation. A nasogastric tube or catheter jejunostomy may be employed for early enteral nutrition posttransplant.

Dictionary of Terms

- **Ascites** – Presence of excess fluid in the peritoneal cavity.
- **Compensated liver disease** – Absence of signs of cirrhosis in patients with chronic liver disease.
- **Decompensated liver disease** – Development of complications like jaundice, encephalopathy, ascites or variceal hemorrhage in the setting of chronic liver disease.
- **Hepatic encephalopathy** – Altered mental status in the setting of chronic liver disease, secondary to metabolic derangements.
- **Bio-electric impedance** – Opposition to the flow of current in a circuit.
- **Indirect calorimetry** – A method to determine energy consumption of the body that relies on quantification of oxygen consumed and carbon dioxide produced.

- **Protein-calorie malnutrition** – Deficient intake of proteins and calories in diet.
- **Respiratory quotient** – Ratio of oxygen consumed to carbon dioxide produced.
- **Sarcopenia** – Loss of skeletal muscle.
- **Visceral adiposity** – Fat collection around the body organs.

Summary

- Hepatitis C is a viral infection of the liver.
- Chronic hepatitis C is often accompanied by nutritional deficits.
- Nutritional impairment can have significant implications on the long-term prognosis of Hepatitis C patients.
- Nutritional deficits in chronic liver disease may present as protein-calorie malnutrition or micronutrient deficiencies.
- Obesity correlates with a poor prognosis in patients with hepatitis C.
- Hepatitis C patients may develop insulin resistance that impairs carbohydrate metabolism.
- Sarcopenia is the most objective feature of malnutrition in chronic liver disease
- Subjective global assessment is the most commonly used screening tool to identify malnutrition in chronic liver disease.
- Dietary supplementation is indicated only in patients with decompensated liver disease.
- Symptomatic patients should be evaluated for micronutrient deficiencies with laboratory assays.
- Enteral feeding is only recommended for patients who are unable to meet caloric needs via oral intake.
- Cirrhotic patients are advised to take frequent small volume meals at least 4-6 times a day.
- Moderate physical activity may help relieve fatigue, stress, and depression in patients with hepatitis C.
- Physical therapy must be carefully prescribed for patients with decompensated cirrhosis.

Abstract

Malnutrition continues to be a problem in chronic kidney disease (CKD) patients on hemodialysis (HD), resulting in increased morbidity and mortality. Factors that reduce food intake and increase hypercatabolism play important role in malnutrition seen in dialysis patients. Various factors contributing to malnutrition syndrome in dialysis are anorexia due to uremia with electrolyte and hormone imbalances, metabolic abnormalities, gastrointestinal disorders, psychological factors, severe dietary restriction, social problems, increased inflammation, hypercatabolism, and nutrient losses during hemodialysis and peritoneal dialysis. Detecting malnutrition in CKD patients is very challenging. Dialysis patients commonly show protein depletion and energy deficit. The term protein-energy wasting (PEW) syndrome describes the loss of body protein mass and reduction in calorie reserves in dialysis patients. Some dialysis patients can also get overweight or obese and do not appear to have energy deficit but may have protein malnutrition. PEW syndrome is associated with a poor prognosis. The pathogenesis of PEW is incompletely understood and has multifactorial etiopathogenesis. Comorbidities and underdialysis also contribute to anorexia and malnutrition in dialysis. Intra-dialysis hyperalimentation may be provided for patients who continue to lose weight despite oral supplementation (at least 50% or more of the prescribed caloric intake).

Keywords

Chronic kidney disease · Dialysis · Malnutrition syndrome · Protein-energy wasting · Malnutrition management

List of Abbreviations

BMI	Body mass index
CKD	Chronic kidney disease
ESRD	End-stage renal disease
GFR	Glomerular filtration rate
IDPN	Intradialytic Parenteral Nutrition
MHD	Maintenance hemodialysis
PEW	Protein-energy wasting
PNA	Protein nitrogen appearance

Introduction

The main function of kidneys is to facilitate waste product (produced from protein metabolism) excretion, to maintain and regulate fluid, electrolyte, and hormonal balance. A progressive decline in kidney function is represented by decrease in GFR.

This leads to accumulation of waste products in the blood like urea and creatinine. This causes uremic toxicity which is a primary indication for renal replacement therapy (dialysis or kidney transplantation).

Chronic kidney disease (CKD) is defined as the presence of kidney damage or a glomerular filtration rate (GFR) of < 60 ml/min/1.73 m^2 for 3 months or more. Markers of kidney damage include the presence of proteinuria or albuminuria, hematuria (after exclusion of other causes), or structural abnormalities confirmed on renal imaging. A progressive decline in kidney function is represented by decrease in GFR. Therefore patients are classified according to GFR, ranging from stages 1 and 2 where there are persistent urinary abnormalities but preserved renal function to stages 3, 4, and 5 that represent advancing CKD leading to end-stage renal disease (ESRD) (GFR <15 ml/min/1.73 m^2). As the kidney function declines to stage 5, the patients of CKD need to undergo renal replacement therapy.

Risk factors for the high mortality rate of individuals with ESRD include comorbid conditions such as diabetes and cardiovascular disease; inflammation; dialysis inadequacy; catabolic effects such as acidosis, hyperparathyroidism, and hyperphosphatemia (Mehrotra and Rishishwar 2015); infections; and insulin resistance. Malnutrition in dialysis patients is often characterized by hypoalbuminemia, decreased prealbumin, hypocholesterolemia, decreased serum creatinine (due to reduced muscle mass), decreased transferrin, and overall dry weight loss including lean body mass and fat mass. Causes of malnutrition in dialysis patients also include inadequate protein and calorie intake due to reduced appetite, dietary restrictions, impaired gastrointestinal motility, social constraints, or physical incapacity. In addition, nutrient losses during dialysis, alterations in protein metabolism, and inflammation may contribute to malnutrition. Malnutrition is highly prevalent in the ESRD population and is a strong predictor of morbidity and mortality. The components of protein-energy wasting are strongly correlated with 100- to 200-fold higher mortality risk, in patients with end-stage renal disease than in the general population. There are multiple issues that may lead to malnutrition in ESRD patients on dialysis and need to be addressed (Chen et al. 2017; Cano et al. 2007).

Chronic Kidney Disease: A Hypercatabolic State

Some CKD patients on dialysis are in hypercatabolic state. Resting energy expenditure (REE) in CKD patients (15 with progressive CKD not on dialysis, 15 on hemodialysis, and 10 on peritoneal dialysis) was found to be 10 to 20% higher than predicted values derived in normal and overweight populations. REE was higher among both peritoneal and hemodialysis patients compared with non-dialysis patients. The net energy expenditure is the total of REE and energy expenditure with physical activity. Many dialysis patients are inactive, so they are in decreased physical activity disbursement. The BMI in some hemodialysis patients shows an increasing trend despite increased resting energy disbursement rate (Anderton et al. 2015; Beddhu et al. 2015; Neyra et al. 2003).

Protein Metabolism Alterations in CKD

Metabolic acidosis, a result of uremia, has been shown to stimulate amino acid and protein catabolism, and also decrease albumin synthesis, and stimulate muscle protein catabolism. Dialysis patients also experience impaired small intestinal protein digestion and absorption as compared to healthy controls. Several gastrointestinal abnormalities are reported in dialysis patients including gastrointestinal motility disorders and small bowel bacterial overgrowth. These could potentially disrupt protein digestion and absorption (Garibotto et al. 2015; Wang and Mitch 2014).

Nutrient Losses During Dialysis

Both hemodialysis and peritoneal dialysis and reuse procedure for hemodialysis result in increased losses of protein into dialysate. Protein loss as high as 20 grams in one hemodialysis session has been reported with polysulfone dialyzers which are reused with bleach. Dialysis procedure also can contribute to amino acid losses of 5 to 8 grams per hemodialysis session, and this increases with high efficiency dialyzers. Albumin losses are seen when dialyzers are reprocessed, specifically after the sixth reuse (Ikizler et al. 1994). Loss of protein-rich blood due to gastrointestinal bleeding, frequent blood collection for laboratory testing, and blood left in the dialyzer may all contribute to malnutrition in dialysis patients. Water-soluble vitamins and other micronutrients are also lost into dialysate during hemodialysis (Carrero et al. 2010; Kalantar-Zadeh et al. 2004).

Protein Depleted and Reduced Calorie Intake and Loss of Appetite in Dialysis Patients

Significant anorexia was reported in 35–50% of ESRD patients (Bossola et al. 2006). Patients on dialysis should have a daily calorie and protein intake of 30–35 kcal/kg body weight per day and 1.2 g/kg/day individually. Calorie and protein requirements are thus greater in dialysis patients than in healthy individuals. However, actual protein and calorie intake are often below the recommendations for dialysis patients. In a cohort of 53,933 MHD patients, low daily protein intake over time was associated with increased risk for death. In a study on hemodialysis patients, protein intake <1.2 g/kg/day was predictive of higher mortality. A longitudinal study of CKD patients on MHD over a 9-year period showed that the dietary intake reduced over time. This study concluded that long-term hemodialysis failed to correct under nutrition in dialysis patients (Shinaberger et al. 2006; Antunes et al. 2010; Mekki et al. 2012).

Most dialysis patients follow potassium-, phosphorus-, and sodium-restricted diets and thus have limited food choices. Comorbid conditions like heart disease, diabetes, gastrointestinal dysfunction, increased infections, inflammatory state due to chronic kidney disease and dialysis, hyperparathyroidism, emotional and

psychological disorders, and inadequate dietary support may all contribute both to reduced nutrient-protein-energy intake and catabolism (Duenhas et al. 2003).

The Dialysis Procedure and Catabolism

In reduced protein synthesis with loss of amino acids in dialysate, we can conclude that dialysis procedure is catabolic. Amino acid losses into dialysate can range from 4 to 8 g/day both with dialysis procedure. The use of bio-incompatible membrane in hemodialysis patients can lose more amino acid. In patients on maintenance hemodialysis where their dialyzer may be recycled can increase the losses of protein and amino acids from dialysate. Increasing adequacy of dialysis with frequent dialysis does not seem to degrade nutritional indices, but results in improvement in malnutrition (Ikizler et al. 2002; Ikizler 2005).

Adequacy of Dialysis and Malnutrition

Evidences suggest that accumulated toxins that result from kidney disease suppress appetite and contribute to the decline of nutritional status in dialysis patients. Wang et al. showed that improved dialysis adequacy is associated with better dietary intake and improved nutrition (Kaysen et al. 2012; Wang et al. 2003). The dialysis adequacy is often reported in terms of Kt/V (where K stands for dialyzer clearance of urea, t for dialysis time, and V for volume of distribution of urea, approximately equal to patient's total body water) which is a dimensionless number. The Kt/V target in hemodialysis is $\geq$1.3, to make sure that the delivered dose of dialysis is at least 1.2. In a study on 44 adult dialysis patients, it was found that serum albumin levels were significantly higher in patients with a Kt/V greater than 1.2 compared to those with a Kt/V less than 1.2 (Terrier et al. 2008). Another study on 140 MHD patients revealed that adequate hemodialysis quality (Kt/V $\geq$ 1.2) was significantly associated with higher values of anthropometric parameters, dry weight, and body protein status (Stolic et al. 2010).

Dietary Restrictions and Medications in Dialysis Patients

Food becomes less palatable when there are strict dietary restrictions, and it also results in reduced protein and calorie intake along with reduced intake of trace elements, vitamin, and micronutrients. The intradialytic weight gain can minimize restriction in fluid and can decrease in caloric intake. Many beverages contain a substantial amount of calories, and some solid food supplements have higher fluid content (Kalantar-Zadeh et al. 2015). Nutritional interventions and dietary restrictions are essential part of dietary prescription for dialysis patients. Medications, such as phosphate binders, can bind and impair nutrient absorption. They can also reduce

appetite and cause constipation (Kalantar-Zadeh et al. 2013). Patient education can be very helpful in getting patient's cooperation for control of mineral bone disorders.

Causes of Malnutrition in MHD Patients

- Loss of appetite
- Diabetic status with gastroparesis and diarrhea, which could cause PEW syndrome
- Inadequate dietary recommendations
- Comorbidity
- Depression
- Inadequate dialysis and its complications (nausea, hypotension)
- Socioeconomic factors (social deprivation)
- Mechanical compression of stomach and intestine in polycystic kidney disease
- Immobility and reduced ability to purchase food
- Chronic inflammation also results from inadequate dental hygiene status
- Dialysis-associated loss of amino acids and proteins
- Metabolic acidosis

Malnutrition, Inflammation, and Atherosclerosis (MIA Syndrome)

ESRD is a multifactorial disease leading to complications like malnutrition, inflammation, and atherosclerosis (MIA syndrome) which is associated with high mortality. Many studies have reported malnutrition in as many as 23–76% of hemodialysis patients. Malnutrition is independently associated with an increased risk of hospitalizations and mortality in patients with ESRD. Factors associated with dialysis that are associated with malnutrition and inflammation are bio-incompatibility of dialysis membrane, loss of residual renal function, presence of infections in the vascular access, dialysis hypotension, impure dialysate, volume overload, and nutrient losses during dialysis. Retention of uremic toxins in the body results in decreased appetite and inflammation. This triggers catabolic pathways in the body, leading to loss of body fat and muscle causing malnutrition (Kirushnan et al. 2017).

Common Causes of Malnutrition in MIA Syndrome

1. Accumulation of anorectic factors
2. Elevated serum leptins
3. Inflammation and/or infection: increased inflammatory and catabolic cytokines (IL-6, TNF-α) and acute phase proteins
4. Gastropathy/enteropathy: blood loss due to GI bleeding
5. Loss of metabolic processes: reduced synthesis of amino acids, glucose, and fatty acids

6. Physiological factors: medication, depression, poverty, and alcohol/drug abuse
7. Hemodialysis-related factors: inadequate Kt/V, post-dialysis fatigue, cardiovascular instability, nausea, and vomiting

Management of MIA Syndrome

Adequate dialysis, using ultrapure dialysate fluid, use of biocompatible dialysis membrane, administration of erythropoietin (EPO) to improve anemia, control of hypertension and hyperlipidemia, and lifestyle modifications (exercise, smoking cessation) all play important role in management of MIA syndrome.

How to Prevent and Treat Malnutrition in Hemodialysis Patients

Malnutrition is strongly related to inflammation and mortality in dialysis patients.

Several approaches to treat and/or prevent malnutrition have been attempted. Nutritional screening, dietary counseling, and improving dialysis adequacy may be effective in malnutrition prevention, depending how early they are implemented. In addition, pharmacological intervention, oral nutritional supplements, IDPN, or artificial nutrition have also been tried with variable success both for prevention and treatment of malnutrition.

Dietary Counseling to Prevent Protein-Energy Wasting

The role of nutritional supplements to treat PEW is also not clear because the recommendations for increased protein intake do not suggest or recommend use of oral protein supplements, unless patients have specific defined clinical indications. The recommended protein intake can be estimated from dry weight. Many obese dialysis patients receive adequate caloric intake despite reduced dietary protein intake (Zha and Qian 2017; National Kidney Foundation 2000).

If a high protein diet is recommended to dialysis patients, then it is important to monitor their metabolic parameters especially blood urea. Sometime very high protein intake could be toxic for dialysis patients as it could worsen uremia, metabolic acidosis, and hyperphosphatemia. Hemodialysis patients should get regular metabolic parameters checked every month. These interventions can improve nutritional status in patients with PEW, when they have history of progressive decrease in protein intake, reduced protein nitrogen appearance (PNA, which is a marker for protein intake in dialysis patients), decrease in serum albumin, and decrease in dry weight. Patients on dialysis should also be carefully evaluated for causes of anorexia and other possibilities associated with PEW. The progressive decrease in BMI, albumin, and PNA should be carefully assessed in all patients who have the history of decreased protein intake. Decrease in appetite may also be caused by a subclinical occult infection. Diabetic patients should be carefully evaluated for

symptoms of gastroparesis and diarrhea, both which are common manifestations of autonomic neuropathy and could cause and aggravate PEW syndrome (Mitch and Remuzzi 2004; Marzocco et al. 2013; Streja et al. 2013).

Oral Nutritional Supplements for Treatment of PEW

For patients selected for treatment of malnutrition with various supplements, it is recommended that oral dietary supplements, which are useful and effective, should be used first. Oral nutritional supplements specifically formulated for dialysis patients are available as a combination of energy and protein, energy only, or protein only. Supplements may be in the form of solid food, powder, or liquid formulation.

For patients who have history of hyperkalemia or volume overload on dialysis, an oral "renal failure" supplement, which has double the calorie and protein and 30–35% less potassium and phosphorus content per mL of supplement, has been formulated. A different approach is required in patients with severe anorexia who are unable to increase their oral intake. Overnight supplementation by nasoenteral feeding tube may be an alternative and more effective in patients with severe anorexia (Cohen et al. 2007).

The Role of Inflammation and Comorbidities in Malnutrition

The nutritional status affects the acute, chronic, or occult systemic illness. In PEW syndrome chronic lung disease, congestive heart failure, and malignancy also contribute both to the production and acceleration of PEW. Poor nutritional status also occurs during acute illness. Serum albumin and nutritional indices are known to worsen after hospitalization. Anorexia and gastroparesis (slowing of gastric emptying) also worsen PEW. PEW is more pronounced in the presence of inflammation (related to increased energy expenditure). PEW is also related to increase in pro-inflammatory cytokine levels and increased oxidative stress (imbalance between the productions of free radicals).

Serum albumin (marker of nutrition) is indirectly related to the inflammatory markers such as C-reactive protein (CRP). Systemic inflammation can also lead to protein wasting. It is not clear how inflammation leads to energy and protein wasting in dialysis patients. Despite comorbidities, high levels of CRP, low levels of plasma albumin, and lower muscle mass, some dialysis patients have tendency to have higher BMI (with evidence of obesity) in comparison to the national norms. The higher CRP levels in CKD and dialysis patients appear to be due to increase in adipose tissue (major source of inflammatory cytokines), associated with obesity as compared to underweight dialysis patients. Some studies have shown negative correlation between nutritional status and inflammation. Inflammation can coexist in ESRD patients who have malnutrition due to associated comorbidities. Malnutrition and inflammation may also be associated with immunodeficiency, nutrient malabsorption, hypercatabolism, and weight loss (PEW) (Kramer et al. 2006; Ramkumar et al. 2004; Axelsson et al. 2005).

The Role of Insulin Resistance in Malnutrition

Some reports in literature have suggested that there is role of insulin resistance in malnutrition which may result in muscle protein breakdown and catabolism in hemodialysis patients (both with and without type 2 diabetes). Improvement in insulin action with oral hypoglycemic agents (rosiglitazone) is reported to ameliorate proteolysis in animal models of diabetes. Insulin resistance seen more in obese dialysis could lead to protein wasting and could result in muscle wasting (Siew et al. 2007; Wang et al. 2006).

The Role of Metabolic Acidosis in Malnutrition

Metabolic acidosis in malnutrition can contribute to proteolysis, and its correction has been reported to provide benefit in CKD dialysis patients in some clinical studies and experimental animal models.

In a randomized trial, oral bicarbonate supplementation was compared to standard of care (no bicarbonate supplementation) in adult CKD patients with reduced creatinine clearance (15 to 30 mL/min/1.73 m2) with metabolic acidosis (serum bicarbonate 16 to 20 mmol/L). At 2 years, nutritional parameters showed improvement with bicarbonate supplementation compared with standard care group who were not given oral bicarbonate (de Brito-Ashurst et al. 2009). In patients on hemodialysis, serum bicarbonate levels inversely correlate with serum creatinine. But serum bicarbonate levels are already elevated in dialysis patients with decreased muscle mass and PEW (Kaysen et al. 2003). The roles of bicarbonate supplementation for improving muscle mass in such dialysis patients who have PEW and alkalosis are not clear.

Role of Various Drugs Which Stimulate Appetite

Megace (megestrol acetate) is an oral derivative of the steroid progesterone. Nutritional benefits of megestrol acetate include increased oral intake, weight gain, and increased serum albumin. However, these drugs when used in dialysis patients have potential side effects that include fluid retention, diarrhea, encephalopathy, depression, hypervolemia, and irregular menses (Bossola et al. 2005).

Role of Intradialytic Parenteral Nutrition (IDPN)

Patients who lose weight continuously and have extremely reduced serum albumin levels below 3.2 g/dL despite oral supplementation and in those who have severe gastroparesis and are unable to tolerate oral supplementation are candidates for IDPN. IDPN, which can be given during dialysis, is convenient to use and can

benefit a select group of such dialysis patients. But IDPN is a costly and less efficient nutritional supplementation than oral supplement. IDPN costs about twice as much as dialysis cost. Thirty percent of the nutrients of IDPN are not delivered to the patient and lost into the dialysate during dialysis. IDPN also fails to provide adequate protein and calories for treating PEW syndrome. IDPN is only used for a hemodialysis patient who can consume at least 50% of the prescribed caloric intake orally. Amino acids, dextrose, and lipids can be infused at the end of dialysis. Adequate clinical and biochemical assessment and monitoring is required during IDPN in dialysis patients to prevent and minimize the risks of complications due to IDPN (Alp Ikizler et al. 2013; Pupim et al. 2002; Kopple 1999).

Growth Hormone Therapy in Dialysis Patients

Administration of recombinant human growth hormone can reduce muscle wasting and catabolism. Growth hormone therapy can improve nutritional status and lower the blood urea nitrogen (BUN) levels in hemodialysis patients. The benefit from recombinant human growth hormone is hypothesized to be mediated by an increase in free insulin-like growth factor-1 (IGF-1) levels (Garibotto et al. 1997; Iglesias et al. 1998).

Growth hormone has been used in children on dialysis with favorable results on growth. But patients can develop growth hormone resistance which can accelerate protein catabolism. This can result in more severe malnutrition in dialysis patients. In a multicenter trial, significant increase in serum high-density lipoprotein, cholesterol, and transferrin levels along with decrease in C-reactive protein and homocysteine levels was observed in hypoalbuminemic MHD patients given growth hormone therapy (Kopple et al. 2011).

Intradialytic Fat Emulsion Use During Dialysis

Fat emulsions have been shown to be an efficient source of energy in malnourished dialysis patients. The use of fat emulsions as a supply of energy is supported by various reports: (a) fat stores in the postabsorptive state are preferentially oxidized in dialysis patients; (b) essential fatty acid deficiency has been reported in dialysis patients; (c) fat emulsions have a high energy to volume ratio and are iso-osmolar, thus allowing tolerable intravenous peripheral infusion. But the dose of fat emulsions should not exceed ~1 g/kg body weight/day. Patients on intradialytic fat emulsion therapy should have regular monitoring of plasma triglycerides.

Recombinant human growth hormone, androgenic anabolic steroids, anti-inflammatory drugs, and zinc have all been studied in dialysis patients with PEW. But their role is still experimental, and these agents should not be used for routine clinical care and interventions (Avery-Lynch 2006; Cano et al. 1994; Druml and Kierdorf 2009).

Androgenic Anabolic Steroids

Limited data on androgenic anabolic steroid use in dialysis patients is available. There are reports of increase in body weight, muscle mass, and serum albumin with the use of androgenic anabolic steroids, but their long-term efficacy and the risk for adverse effects are unclear (Gascón et al. 1999; Johansen et al. 1999; Barton Pai et al. 2002).

Role of Zinc and Various Anti-inflammatory Agents

Dialysis patients often have decreased taste acuity, which has been reported to be associated with zinc deficiency. But role of zinc deficiency in malnutrition has not been established (Atkin-Thor et al. 1978).

Anti-inflammatory agents have been used in patients with malnutrition-inflammation syndrome complex. But their role is also not very definite (Kalantar-Zadeh et al. 2003).

Role of Vitamin D Supplementation Use During Dialysis

Vitamin D deficiency is very common in patients with CKD and in health population, also associated with muscle protein imbalance. In CKD patients during dialysis, bone mineral disorder (BMD) is common, resulting from vitamin D deficiency, increased fibroblast growth factor-23, and also secondary hyperparathyroidism (Mehrotra et al. 2016). Vitamin D deficiency also contributes to muscle degradation, and vitamin D supplementation (both calcirol D2 and 1,25-OH2 vitamin D) has been shown to improve muscle size, strength, and metabolism and also results in improvement in serum albumin levels (Gordon et al. 2007).

Enhanced activity of catabolic hormones, acidemia, inflammation, and decreased nutritional intake in dialysis patients can cause PEW with loss of body mass and muscle wasting (Tripathi et al. 2010).

Association of various demographic, anthropometric, inflammatory and appetite regulating markers has been investigated with malnutrition-inflammation syndrome in ESRD patients. Genetic aspect of the inflammation and appetite regulation has also been evaluated. The results obtained from demographic and anthropometric data in our study revealed that CKD patients have mixed type of malnutrition. Almost 69.3% patients had malnutrition and 37.3% had malnutrition with inflammation. The patients in severe group of malnutrition had low BMI, skinfold measurements, body fat percent, and dry weight. Age $>$ 50 years, serum albumin ($<$3.5gm/dl), low serum protein ($<$6.0 mg/dl), hyper-ferritinemia ($>$200 ng/ml), low TIBC ($<$270 μg/dl), $<$10% body fat, high risk group with comorbidities, and severe degree of malnutrition were associated with reduced overall survival.

On studying the inflammatory markers, it appears that inflammation has a major role in inducing malnutrition. Inflammation apart from uremia along with other

associated factors is also governed by the genotypic makeup of patients. Our study suggests that TNF-α is a key marker as it is related with both higher risk associated of ESRD (TNF-α-238 AA, TNF-α-308 A) and malnutrition (TNF-α-308 A) and higher death hazard (TNF-α-238 AA). IL-10-592 AA/IL10–819 TT genotype was associated with higher risk of inflammation in these patients on dialysis. Serum levels of IL-6 and TNF-α are elevated in severe malnutrition and in inflamed (elevated CRP group) patients. Thus inflammation both induces and accelerates malnutrition. IL-10 levels were increased in non-inflamed patients, suggesting its protective role against inflammation. The combined effect model of alleles associated with high IL-6, TNF-α, and low IL-10 revealed risk association with ESRD and poor nutritional and survival status (Sharma et al. 2013a).

In our study evaluation of the appetite and energy-related markers showed that ghrelin is a major marker and its genetic variants are associated with susceptibility to develop malnutrition (Ghrelin 72Met and 51Gln) and inflammation (Arg51Gln) in ESRD patients on hemodialysis. In silico analysis revealed that mutated allele of ghrelin 51Gln is associated with higher binding energy to the ghrelin receptor and hence lower stability binding as compared to the wild version of the ghrelin peptide. The combined effect model of alleles associated with low leptin, high ghrelin, and low RMR revealed association with ESRD and poor nutritional status. The levels of acyl ghrelin were lowest in the severe group of malnutrition. The appetite was lowest in severe SGA group followed by lower plasma levels of acyl ghrelin in the poor appetite group. Leptin levels are increased in the normal and mild category of SGA showing protective effect of higher leptin levels for malnutrition. Further studies on appetite and energy homeostasis regulating markers are required for establishing their exact role in malnutrition (Sharma et al. 2013b).

Policies and Protocols

There is no single objective method which can diagnose malnutrition accurately in dialysis patients. Height, weight, BMI, measures of body composition, anthropometric measurements, and biochemical tests like serum protein and albumin can give an estimate of degree of malnutrition. Assessment of malnutrition in dialysis patients also includes inflammatory status of patients. But inter-observer variation, lack of nutritional standards, and lack of objective criteria for malnutrition assessment in dialysis patients are important aspects of difficulties faced about nutritional evaluation.

Evaluation of nutritional status in HD patients:

- Dietary assessment: DPI, protein equivalent of total nitrogen appearance (PNA), dietary recall diary, and history
- Anthropometrics: body weight/height, BMI, skinfold thickness, and muscle strength
- Biochemical: serum albumin, serum transferrin, serum insulin-like growth factor (IGF)-1, serum prealbumin, total cholesterol, plasma and muscle amino acid

concentration, serum creatinine, C-reactive protein (CRP) which correlates negatively with serum albumin, and blood urea nitrogen (BUN) levels
- Body composition, BIA, DXA, SGA, and composite assessments; CNI, SGA + anthropometric indices and serum albumin; MIS, SGA + BMI, serum albumin, and total iron-binding capacity

Dietary recommendations for hemodialysis patients are (a) 1.2 g/kg body weight, protein intake per day of which at least 50% should be of high biologic value, and (b) 30 to 35 kcal/kg body weight of caloric intake per day. Patient's history of decreased protein intake and evidence of progressive decrease in BMI, serum albumin, and PNA need to be carefully evaluated for cause of malnutrition.

Indications for interventions and treatment with dietary supplementation contain an unintentional loss of 5% of dry (non-edematous) weight over 3 months or 10% of dry weight over 6 months or a serum albumin value of <3.8 g/dL. Patients should first be given treatment with oral dietary supplements, rather than intravenous hyperalimentation. An exception is patients who continue to lose weight despite oral supplementation and have very low serum albumin (<3.2 g/dL) despite oral supplementation given for 3 months or who are unable to take orally. For such patients, IDPN could be useful.

Dictionary of Terms

- **Malnutrition** – a term used to refer to any condition in which the body does not receive enough nutrients for proper function. Malnutrition may range from mild to severe and life-threatening.
- **Body mass index (BMI)** – is a measure of body fat based on weight in relation to height and applies to most adult men and women aged 20 and over. For children aged 2 and over, BMI percentile is the best assessment of body fat.
- **Chronic kidney disease (CKD)** – describes the gradual loss of kidney function. Kidneys act as filter wastes and excess fluids from blood, which are then excreted in urine. When chronic kidney disease reaches an advanced stage, dangerous levels of fluid, electrolytes, and wastes can build up in the body.
- **Dietary protein intake (DPI)** – protein and the CKD patient. When protein is ingested, protein waste products are formed. Unhealthy kidneys lose the ability to remove protein waste, and it starts to build up in the blood. Dietary protein intake for patients with CKD is based on the stage of kidney disease, nutritional status, and body size.
- **Glomerular filtration rate (GFR)** – is a test used to check how well the kidneys are working. Specifically, it estimates how much blood passes through the glomeruli each minute.
- **Maintenance hemodialysis (MHD)** – is renal replacement therapy for patients with end-stage renal disease. It prolongs survival, reduces morbidities, and improves quality of life.

- **Intradialytic Parenteral Nutrition (IDPN)** – is the infusion of an intravenous nutritional formula of hyperalimentation, such as amino acids, glucose, and lipids, during dialysis, to treat protein calorie malnutrition in an effort to decrease the associated morbidity and mortality experienced in patients with renal disease.
- **Protein nitrogen appearance (PNA)** – is also known as protein catabolic rate (PCR). It reflects the daily protein intake in maintenance hemodialysis (MHD) patients.
- **Protein-energy wasting (PEW)** – a term proposed by the International Society of Renal Nutrition and Metabolism (ISRNM). It refers to the multiple nutritional and catabolic alterations that occur in chronic kidney disease (CKD) which are associated with increased morbidity and mortality. Also defined as reduced somatic and/or circulating body protein mass and decreased fat mass, usually associated with reduced protein and energy intake. Its prevalence is variously estimated to be 18% to 75% in maintenance hemodialysis.
- **Proteinuria** – People with proteinuria have urine containing an abnormal amount of protein. This condition is often a sign of kidney disease. Glomerular filters damaged by kidney disease may let proteins such as albumin leak from the blood into the urine. Proteinuria can also be result of overproduction of proteins by the body.
- **Albuminuria** – indicates presence of albumin in the urine, typically as a symptom of kidney disease.
- **Hematuria** – denotes the presence of blood in urine.
- **End-stage renal disease (ESRD)** – is CKD when kidneys are functioning below 10% of their normal function.
- **Hyperparathyroidism** – is an excess of parathyroid hormone in the blood due to overactivity of one or more of the body's four parathyroid glands.
- **Inflammation** – is the immune system-regulated white blood cell response to infection and illness.
- **Dialysis adequacy** – The two methods generally used to assess dialysis adequacy are urea reduction ratio (URR) and Kt/V. A patient's average URR should exceed 65%. A patient's average Kt/V should be at least 1.2. A patient's URR or Kt/V can be increased either by increasing time on dialysis or increasing blood flow through the dialyzer.
- **Bioelectrical impedance analysis (BIA)** – is a method of assessing body composition, the measurement of body fat in relation to lean body mass. It is an integral part of health and nutrition assessment.
- **Dual-energy radiograph absorptiometry (DXA)** – is a means of measuring bone mineral density (BMD). Two X-ray beams, with different energy levels, are aimed at the patient's bones.
- **Subjective global assessment (SGA)** – This is a clinical technique called SGA, which assesses nutritional status based on features of the history and physical examination.
- **Composite nutritional index (CNI)** – It is worth identifying the indicators by different levels of poverty. As poverty is a multidimensional phenomenon, a composite index based on socioeconomic, demographic, health, and dietary

indicators is of interest for making comparison between various ethnic groups.

- **Malnutrition-inflammation score (MIS)** – is correlated with morbidity and mortality in maintenance hemodialysis patients. Malnutrition-inflammation complex syndrome (MICS) occurs commonly in maintenance hemodialysis (MHD) patients and is associated with increased morbidity and mortality.

Summary Points

- Protein malnutrition can be prevented and substantially reversed with ongoing dietary monitoring and nutritional therapy. It is common in patients with CKD, a growing patient population worldwide, and also is associated with increased morbidity and mortality.
- As per guidelines, daily energy intake in CKD patients should be 30–35 kcal/kg (ideal body weight), and protein intake should be of 0.6–0.8 g/kg/day for non-dialysis CKD patients and 1.0–1.2 g/kg/day for patients on peritoneal dialysis or hemodialysis, with >50% high biological value (HBV) proteins.
- Metabolic acidosis adversely affects both the kidney and patient outcome, and should be corrected, starting in patients with stage 3 CKD even without evidence of metabolic acidosis. Dietary modification with increased base content like vegetables and fruits may be initiated in stage 3 CKD to prevent metabolic acidosis which could be related to multiple metabolic derangements.
- Constipation and abnormal bowel habits can compromise gut epithelial cell integrity. This can also promote inflammation and uremic toxin accumulation. Based on patient's capacity, exercise should be incorporated as part of the CKD management.
- Current recommendation is to supplement 25(OH)-vitamin D for CKD patients with low vitamin D concentration.

Contents

Abstract

Cancer has become one of the most common and devastating health problems in the aging population worldwide. Patients often suffer from a range of complications associated with cancer and cancer treatments that impact their quality of life and may reduce overall survival. Among those secondary to cancer and treatment

are malnutrition and cachexia, which may be a result of the malignancy itself or of the treatment approaches, especially chemotherapy. Depending on the specific cancer type and stage, the prevalence of cachexia ranges from 28% to 57% as evaluated by clinical trials. This chapter will address the following topics related to malnutrition and cancer cachexia:

- Contributing factors to the development of malnutrition and cachexia
- Underlying pathophysiology and biochemical derangement
- Potential biochemical screening markers for malnutrition and cachexia
- Current and future treatment approaches and preventative strategies

The chapter furthermore aims to provide a best practices approach to guide clinicians in the diagnosis, prevention, and treatment of cancer cachexia to optimize quality of life for the patient and improve survival.

Keywords

Malnutrition · Cancer cachexia · Inflammation · Chemotherapy · Hypothalamus · Orexigenic · Metabolism · Anorexigenic · Body composition · Ghrelin

POMC	Proopiomelanocortin
RR	Relative risk
SARM	Selective androgen receptor modulator
TNF	Tumor necrosis factor

Introduction

Cancer is a leading cause of mortality and morbidity in the world, and access to medical treatment may be limited based on location and socioeconomic status of the patient (Ohlen et al. 2017). Depending on the cancer type, stage, and the treatment, a range of symptoms may present that can impact a patient's quality of life and require complementary treatment to adequately maintain health and well-being (Fig. 1). Cancer is defined as a group of disorders involving abnormal cell growth of an organ that may impact normal physiological function and spread to other body locations (Anand et al. 2008). Abnormal cell growth in general is referred to as a tumor and may not always be malignant in nature. One such example is benign prostate hyperplasia often encountered in older men (Ravery 1999). Depending on the location of the tumor, the rate of growth and signs and symptoms may have a profound impact on quality of life, morbidity, and mortality (Movsas et al. 2009; Guckenberger et al. 2013; Fernando et al. 2015). Common signs of malignant tumors of the liver, kidney, stomach, intestines, and pancreas are unexplained and sudden weight loss, loss of appetite, and change in bowel movements (diarrhea or constipation, especially for cancers of the small and large intestines) (Farhat et al. 2008).

Pharmacological treatment and the cancer itself can contribute to the loss of appetite in cancer patients, leading to malnutrition as the first stage of metabolic derangement. In addition, the abnormal cell growth diverts metabolic resources away from essential cellular maintenance of healthy tissues, thus leading to weight loss. Malnutrition is more prevalent in cancer patients who live in countries where

proper nutritional resources are limited (Isenring et al. 2010; Sala et al. 2012) although malnutrition in general can occur in all cancer patients initially if not recognized. Due to the metabolic demands of the tumor and accelerated protein turnover, malnourishment develops over an extended period of time during the initial stages of aggressive and invasive tumors such as pancreatic, stomach, and liver cancer (Arends et al. 2017). A gradual weight loss follows initial derangement of protein metabolism which is focused on muscle loss rather than fat loss due to the high demand of the tumor for amino acid sources (Horstman et al. 2016; Vanhoutte et al. 2016). Loss of muscle mass specifically is referred to as sarcopenia and is often a hallmark of the progression of malnutrition to cachexia (Santarpia et al. 2011; Peterson and Mozer 2017). Although sarcopenia can occur in the absence of cancer (Table 1), loss of skeletal muscle mass and malaise occurring together are strong indicators of a malignancy (Gonzalez and Heymsfield 2017; Peterson and Mozer 2017). Cachexia is the result of progressive malnutrition, loss of appetite, and development of sarcopenia including muscle mass related to a disorder with at least 5% body weight loss over the past 6 months (Arends et al. 2017). Cachexia is prevalent in 50% of cancer patients overall and rises to 80% in terminal cancer patients (Yoon et al. 2015; Arends et al. 2017) presenting a significant factor in morbidity, low quality of life, and mortality in this population (Fig. 1). In contrast to starvation and sarcopenia, cachexia presents with an inflammatory process as a differentiating factor (Table 1).

Contributing Factors to the Development of Cancer Malnutrition and Cachexia

Throughout life, abnormal cell growth may occur. Our body has various ways to detect and stop such cells from replicating and spreading to become a malignancy. However, once a tumor has formed, its metabolic demands will determine what nutritional resources are diverted from normal physiological processes. This initial step in tumor formation and metabolic deregulation may be small and insignificant

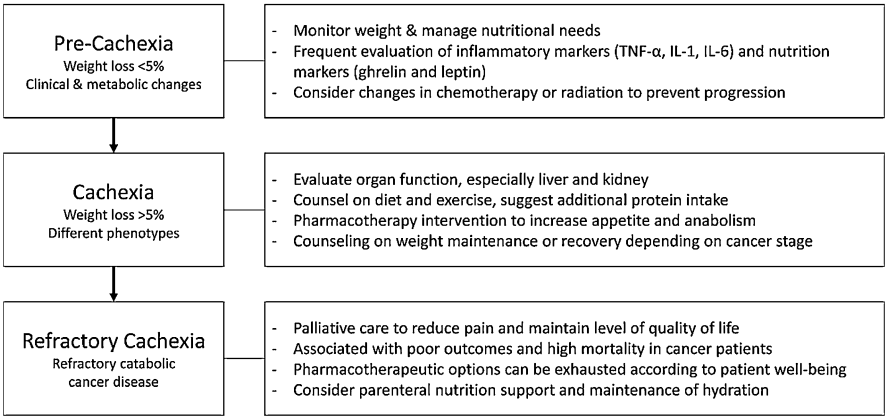

Fig. 2 Stages of cachexia in cancer patients. Clinical symptoms and management of precachexia, cachexia, and refractory cachexia. Depending on progression of cancer pharmacotherapy to prevent progression needs to be considered. *TNF-α* tumor necrosis factor α, *IL-1* interleukin-1, *IL-6* interleukin-6

but is an important predetermining factor in the development of malnutrition. Associated with metabolic deregulation are endogenous stress factors that contribute to the growth of a tumor and specialized cell types reverting to basic functions that disable proper functioning of the tissue (Hill et al. 2009). A number of independent factors that have been shown to contribute to the development of cancer malnutrition are age with adults older than 60 (adjusted RR 1.36), smokers (adjusted RR 1.21), lower socioeconomic status (adjusted RR 1.44), and impaired performance or inability to be physically active (adjusted RR 1.50) (Silva et al. 2015). It is imperative to detect early signs of malnutrition by frequently monitoring weight and food intake and prevent its progression to cachexia and metabolic deregulation which promotes stress and tumor growth (Santarpia et al. 2011; Arends et al. 2017). Early intervention is critical to improve quality of life and prolong survival time in cancer patients because it is extremely difficult to reverse once a patient reaches the refractory cachexia stage (Fig. 2).

Once malnutrition reaches a point of negative protein synthesis and positive proteolysis, the patient may be at risk of developing cachexia. The progression usually occurs over some time as the tumor advances and pro-inflammatory mediators reach concentrations that shift the balance from a positive protein balance that allows for maintenance of muscle mass to a negative protein wasting (Fearon et al. 2011; Peterson and Mozer 2017). It has not been determined what the critical point for this shift is, but it varies depending on the specific tumor location, its growth, and the general health of the patient, among other factors. Early detection and treatment access to prevent progression may impact the development of malnutrition and cachexia.

Weight change is the most commonly monitored indicator to differentiate between precachectic and cachectic patients. If weight remains stable or does not

decrease by more than 5% over the course of 6 weeks, the patient can usually continue their regular chemotherapy or radiation schedule. If weight loss reaches more than 5% or caloric intake is significantly impaired, delays in chemotherapy may become necessary to prevent progression of a pre-cachectic patient to cachexia. Once a patient has lost more than 5% of body weight within 6 weeks, more aggressive measures such as pharmacotherapy, nutritional counseling, and parenteral nutrition may have to be instituted (Fig. 2).

Underlying Pathophysiology and Biochemical Derangement

A key factor that has been identified in the development of cancer cachexia in the 1980s was the activation of the immune system with a resulting increased immune response and general inflammation (Moldawer et al. 1987). This increase in circulating pro-inflammatory mediators such as interleukins (IL), tumor necrosis factor (TNF), and cortisol has a global impact on the balance between anabolism and catabolism in the body (Suzuki et al. 2013). While our body will decrease metabolism and increase food intake during starvation, the opposite occurs during cachexia with increased energy expenditure and decreased food/caloric intake (Thomas 2007). This has been attributed to a profound dysregulation of the hypothalamic neuropeptide circuitry that is influenced by two key hormones released in the periphery, leptin and ghrelin (Ashitani et al. 2009).

Leptin is an adipocytokine that is released in response to food consumption and acts in the hypothalamus through the release of proopiomelanocortin which signals production of corticotropin-releasing hormone (Fig. 3) and suppresses further food intake (Kerem et al. 2008). It has been shown to be differentially expressed in cancer patients depending on the specific cancer type, being low in gastrointestinal cancers but high in breast and gynecological cancers (Wolf et al. 2006). Together with insulin, leptin is considered a major contributor to the development of obesity and anorexia. Both are intricately involved in the cellular uptake and metabolism of lipids and glucose, hence energy homeostasis, both in the periphery and in the CNS (Thon et al. 2016).

Ghrelin is a hormone excreted by enteroendocrine gastric cells to stimulate release of growth hormone and increase appetite (DeBoer 2011). It serves the function to balance energy homeostasis in conjunction with leptin and has been shown to fluctuate opposite to leptin in the bloodstream and stimulate appetite in cachectic patients following injection (Gonnissen et al. 2013). The mediated effects of growth hormone lead to the release of neuropeptide Y in the arcuate nucleus of the hypothalamus which then in turn signals the release of orexin (Fig. 3) in the left hypothalamic area with the resulting orexigenic (appetite-increasing) effect (Kerem et al. 2008).

During starvation, the physiological response would be to increase ghrelin release and thereby stimulate orexigenic processes to increase food intake and decrease energy expenditure to restore glucose and lipid stores until required levels have been reached. When this has been accomplished, leptin will be released and ghrelin will

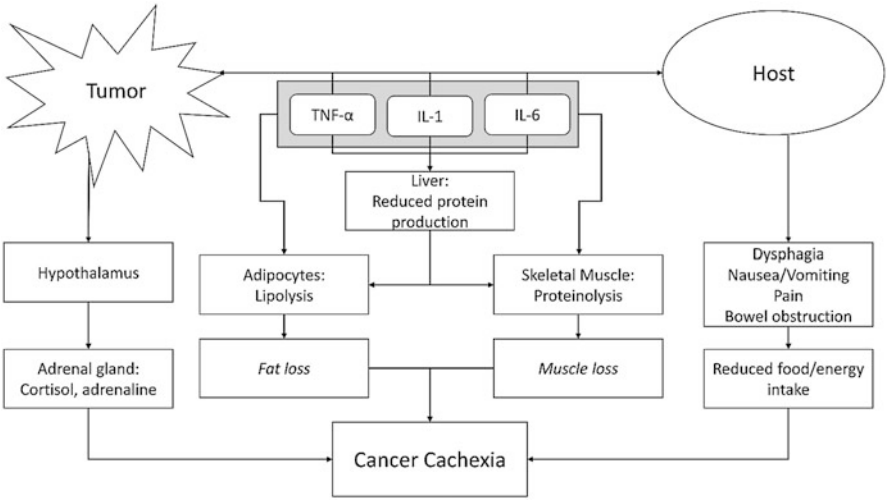

Fig. 3 Tumor-host interactions leading to lipolysis and proteinolysis. The major factors contributing to fat and protein loss as well as release of cortisol and increased activation of the sympathetic nervous system through release of epinephrine from the adrenal gland. Functional factors of the host may accelerate cancer cachexia through decreased food and caloric intake. *TNF-α* tumor necrosis factor α, *IL-1* interleukin-1, *IL-6* interleukin-6

be reduced to signal satiety (Williams et al. 2016). In cancer cachexia, the balance between ghrelin and leptin is not functioning due to systemic inflammation that profoundly impacts metabolic processes and impairs the ability of the body to properly metabolize macronutrients and maintain both adipose and muscle tissue.

Both TNF-α and IL-1 have been associated with cachexia and increased circulating levels of these pro-inflammatory mediators have been confirmed in cancer patients (Mantovani et al. 2000). While IL-6 levels are increased in patients with cancer cachexia, leptin levels are inversely correlated and appear to decrease with advanced cancer stages which shifts homeostasis towards ghrelin and therefore should stimulate appetite. Indeed, increased serum ghrelin levels have been reported in patients with cancer cachexia compared to cancer patients without cachexia or healthy individuals (Chopin et al. 2012). Since ghrelin stimulates the release of growth hormone, it may play a role in tumor growth although there is conflicting data to date. It also remains uncertain why cachectic patients do not gain appetite with increased circulating ghrelin levels as would be expected and it has been theorized that a resistance to ghrelin has evolved in these patients. Supporting evidence for this theory is a lack in increase of insulin-like growth factor-1 (IGF-1) levels, which would normally accompany ghrelin release (Garcia et al. 2013).

The pro-inflammatory environment that promotes tumor growth and often advances progression of malnutrition to cachexia in cancer patients is a crucial factor to consider in the diagnosis and treatment of the patient. The opposing mediators of food intake in the CNS are proopiomelanocortin for anorexic and neuropeptide Y for orexic effects (Fig. 3). Interleukin-6 is generated both in the periphery and centrally

to exert diverse effects on a global scale. It has been shown that IL-6 does promote tumor growth through increased proliferation, shaping of the microenvironment, and involvement in metastasis (Chang et al. 2013). In the CNS, IL-6-mediated intracellular signaling leads to less release of neuropeptide Y and hence decreased production of orexin which would stimulate food intake and appetite (Schele et al. 2013). Furthermore, IL-6 receptors are primarily located in the hypothalamic arcuate nucleus which is in close proximity to the anorexigenic pathway involving POMC and corticotropin-releasing hormone. Therefore, a decrease in neuropeptide Y may directly shift the balance towards decreased food intake.

Another pro-inflammatory mediator that is associated with the development of cancer cachexia and tumor growth is tumor necrosis factor α (TNF-α). Especially in the early development of tumors in promoting growth, invasion, and angiogenesis, circulating levels of TNF-α have been shown to play a significant role in various cancers. However, its levels are not directly correlated with cancer cachexia in the same manner as for IL-6 in a proportional manner. Rather, TNF-α is a global marker of inflammation (Fig. 4) and an indicator of potential progression of malnutrition to cachexia in conjunction with IL-6. While IL-6 decreases neuropeptide Y, TNF-α directly promotes proteolysis and muscle degradation of skeletal muscles (Fig. 4) by

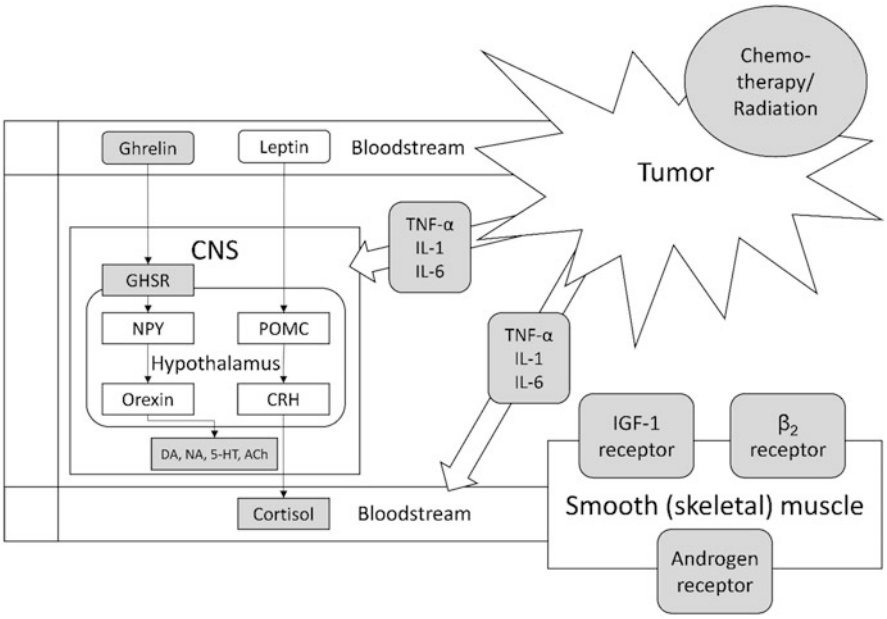

Fig. 4 Potential therapeutic targets for treatment of cancer cachexia. Grey shaded areas are current and potential targets for cancer cachexia including treatment of tumor. inducing apoptosis of fast muscle type II fibers through upregulation of the intracellular p38/MAP kinase pathway leading to reduced protein synthesis and muscle atrophy (Phillips and Leeuwenburgh 2005).

Given that the hypothalamus is part of the hypothalamic-pituitary-adrenal (HPA) axis, its activation will lead to the release of cortisol from the adrenal cortex into the bloodstream (Figs. 3 and 4). Cortisol is the endogenous glucocorticoid often associated with glucose, fat, and protein metabolism and suppression of the immune system (Nolten et al. 1993). In common terminology, it is often also referred to as the "stress hormone" since it stimulates the release of epinephrine from the adrenal medulla. Cortisol is released in response to production of proopiomelanocortin from the hypothalamus and release of corticotropin-releasing hormone and exerts anorexigenic effects by increasing lipolysis, proteinolysis, and both gluconeogenesis in the liver as well as glucose uptake by cells in the body (Cavagnini et al. 2000). Continued release of cortisol will cause loss of fat and muscle mass and eventually lead to a build-up resistance to sympathetic system activation (Fig. 4). This may be a positive modulator for tumor growth and progression of cancer cachexia although its exact role remains unclear.

Potential Biochemical Screening Markers for Malnutrition and Cachexia

The extensive search for biomarkers to predict a range of disorders and their severity has resulted in a wealth of information about the disorders themselves but not necessarily always yielded good markers for identifying or determining the severity of a disorder. An important determinant for a good biomarker of a disorder is its value in causation and correlation with the disorder. If the biomarker has a causative impact on the development of the disorder, then it can serve as a good predictor for its development. One drawback to this may be that the same biomarker can be indicative for the development of a range of disorders and hence lack specificity. Another limitation is the potential sensitivity of the biomarker and its careful interpretation in conjunction with other symptoms and observations. In many cases, biomarkers may be used after an initial diagnosis has been made or a suspicion for a disease state has sufficiently narrowed down potential choices.

With this in mind, the healthcare team needs to be aware to interpret any biomarker results within the context of the overall patient presentation and concomitant disorders. From prior discussions, it is clear that cancer patients are at risk of developing malnutrition with advancing cancer stages. Hence, weight, diet, and caloric intake should be frequently monitored. Biomarkers that can serve as indicators for malnutrition but are not specific to cancer malnutrition are low carnitine levels (Rabito et al. 2013), glutamine deprivation (Schlemmer et al. 2015), and to some degree total blood protein and serum albumin (Miyoshi et al. 2015). Malnutrition initially indicates a shift in caloric intake towards higher energy expenditure but may not yet involve proteolysis and lipolysis. Furthermore, malnutrition can develop both from the tumor growth and as a result of the chemotherapy

(Nicolini et al. 2013; Caillet et al. 2016). Serum albumin has often been used as a general indicator in conjunction with weight loss and complete blood counts to assess patients undergoing chemotherapy for potential malnutrition and chemotherapy-related toxicity (Arrieta et al. 2010; Hasenberg et al. 2010; Baicus et al. 2014). A range of nutritional assessment questionnaires have been utilized to evaluate patients, which can be used in conjunction with biomarkers such as the Nutrition Risk Screening 2002 (NRS-2002), Mini Nutritional-Assessment Short-Form (MNA-SF), Patient Generated Subjective Global Assessment (PG-SGA), Malnutrition Screening Tool (MST), and the Malnutrition Universal Screening Tool (MUST) (Isenring et al. 2010). Aside from the potential but unreliable use of carnitine, glutamine, and serum albumin as early indicators of malnutrition in cancer patients, a genomic marker study has revealed a correlation between the mRNA expression for the serine/threonine kinase enzyme CaMKII, which is directly related to exercise-induced inhibition of protein muscle synthesis and weight loss in cancer patients (Stephens et al. 2010). In this transcriptomic study, no correlation between the mRNA expression or protein levels of pro-inflammatory mediators or enzymes that generate cytokines and weight loss were observed in sampled skeletal muscle tissue, indicating that pro-inflammatory signaling mechanism alone may not explain the pathophysiological processes involved in cancer cachexia (Stephens et al. 2010).

Since pro-inflammatory cytokines are associated with cancer progression and appear to play a role in the development of cancer cachexia, a number of studies have focused on using interleukins, TNF-α, and C-reactive protein (CRP) as biomarkersand predictors of morbidity and mortality (McMillan 2009; Bilir et al. 2015). Morbidity and activities of daily living were significantly impacted with increasing CRP levels in patients with advanced cancer that also presented with weight loss and cachexia (Amano et al. 2017). There was no difference in regards to gender, but the researchers reported an increased odds ratio for patients with metastatic cancers and those with impaired performance status. Overall CRP levels showed a stronger correlation with activities of daily living than symptoms such as jaundice, anorexia, or pressure ulcers which is likely based on the specific cancer location. CRP can serve as a valuable predictor for the current health status and progression of a patient in regards to overall health and nutritional status (Dev et al. 2017).

In a small study with lung cancer patients, a correlation between the blood levels of the pro-inflammatory cytokines interleukin-1 and interleukin-6, TNF-α, and leptin and ghrelin was observed with the hypothalamic oxygen requirement in patients who were anorexic compared to controls and cancer patients who were not anorexic (Molfino et al. 2017). Lung cancer patients with anorexia had a lower hypothalamic oxygen level than their nonanorexic counterparts, which may explain their decreased appetite which also related to lower levels of leptin and ghrelin in anorexic patients compared to healthy controls. The authors therefore hypothesized that the hypothalamus may play a central role in appetite regulation and contributing to the development of both anorexia and cachexia in cancer patients.

TNF-α may not serve as the best biomarker for cancer cachexia since it is also released by many tumors and associated with local and systemic inflammation (Patel

and Patel 2017). Despite this dual role, TNF-α can often provide an indication on the progression of cancer cachexia in association with the weight loss and other parameters such as body fat mass and lean muscle mass. In early stages of tumor progression, TNF-α often initiates the loss of lean muscle mass and promotes lipolysis in fat tissue, whereas in later stages once catabolism has reached the stage of cachexia and TNF-α promotes the conversion of glucose into lactate leading to increased tumor lactate levels (Patel and Patel 2017).

Current and Future Treatment Approaches and Preventative Strategies

Malnutrition and cachexia in cancer patients are of obvious concern since it contributes to worse outcomes and lower quality of life, often leading to increased morbidity and mortality. Hence, early detection and intervention is essential and monitoring of weight changes and diet has been the primary measures for clinicians to initiate pharmacological and nutrition intervention. An additional factor contributing to weight loss and reduced quality of life are chemotherapy or radiotherapy itself that often impact immune function and weaken organ systems, especially liver and kidney function (Persson and Glimelius 2002). Pharmacological intervention most commonly employed includes the progesterone hormone, megestrol acetate, and other corticosteroids to stimulate appetite and increase weight (Table 2). However, a meta-analysis indicated that megestrol acetate compared to placebo only led to small weight gains and moderate appetite improvement and was associated with higher morbidities such as edema and thromboembolism as well as higher mortality (Ruiz Garcia et al. 2013). Other treatment options such as the cannabinoid dronabinol or the omega-3 fatty acid eicosapentaenoic acid (EPA) for appetite stimulation presented with conflicting result in clinical trials in regards to weight gain (Tuca et al. 2013).

Nonpharmacological approaches for the prevention or treatment of cancer cachexia and malnutrition often lack sufficient clinical data. However, a number of studies indicate that along with nutritional support and pharmacotherapy, certain complementary interventions may provide benefits to patients and improve quality of life and at least halt further progression of cancer cachexia. One such intervention is acupuncture which has been studied for a range of disorders since it has shown to improve immune function and hence may counteract pro-inflammatory mediators that contribute to the development and progression of cachexia (Yoon et al. 2015). In a feasibility study, improvement in body composition and appetite scores was observed, indicating a potential benefit for targeted acupuncture treatment in patients with gastrointestinal cancer (Yoon et al. 2015).

Based on the mechanism in this chapter that contributes to the development of cancer cachexia, there appear to be multiple targets for new drugs. However, it has been challenging to develop drugs that are not associated with significant adverse effects that also impact quality of life of patients that are often already weakened by chemotherapy and radiation treatment.

Table 2 Current treatment approaches for cancer cachexia

First line pharmacotherapy
Glucocorticoids
Dexamethasone
Methylprednisolone
Prednisolone
Progesterone derivatives
Medroxyprogesterone
Megestrol
Secondary therapy
Cannabinoids
Dronabinol
Cyproheptadine
Equivocal and investigational agents
Anticytokine agents
Melatonin
Omega-3 fatty acids
Pentoxiphylline
Thalidomide
Anabolic agents (testosterone derivatives)
Fluoxymesterone
Nandrolone
Oxandrolone
Metabolic inhibitors
Hydrazine
Beta-blockers
Albuterol
Espindolol
Appetite stimulants
Atypical antipsychotics
Olanzapine
Antidepressants
Mirtazapine

One target for the prevention of loss of skeletal muscle mass has been the androgen receptor with the administration of testosterone analogs (Dev et al. 2014). In case reports, clinical trials, and clinical practice, testosterone and its analogues (Table 2) are already used for this purpose but presented with unclear results in male patients (von Haehling and Anker 2014). Another selective androgen receptor modulator (SARM), enobosarm, has shown promising results in clinical trials by preventing muscle wasting and increasing lean skeletal muscle mass in patients already presenting with cachexia (Srinath and Dobs 2014). The drug is now awaiting FDA approval after two large phase III trials, POWER1 and POWER2, were completed in 2013.

Ghrelin has been a successful target for the treatment of cancer cachexia to stimulate appetite and increase food intake. The direct administration of the peptide ghrelin has to occur intravenously or subcutaneously since it is not orally available, making it an expensive treatment option to physicians and patients alike. In addition, ghrelin has a short half-life and has to be administered twice daily to achieve its desired effect (von Haehling and Anker 2014). A small-molecular peptidomimetic, the orally available anamorelin acts as an agonist at the central ghrelin/growth hormone secretagogue receptor (GHSR) stimulating the release of ghrelin and in turn increasing appetite and presenting with anabolic effects (Pietra et al. 2014). The increase in body weight observed in clinical trials was directly correlated with increased IGF-1 levels providing for the anabolic effect (Garcia and Polvino 2009). The drug was investigated in two phase III clinical trials and is now being considered for approval by the European Medicines Agency (EMA).

Another target for reversal of weight and muscle mass loss is the use of β_2-receptor agonists such as albuterol (Table 2). The use of β_2-receptor agonists for the treatment of asthma has a long tradition and one of its side effects has been a gain in muscle mass that has led to its occasional misuse as a doping agent. A novel partial β_2-receptor agonist, espindolol, which also acts as a β_1-receptor antagonist and a serotonin 5-HT_{1A} antagonist has been tested in patients with cancer cachexia and improved fatigue, gains in lean muscle and body weight, and increased grip strength (Stewart Coats et al. 2016). The drug requires further clinical studies to evaluate its effectiveness in cancer cachexia and potential adverse outcomes.

Policies and Protocols

Despite advances in the understanding of the pathophysiology and underlying contributors of malnutrition and cancer cachexia, the current best practices and protocols for the prevention and treatment of these conditions have not changed much over the past few decades (Molfino et al. 2014). The European Society for Clinical Nutrition and Metabolism (ESPEN) has issued guidelines for nutrition in cancer patients, which emphasizes early detection of malnutrition and weight loss to provide nutritional and exercise support and prevent the progression to cachexia with muscle loss (Arends et al. 2017). This general policy is repeatedly referred to in the literature as an essential hallmark in the prevention of cachexia and reduction in morbidity and mortality. One limitation of using changes in body weight as the sole predictor for malnutrition and cancer cachexia is its nonspecific nature in regards to body composition. Patients can present with relatively stable body weight due to water retention such as edema while losing lean body mass indicative of muscle wasting over many months. The metabolic derangement would potentially go unnoticed until diuresis coincides with weight loss. At that point, however, muscle wasting has already taken place and the patient presents with significant loss of lean body muscle mass. A better approach in this case is the use of body composition measurements using bioelectrical impedance analysis (BIA) which allows for measurement of body water, fat, and muscle distribution

(Kyle et al. 2004; Grundmann et al. 2015). It is worth noting that most oncologists will use a multimodal approach to preventing or treating malnutrition and cachexia in cancer patients: early recognition and intervention are essential which requires monitoring of the patient in consultation with the healthcare team. Referral and collaboration with other members and the support network of the patient can significantly improve quality of life and delay progression, especially if effective measures are implemented such as pharmacotherapy in conjunction with diet counseling, exercise, and complementary approaches that are well received by the patient, and continuous support to the patient and their environment in all activities of their daily living including cancer treatment and meeting their dietary and exercise goals (Bruggeman et al. 2016).

Dictionary of Terms

- **Cachexia** – A pathological condition involving involuntary weight loss involving decreases in lean muscle mass, fat tissue, and general increase catabolic activity. Loss of appetite, fatigue, and weakness are often symptoms of this wasting syndrome. Cachexia increases mortality.
- **Cancer** – A cell conglomerate that shows abnormal growth patterns absent the regular control of the surrounding tissue. Tumorous cancers may grow and expand to other tissues. Cancer cells show genetic abnormalities that allow them to resist apoptosis and regular growth patterns.
- **Inflammation** – A complex sequence of responses of the body to a harmful insult often involving activation of the immune system. Cardinal signs of inflammation include pain, swelling, functional loss, redness, and heat.
- **Malnutrition** – A condition involving a lack of proper supply of macro- and micronutrients as part of a balanced diet leading to an imbalance in nutritional needs for proper physiological functions. It can involve undernourishment or overnourishment in terms of caloric consumption. In association with diseases, it is most often undernourishment of macronutrients which leads to malnutrition.
- **Sarcopenia** – The loss of muscle strength due to atrophy. Sarcopenia can occur independent from cachexia as a progressive aging process due to decreased anabolic processes and protein metabolism as well as decreased quality and strength of muscle mass building.

Summary Points

- Cancer cachexia is prevalent in later stages of the disease and is often associated with poor outcomes leading to increased mortality and morbidity.
- Progression to cachexia has been linked to systemic inflammatory processes mediated by the tumor and perpetuated pro-inflammatory mediators tumor necrosis factor α (TNF-α), interleukin-1 (IL-1), and interleukin-6 (IL-6).

- Patients with cancer cachexia present with an underlying metabolic disorder with dysregulation in protein and fat metabolism as well as muscle wasting mediated by the neurohormones leptin and ghrelin.
- Early detection of malnutrition and adequate treatment can reduce morbidity and increase quality of life by preventing progression to cachexia.
- New drug targets are being investigated to treat cancer cachexia by stimulating appetite, reducing muscle wasting, and preventing protein and fat catabolism.

Contents

Abstract

Of the possible forms of child maltreatment, neglect is the most uncommon in industrialized countries. Neglect is associated with deprivation of necessities or caregiver's inability to provide for child's basic needs and/or failure to provide adequate supervision according to the child's developmental age. Starvation is an extreme form of nutrient deficiency which can be unintentional or deliberate,

depending on the motivation of perpetrators. Lethal neglect, resulting from dehydration and failure to supply food and provide child medical care, remains a relatively uncommon and not well-identifiable cause of death in industrialized countries. When child neglect and starvation are suspected, forensic pathologists must perform a comprehensive assessment of all circumstantial data and medical records keeping in mind that many natural diseases can mimic abuse. In lethal cases, complete information about the child and their family life, crime scene investigation, and forensic autopsy coupled with laboratory findings orient the diagnosis and rule out other causes of death. Starvation can be acute or chronic. Assessing the duration of starvation is of paramount importance but it can rarely be done reliably. The reason for determining duration of fasting is to understand whether and how long prior to death any signs should have been recognizable by caregivers or health care workers, to enable the victim to receive medical care. In suspected child neglect and starvation a skeptical approach is fundamental. A neglected child can die in various ways, and neglected children may not show any signs of physical abuse.

Introduction

The literature contains a wide variety of definitions of child abuse, maltreatment, and neglect, including international and legal variations (Krug et al. 2002). The terms "child abuse" and "neglect" are included in the broad definition of child

maltreatment set out by the World Health Organization (WHO) Consultation on Child Abuse Prevention as follows:

Child abuse or maltreatment constitutes all forms of physical and/or emotional ill-treatment, sexual abuse, neglect or negligent treatment or commercial or other exploitation, resulting in actual or potential harm to the child's health, survival, development or dignity in the context of a relationship of responsibility, trust or power. (Krug et al. 2002, 59).

Welch and Bonner (2013) defined neglect as (1) deprivation of necessities or caregiver's inability to provide for child's basic needs (e.g., food, water, shelter, medical care, clothing, and education) and (2) neglect or failure to provide adequate supervision according to the child's developmental age.

According to the UK's National Society for the Prevention of Cruelty to Children (NSPCC), child abuse includes physical, psychological, or emotional abuse; sexual abuse; and neglect (NSPCC 2009).

A child can be neglected in many ways, including lack of attention to their primary needs, relative to their age, lack of education, shelter, protection, medical care, supervision, and lack of care to avoid harm.

Of the possible forms of abuse, neglect is probably the most uncommon in industrialized countries. Perhaps the worst form of neglect is failure to supply food and fluids, which can lead to death from starvation and dehydration. This form of neglect seems inexplicable in these countries, and although a cause of child death, it is not always identified as such.

It may manifest in some children as a failure to thrive (FTT), a form of neglect defined by American Academy of Pediatrics Committee on Nutrition (AAPCN) as "a significantly prolonged cessation of appropriate weight gain compared with recognized norms for age and gender after having achieved a stable pattern" (Block and Krebs 2005, 1234).

Starvation is an extreme form of nutrient deficiency which can be unintentional or deliberate, depending on the motivation of perpetrators (Block and Krebs 2005; Knight and Collins 2005; Smitherman 2011; U.S. Department of Health & Human Services et al. 2017).

Unintentional starvation can be related to organic diseases including cancer, chronic infection, hypoxemia from congenital heart defects, surgical interventions, gastrointestinal diseases (malabsorption, cystic fibrosis, celiac disease, liver diseases, and severe gastro-esophageal reflux), and malformations such as cleft palate, neurological impairment, and psychiatric illness. Starvation can also result from nonorganic causes including inadequate nutrition, for example, from prolonged breastfeeding without adequate supplementation, over-dilution of formula milk, diets low in protein, inappropriate composition of homemade formula milk, parental beliefs about food and feeding, and poor diet selection (Block and Krebs 2005; Knight and Collins 2005; Smitherman 2011; Friedman and Billick 2015; U.S. Department of Health & Human Services et al. 2017).

Deliberate starvation is an extremely life-threatening and uncommon form of child abuse (Catanesi et al. 2012). Knight and Collins in 2005 reported that victims of malnutrition/starvation and dehydration are usually aged between 6 and 18 months, and that the primary caregiver at the time of death is usually the mother

(Knight and Collins 2005; Ross and Juarez 2014; Barroso et al. 2016). Intentional starvation is more likely to be associated with particular circumstances, including a family structure complicated by divorce, religious beliefs, unconventional style of life, revenge against partner, and children from unplanned pregnancies. These children may come to personify parental frustration, and become the target of psychological and physical maltreatment, including the lethal complete deprivation of food and water (Ragan 2011). In the most extreme cases, this may be considered a form of torture including repeated physical injury, deprivation of the essential needs, severe psychological abuse, isolation, forceful restriction, and forced and long-lasting exposure to high or low temperature (Catanesi et al. 2012).

Generally speaking, there are two scenarios to consider for forensic pathologists facing cases of suspected child neglect with starvation:

1. *Unintentional neglect or harm*, where parents or caregivers can unintentionally put the child in danger, because they do not understand the child's needs and may be unaware of the potential danger of:
   - Not giving the child enough food, or food inadequate for the phase of growth; or.
   - Not asking for pediatric assistance if there are eating disorders or underlying organic diseases, because "*the situation is not so worrisome*" or the child is believed to be making a fuss.

   These situations occur regardless of the family's socio-economic status.
2. *Deliberate child neglect (and starvation).* Several factors may increase the risk of child neglect and starvation and can affect parents, family, and caregivers. The risk increases if the mother is very young and inexperienced, alone, with a stressful lifestyle, poorly educated, or affected by a mental or physical health issue or learning disability which may impair her ability to care for her children, or mean that she does not realize she is neglecting them. Fathers are more likely to physically abuse than neglect children (Ragan 2011; Catanesi et al. 2012; Miyamoto et al. 2017). A particular issue is obese caregivers who "compensate" for their own loss of control by restricting the diet of their children (Kudek et al. 2016).

The US National Child Abuse and Neglect Data System (NCANDS) defines "child fatality" as "as the death of a child caused by an injury resulting from abuse or neglect or where abuse or neglect was a contributing factor" (Catanesi et al. 2012, e14). Therefore, child deaths can result from a wide range of treatments, including those not directly related to child abuse and neglect (Ragan 2011). Data from the NCANDS for 2015 showed that 75.3% of children recorded had suffered from neglect and 17.2% from physical abuse; children under 3 years old accounted for 74.8% of fatalities because they are the most vulnerable (U.S. Department of Health & Human Services et al. 2017).

The physical and psychological effects of starvation were first studied in a group of conscientious objectors during World War II, known as "The Minnesota Starvation Experiment." In patients with a normal prestarvation weight, a weight loss of

5% impairs mental and physical function. After losing 10–15% of body weight, nutritional intervention may be necessary. A loss of 35% is life threatening (Madea et al. 2016).

When child neglect is suspected, forensic pathologists must perform a comprehensive assessment of all findings that can confirm abuse, bearing in mind that each family is unique. The investigation should broadly include:

1. The lifestyle and clinical history of the child.
2. Investigation of the scene.
3. A physical examination.
4. A radiographical assessment.
5. Autopsy and histological findings and.
6. Laboratory analyses.

Some investigations, such as an autopsy, cannot be performed on living people and certain clinical signs and symptoms are impossible to detect in a cadaver, but this sets out the broad steps.

Everything must be documented with detailed pictures, and if possible, including samples for laboratory testing (e.g., blood, residues of vomit, urine, feces, etc.).

Cause of Death in Child Neglect and Starvation

To confirm neglect and/or starvation, findings from the history and scene investigation must be coherent with the autopsy and laboratory results, and both point to this diagnosis. A neglected child can die in various ways, and neglected children may not show any signs of physical abuse. A diagnosis of fatal starvation is possible after ruling out all other causes of death, in the presence of circumstantial findings and with the victim's appearance indicative of some neglect (Fieguth et al. 2002).

Death from starvation is affected by several parameters, including age, preexisting disease, preexisting nutritional status and health, the amount of fat tissue, coexisting or intercurrent infectious diseases, physical exercise, intake of any fluid, and environmental factors (extreme temperature). Deprivation of food is often correlated with deprivation of water, which accelerates death. Hypertonic dehydration, resulting from liquid decrease in the body, causes hypovolemia and terminal shock. Survival with decreased or insufficient intake of water is possible only for a short period. Survival time has been reported as ranging from 17–76 days (median 40 days) to 60 days for food deprivation and 8–21 days for combined food and liquid deprivation (Dettmeyer et al. 2013). However, the loss of about 35–50% of body weight may cause death (Madea 2005).

In starvation, acute hypoglycemia or ventricular tachyarrhythmia can be the immediate cause of death, alongside secondary infections, especially of the lungs and the kidneys. Malnourished children are more susceptible to invasive infections, and aspiration of the stomach contents can also contribute to death (Madea 2005). Extremely high ketones body production and subsequent ketoacidosis may lead to

death, but only when all postmortem findings have excluded alternative causes of death (Palmiere et al. 2016).

Further Forensic Issues

All these investigations should allow the forensic pathologist to draw the following conclusions when facing a case of suspected neglect:

1. There is no coherent and comprehensible explanation for accidental injury and/or the history, as reported by the caregivers, does not match the established findings from the scene and physical and radiological examination.
2. A thorough examination of the victim reveals external or internal injuries highly suggestive of abuse (localization, patterned bruising, repeated and clustered injuries) and/or not congruent with the child's motor development and age or the situation described by the caregivers.
3. Injuries are not detected but findings from the scene and medical records are strongly indicative of neglect.
4. The manner of death is not natural or accidental, and all reasonable possibilities for the cause of death have been ruled out.

Manner of Death

In cases of starvation, specific issues have to be identified. The manner of death from inanition may be suicidal (hunger strike, protest, exhibitionism, psychiatric illness), homicidal (deliberate withholding of food and water), or accidental (shortage of food in famine, war, entrapment, and calamity, caregivers' ignorance and inability to provide care, and natural diseases). Homicidal and accidental inanition are both encountered in childhood, especially in infants under 3 years of age (Madea 2005).

Duration and Severity of Starvation

Assessing the duration of starvation is of paramount importance but it can rarely be done reliably, because data from literature are mainly limited to adults with acute food and water deprivation (e.g., hunger strikers), or to infants affected by malformations of the upper gastrointestinal tract (Madea et al. 2016). Starvation can be acute or chronic. Acute fasting is a sudden and complete interruption of food and water supply which leads to death. In chronic starvation, the lack of nutrient intake is prolonged and gradual. The duration of starvation also depends upon the severity of undernourishment, and whether it is associated with exacerbating factors such as concurrent diseases, which may often result, in turn, from starvation. The reason for determining duration of fasting is to understand whether and how long

prior to death any signs should have been recognizable by caregivers or health care workers, to enable the victim to receive medical care.

Classifications in the literature refer to Jelliffe's so-called protein-energy malnutrition (PEM), indicating the lack of protein associated with impaired intake of calories in developing countries (Batool et al. 2015).

The standard diagnosis of starvation was commonly made through comparison of anthropometrical data and organ weights of starved children with those of a reference population, using percentile charts (Madea et al. 2016). However, this method did not permit an estimation of degree of malnutrition, especially helpful in a forensic setting to classify infantile malnutrition in cases of deliberate neglect. PEM classifications can be helpful in distinguishing acute from chronic malnutrition (Ross and Juarez 2014).

Since the 1950s, different classifications have been proposed by several authors (Gomez, Wellcome, Kanawati and McLaren, Waterlow) based on parameters including weight, height, and age, the presence of edema, and midarm circumference/head circumference ratio (Gernaat and Voorhoeve 2000; Dettmeyer et al. 2013; Batool et al. 2015; Madea et al. 2016).

The Waterlow classification system (WCS) was used for forensic purposes in 1994 by Madea et al., investigating the death of monozygotic twins from starvation (Madea et al. 1994). In a more recent review published by Madea et al. in 2016, data from case reports of starved infants in the forensic literature were elaborated, and measurements and weights determined at autopsy were evaluated using the same system. The WCS was shown to be suitable for grading severity of starvation, even though a threshold of values for lethal starvation has not yet been described (Madea et al. 2016). The WCS, together with standard growth curves, is helpful in distinguishing between acute and chronic malnutrition and identifying duration (Fieguth et al. 2002).

Anthropometric parameters are not always available and precisely measurable. The examination of medical records has a key role in providing as much evidence as possible of the duration of starvation, considering that absolute withholding of nutrients results in a total body weight loss of about 0.7–1.0% per day (Madea 2005). It may therefore be possible to identify time interval prior to death. Alternative methods have been proposed where records are not available, including analysis of stable carbon and nitrogen isotopes of hair (Baković et al. 2017).

When a forensic pathologist is examining skeletonized bodies, assessing starvation or fatal neglect is even trickier. Medical and family history becomes fundamental together with skeletal indicators that could be diagnostic for malnutrition or undernutrition. These include discrepancies between different standards of hard tissue aging, abnormal dental development, and long bone lengths (Ross and Juarez 2014).

An early recognition of signs indicative of child neglect and abuse can be vital to prevent the situation from worsening, requiring prompt medical care and social support. Missed diagnoses of abuse and neglect because of carelessness towards children and/or records by health and social workers have been reported in literature (Koc et al. 2014). The reasons for this failure include inadequate training in

recognizing child neglect and a resistance to reporting suspected cases because of a wish to avoid legal involvement or not "betray" the child's family (Gunn et al. 2005). One survey demonstrated that more detailed medical records result in higher rates of conviction in cases of suspected abuse (Janßen et al. 2017).

Policies and Protocols

Policies: Forensic Approach

General Information About Child's Life The child's history is likely to be provided by parents or caregivers for very young people. General information about the child and their family life is acquired through a detailed narrative account of events around the death from social services or other agencies, particularly if the child was the subject of previous protection concerns, from neighbors, witnesses, school personal, and schoolmates, for example, if they noticed anything about the child's general appearance, clothing, or behavior that might be relevant (such as stealing or withholding food). Pediatricians may also provide information, if the child has ever seen one, so it is important to collect all medical records and details of any previous examinations. The mother is an important source of information about her pregnancy, and the child's birth, neonatal period, breastfeeding, growth, development, behavior, habits, immunizations, and dental care or treatments. It is important to understand whether the caregivers failed to bring the child to medical appointments and if they sought medical treatment when the child was ill. It is also vital to consider other children in the same family, especially if there are siblings to whom food and medical care were provided while the victim was starving (Kellogg and Lukefahr 2005; Platt et al. 2006; Ross and Juarez 2014).

Investigation of the Scene An extensive investigation of the house or facility where the child lives or has been living must be performed as soon as possible, to avoid alterations designed to misdirect investigation. The forensic pathologist must assess the appearance of the house, its suitability for infants or children (Fig. 1); the availability of food and liquids; how food is kept; whether food and water are adequate for the age of the children; whether clothing, shelter, blankets, and toys are in adequate places for sleeping and playing; the degree of cleanliness (if there are animals, insects infestation, excrement, residues of food, accumulated unwashed dishes, garbage, rubbish, etc.); any hazards such as weapons or drugs within the reach of children and safety measures taken to avoid harm; the presence of suspect objects as belt, or sticks, weapons, tools, cigarettes or cigars, drug paraphernalia; whether medication is available if the child is ill; the existence of school material; and the condition of the house's ventilation and heating (Platt et al. 2006; Ross 2011; Solarino et al. 2012; Lefebvre et al. 2017).

Physical Examination Physical examination in neglect and starvation cases aims to identify any inadequate/insufficient nutritional intake which could determine growth

Fig. 1 Scene of death. A 4-month-old infant, dead at hospital, lived in an apartment that was in a state of extreme neglect

defects, against the growth-curves provided by the National Center for Health Statistics (NCHS) (Smitherman 2011). All findings must be documented, including pictures and details of any injury, because these can all be signs of abuse (Fig. 2a–d).

It is important to consider whether external signs may be caused by physical violence (Smitherman 2011; Gilbert-Barness et al. 2014; Tsokos 2015) (Fig. 3). This will depend on the nature of the force involved and the extent of any injury. Indirect signs of neglect may include dermatitis, parasite infestations, insect bites, and scratching injuries. A careful and comprehensive intraoral and perioral examination is necessary in all cases of suspected abuse and neglect, because this is likely to include dental neglect (caries, gingivitis, etc) (AAPCN et al. 2008).

Any injury should be considered potentially abusive when (Tsokos 2015):

- There is no reasonable explanation for an accidental event.
- There are discrepancies between the injury and the caregiver's description of the incident.
- The child's motor development is not congruent with the history described.
- The child behaves abnormally during a medical examination.
- Cutaneous injuries show particular localization and patterned bruising, and they are repeated (juxtaposition of injuries of different ages) and clustered (three or more individual injuries in the same body region).

In *clinical starvation*, the skin may show atrophy, fissuring, and sores. Changes of hair and nails color and texture can result from decreased protein availability, and changes in cardiac rate and rhythm occur as a result of severe malnutrition/

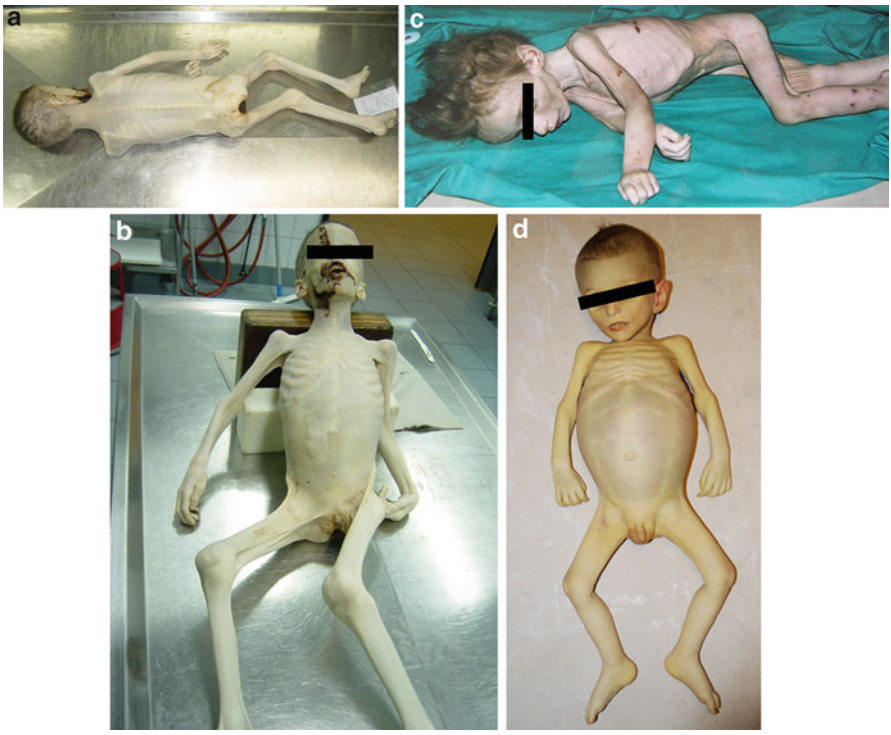

Fig. 2 Typical external appearance of the body in starvation. (**a**) The body of a 7-year-old girl (weight of 9.6 kg, height of 105 cm) with skeletal limbs, and signs of poor hygiene with fecal concretions; (**b**) extreme emaciation with "scaphoid" abdomen and protrusion of the iliac crests and the rib cage; (**c**) the body of a 16-month-old child (weight and height values less than the third percentile) with loss of Bichat's fat pad, sunken eyes, and bruises on the chest and on the limbs resulting from physical violence; (**d**) inanition in a 4-month-old infant resulting from malnutrition and concurrent acute lymphoblastic leukemia

undernutrition (Kellogg and Lukefahr 2005). Almost all organs are affected by nutrition deficiencies, including impairment of pulmonary and renal function (decreased ability to concentrate urine), bone marrow production, secretion of hormones, and brain growth and development. One of the major effects of severe malnutrition is atrophy of the thymus, which decreases immune defenses and increases the likelihood of opportunistic infections (Piercecchi-Marti et al. 2006). If a *fatal event* has occurred, algor, rigor mortis, livor mortis, bodily temperature, and possible putrefactive changes have to be registered to estimate the time of death. Anthropometric parameters including measurement of crown-heel, crown-rump, head diameter, foot length, exact weight, and height must be detected accurately; results are compared with standard pediatric percentile growth charts by age, birth weight, sex, and race. Diameter of limbs, thorax, and abdomen should be measured with a flexible tape (Saukko and Knight 2016). Photographs should be taken in a good light source, to highlight skin color and injuries, and show the general aspect of the body.

Fig. 3 Signs of physical abuse in a starvation death. Multiple abrasions and bruises at varying healing stages on the face and the scalp caused by objects thrown at her head and beating with a metal spoon

The classical external findings in cases of fatal starvation are extreme emaciation with loss of weight. Saukko and Knight (2016) identified two main patterns of starvation:

- *Wet-type starvation* (edema of face, trunk and limbs, pleural effusions, ascites) because of hypoproteinemia caused by breakdown of proteins to provide energy in the absence of sugar or inadequately intake of fat.
- *Dry-type starvation* resulting in loss of up to half the normal weight, with extreme emaciation, and leg edema.

Knight suggested that nutritional neglect and physical abuse are not always found together, because emaciated children are often uninjured, and battered children may be well-nourished. However, neglect and starvation are generally considered concurrently (Saukko and Knight 2016). Appearance in starvation is well defined and may enable a diagnosis of malnutrition/ undernutrition on sight (Madea 2005; Solarino et al. 2012; Madea et al. 2016). Concurrent dehydration is common, and this may be the main cause of death especially in newborns and infants. The skin's appearance may alter by duration and the type of nutritional deficiency. It can be dark brown or pale, but will be thin, wrinkled, and dry and remain ridged when pinched because of loss of subcutaneous fat and fluids (Fig. 4). Cheekbones are prominent because of the loss of Bichat's fat (the last subcutaneous adipose store to disappear), as are the occiput and ribs, with concavities in intercostal spaces and clavicles, and sunken supraclavicular fossae. In infants, fontanelles are depressed from loss of pressure of cerebrospinal liquid (LCS), eyes are sunken from loss of orbital fat and dehydration, tongue is dry and furred, lips are dry and cracked, hair are dry and

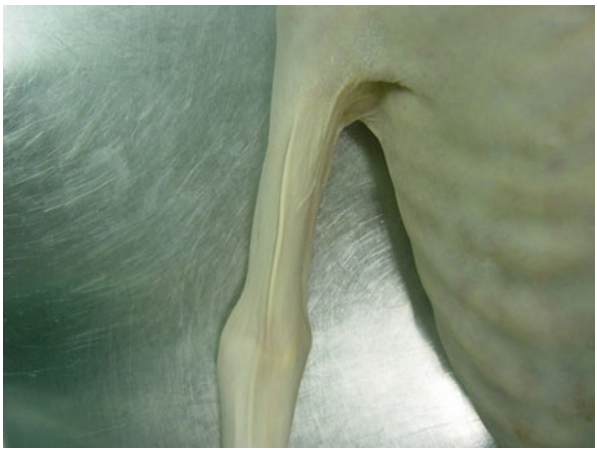

Fig. 4 Postmortem finding of extreme dehydratation. Skin of the upper arm remains ridged when pinched because of loss of subcutaneous fat and fluids

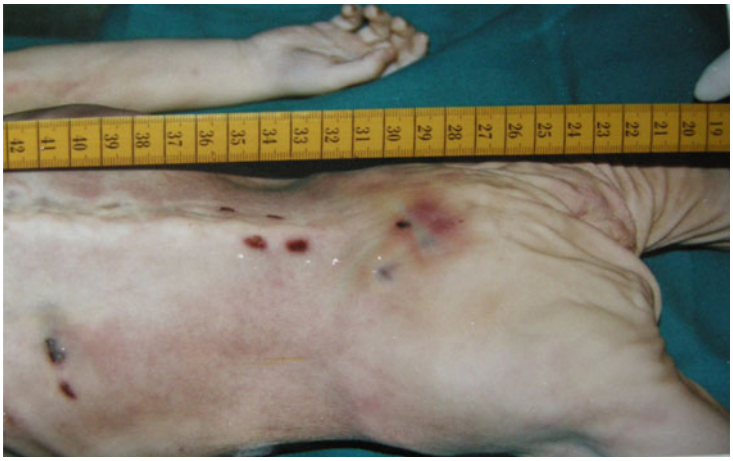

Fig. 5 Signs of neglect and physical abuse. Loss of subcutaneous tissue with protruded spine and pressure sores on the buttocks and spine in infant who have been forced to spend all time sitting in a stroller facing the wall (each injury measured 0.8 mm in diameter)

brittle, and alopecia may be present. The neck is thinned, with very little fat; the abdomen has a scaphoid shape, with concavity from the costal margin to the iliac crests, which will protrude. The limbs may be skeletal from loss of muscular and fatty tissue; edema may also be present, though this is rarely seen, as a result of hypoproteinemia. Signs of insect activity, ante- or postmortem, must be noted. Several signs may indirectly indicate neglect, including cutaneous infections and dermatitis as the result of poor hygiene, pressure sores on the occiput, buttocks, heels, and spine in infants who have been lying inert because they are either very weak or have been forced to do so (Fig. 5). Malnutrition induces a vicious cycle, because it predisposes to decubitus ulcers and infections, which lead to increased

calorific use. This in turn worsens the malnutrition and strengthens the predisposition to ulcers and infections (Madea 2005; Solarino et al. 2012; Madea et al. 2016).

Radiographical Assessment of Neglect Before autopsy, a complete body scan (CT scan or radiographic) is mandatory, to find any traumatic bone lesions or alteration of ossification and mineralization. Some fractures are strongly indicative of inflicted injury, especially multiple unexplained fractures in various stages of healing (Solarino et al. 2009; Ross and Juarez 2016). In starvation, osteopenia/osteoporosis and a deficiency of vitamin C can occur as scurvy, related to defective osteoid matrix formation and cartilage maturation. Radiological assessment can reveal Harris lines (or growth arrest lines) with delayed bone maturation as a nonspecific marker of stress. These appear as a radiopaque transverse trabeculation in metaphyses of long bones, instead of normal trabeculation, which is longitudinal. This finding results from missed mineralization of cartilage consequent on temporary arrest of biological processes of calcification (Piercecchi-Marti et al. 2006).

Autopsy and Histological Findings Typical findings are loss of body and organ weights. The decrease becomes slower after 3 months of starvation, after an initial rapid decrease. Decreasing body weight is the result of loss of subcutaneous adipose tissue and fat surrounding organs, and of organ and muscles atrophy (Fig. 6). Major viscera have to be weighted and compared with standard tables for sex and age. At section, internal fat stores such as the omentum, mesentery, and perirenal area will be lacking; organs except the brain will be very small; the gallbladder will be distended and filled with greenish bile because no food stimulates its emptying; the small bowel will be swollen, with reddish discolored mucosa, the walls of the stomach and bowel translucent and thin, with loss of mucosal layers. The stomach and small bowel will normally be empty, with dry feces in the colon and rectum, especially in fluid restriction and dehydration. In infants, stools may be fluid if dehydration was not severe. The bowel lining can appear ulcerated by fecaliths; foreign bodies can be found in the colon because starving people may try to eat anything accessible before death. Edema and pleural or peritoneal effusion may also occur; atrophy of

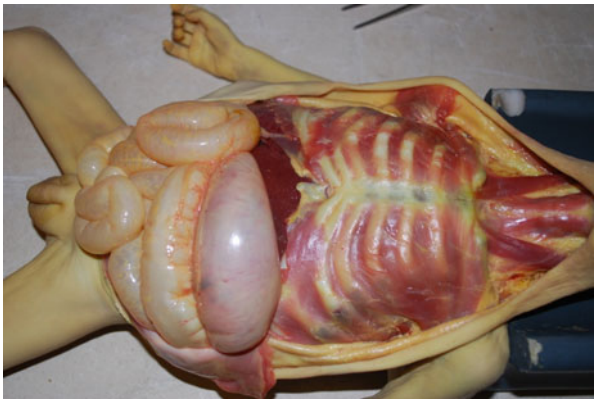

Fig. 6 Typical autopsy finding in starvation. Loss of subcutaneous adipose tissue and fat surrounding organs and severe atrophy of skeletal muscles

endocrine organs, lymphatic tissue, and reproductive glands (ovaries and testes) is a common finding. In infants, a complete atrophy of the thymus is symptomatic of starvation (Madea 2005; Tattoli et al. 2012; Solarino et al. 2012; Gilbert-Barness et al. 2014; Madea et al. 2016; Saukko and Knight 2016).

Histological findings are useful to support macroscopic observation; they are not specific for pediatric starvation but help to exclude underlying natural illnesses. The results reflect the alterations of the organ system, including the endocrine system (insulin, thyroid, and growth hormone are the main hormones affected), immune system (with atrophy of the thymus, lymph nodes, and tonsils), and gastrointestinal system (villous and pancreas atrophy, fatty infiltration of the liver). In particular, hepatocytes vacuolization and microvescicular steatosis from protein deficiency is often found in the liver; loss of glycogen in the liver can be observed on a periodic acid–Schiff (PAS) stain. A secondary siderosis as a result of protein deficiency in the spleen and the liver can occur. Food residues may be found in the lungs, as a sign of aspiration of the stomach contents, which could contribute to death. Bone histology may show vitamin deficiencies or growth disturbances, such as rickets with resorption lacunae and osteoclasts. Bone marrow can reveal gelatinous transformation, fat atrophy, and hypocellularity (Tattoli et al. 2012; Solarino et al. 2012; Osgood et al. 2014; Madea et al. 2016; Saukko and Knight 2016). Thymic involution is found with microscopic findings such as a "starry sky" appearance of the cortex, as a result of stress reactions of the thymus. Calcification of thymic Hassall's corpuscles and fibrofatty replacement have also been described (Kollins 2010).

Laboratory Analyses Supplementary analyses include biochemical investigations, toxicological dosages on available body fluids, virology and microbiology analyses, and metabolic screenings. These are mainly necessary to rule out other causes of death. Vitreous fluid is ideal for postmortem chemical analysis, because it is relatively isolated from other body fluids affected by postmortem changes of redistribution and concentration (Madea et al. 2016). An increase of electrolytes concentrations such as sodium, chloride, and urea nitrogen detected postmortem is a characteristic dehydration pattern. This measurement reflects electrolyte concentrations in serum at the time of death, considering the loss of selective membrane permeability occurring postmortem. A vitreous sodium level of more than 155 mEq and a chloride level of more than 13 mEq are likely to indicate dehydration (Dix and Calaluce 1999). Increased ketone (acetoacetate, beta-hydroxybutyrate, and acetone) body levels in blood, vitreous, pericardial fluid, and urine are linked to starvation-induced ketoacidosis and metabolic acidosis. Depletion of hepatic glycogen stores with mobilization of free fatty acids from adipose tissue increases ketone synthesis in starvation (Lee et al. 2016). Ketoacidosis is also, however, occasionally observed in other forensic settings, such as uncontrolled diabetes mellitus, exposure to low temperature, and alcoholic ketoacidosis (Palmiere et al. 2016). Starvation causes hypoglycemia, so glucose and lactate levels may be determined in LCS or vitreous fluid. Lower range sum values of 50–80 mg/dl and 10–160 mg/dl, respectively, are seen in fatal hypoglycemia. Hyperglycemia and diabetic coma may also occur, with

glucose level greater than 362 mg/dl in LCS (Dettmeyer et al. 2013). A combined analysis of ketones, glucose, and HbA1c in blood and body fluids has been proposed to support diagnosis of metabolic disorders in malnutrition as cause of death (Chen et al. 2015).

Protocols: Differential Diagnosis

An emaciated appearance of the body and signs of neglect may be not enough to identify starvation. A full investigation must include findings from the investigation of the scene and history, postmortem assessment including laboratory testing, and histopathological, neuropathological, ophthalmological, and radiological analysis. The forensic pathologist must be open-minded about all reasonable causes of death and aware that many potential mimickers of neglect exist as causes of starvation. Several natural illnesses, especially cutaneous diseases, may mimic child neglect or physical and sexual abuse (e.g., hemangiomas, allergic contact dermatitis, mongolian spots, purpura) (AlJasser and Al-Khenaizan 2008).

Anorexia-Cachexia Syndrome is found in up to 80% of patients with advanced cancer. It presents with anorexia, weight loss, wasting of muscle and adipose tissue, hyperlipidemia, and other metabolic abnormalities, so can mimic neglect (Tattoli et al. 2012; Madea et al. 2016). All natural diseases that can result in emaciation (e.g., malabsorbitive syndromes, underlying protein losing, endocrine and metabolic imbalances, cystic fibrosis, hematological diseases, and many others) must be excluded by autopsy, skeletal survey, toxicology, and chemical and metabolic testing (Block and Krebs 2005; Madea et al. 2016).

Several genetic problems, sometimes underestimated, including chromosomal number disorders, microdeletion/duplication syndromes, uniparental disomy/methylation disorder, disorders of DNA repair, teratogens, metabolic syndromes, and skeletal dysplasias may also cause starvation (Rabago et al. 2015).

The potential presence of eating disorders must be evaluated, as these can lead to starvation (Seeman 2014).

In the first few weeks or months of life, an infant can have difficulties in breastfeeding and feed poorly, potentially showing a significant FTT, or even starvation and inanition, which can be mistakenly considered to be a result of neglect (Lawrence and Lawrence 2016).

Palmiere et al. (2016) evaluated several postmortem biochemical markers in body fluids (including glycated hemoglobin, glucose, adrenaline and metanephrine, ethanol, urea nitrogen, creatinine and uric acid, proteins, thyroid hormones and thyroglobulin, and ethyl glucuronide) to enable exclusion of common causes of increased blood ketone levels.

The hypothesis of starvation may be formulated only after a comprehensive review of findings from the investigation at the scene, medical and social histories (even though antemortem biochemical data are often unavailable), autopsy, histology, toxicology, and biochemistry. If the pathologist suspects starvation-induced hyperketonemia, toxicology and postmortem biochemistry can orient the diagnosis.

Dictionary of Terms

- **Child** – every human being below the age of 18 years
- **Clinical forensic medicine** – accurate evaluation of the physical condition of living victims and alleged perpetrators
- **Forensic pathology** – a branch of medicine whose aim is the investigation of deaths with medico-legal implications (criminal such as murder, rape, and assault, or civil such as traffic or work-related fatality)
- **Histological analysis** – microscopic study of specimen from body tissues under a light or electron microscope, after samples have been sectioned, stained, and placed on microscope slides
- **Investigation of the scene** – careful examination of the death scene and medical evaluation of trace evidence found at the scene

Summary Points

- Child starvation is common in war scenarios and in undeveloped countries, and it is rare in industrialized country.
- Deliberate starvation of an infant or child is a rare but severe form of child abuse.
- In fatal starvation cases, forensic investigation should include thorough autopsy findings, full investigation of the crime scene, and information including past medical records, family history, and social background.
- Physical examination in neglect and starvation cases aims to identify any inadequate or insufficient nutritional intake.
- Symptoms of starvation need to be addressed in a broad spectrum of nutritional disease.
- Estimating protein-energy malnutrition (PEM) can be helpful in distinguishing acute from chronic malnutrition.
- Clinical starvation findings may include skin, hair, and nails abnormality and impairment of almost all organ systems.
- Performing radiological surveys helps to gather additional evidences when suspicion for nonaccidental neglect arises.
- Autopsy, histological, and laboratory findings contribute in diagnosing the cause and the manner of death in child starvation.
- Forensic pathologist must be open-minded about to all reasonable possibilities of death occurrence and aware that many potential mimickers of neglect exist as causes of starvation.

Nutritional Consequences of Amyotrophic Lateral Sclerosis

52

Contents

Abstract

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disorder characterized by degeneration of the motor neurons in the brain, brain stem, and spinal cord. Clinically, there are dysphagia and dysarthria from bulbar involvement and muscle weakness with atrophy that result in profound and progressive weakness, respiratory failure, and death within 3 to 4 years from onset. Malnutrition is present in a substantial proportion of patients, with energy or caloric deficiency predominating. The malnutrition is of multifactorial origin, resulting not only from decreased energy intake but also from increased caloric expenditure related to physical activity and hypermetabolism. Several techniques detect malnutrition, ranging from simple anthropometry to the estimation of body composition to

define loss of muscle and body fat, indirect calorimetry to demonstrate increased resting energy expenditure, and doubly labeled water methodology to show increased total daily energy expenditure. Malnutrition has several adverse consequences, including accelerated disease progression and early death. This chapter describes an algorithmic approach to nutritional care in ALS, preferably undertaken through regular visits to a multidisciplinary clinic with staffed experienced healthcare providers. This chapter also provides recommendations for reliably estimating energy intake and expenditure needs of patients to ensure energy balance.

Introduction

Amyotrophic lateral sclerosis (ALS) (*Syn*: motor neuron disease, Charcot's disease) is a progressive neurodegenerative disorder of the aging population. The clinical manifestations, dysfunction, and disability in the disease result from degeneration of motor neurons in the spinal cord, brain, and brain stem with ensuing atrophy, fasciculation, and weakness of skeletal muscles from denervation. Concomitant spasticity in the oropharyngeal and limb muscles, due to corticospinal tract degeneration, adds to the morbidity in the disease (Van Damme and Robberecht 2013). The diagnostic criteria are well established and allow diagnostic classification of "definite," "probable," "laboratory-supported probable," and "suspected" cases. About 10% of cases with autosomal dominant inheritance harbor a mutation in the superoxide dismutase 1 (SOD1) gene (familial ALS, FALS), and in recent series, up

to 40% of patients in some regions have a mutation in the C9*orf*72 gene. Mutations involve several other genes in familial cases but are present in rare cases with apparent sporadic ALS (SALS). The incidence of the disorder is 1 – 2 cases/100,000 population, and the prevalence is 5 – 6 cases/100,000 population worldwide. The peak age of onset is in the sixth decade; it is almost twofold more common in men. Onset is insidious with limb muscle involvement in about 70 – 75% of cases and bulbar symptoms (dysarthria or dysphagia) in the remainder. Over time the weakness spreads to other body regions, usually in an orderly fashion, including to the oropharyngeal and respiratory muscles, while it continues to advance in muscles already involved. Death is from respiratory failure; the median survival is about 3–4.5 years from onset of weakness. Oropharyngeal and upper limb involvement limits the ability to handle food, in turn leading to progressive compromise of nutrition and hydration. Striking and often early and rapid loss of weight, usually accompanying dysphagia and malnutrition, is common but occurs in patients without dysphagia.

This chapter will discuss the frequency and causes of malnutrition, relevant studies in the literature, the consequences of energy imbalance, and an algorithmic approach to the evaluation and management of malnutrition in ALS patients.

Malnutrition

Malnutrition is common in ALS patients during the course of the disease. The nutritional deficiency resembles marasmus, a state of caloric deficiency, which commonly results from starvation in other parts of the world especially under conditions of war or famine. Protein-to-calorie intake, however, is unimpaired in ALS. Diminished caloric intake is mainly due to dysphagia resulting from bulbar muscle involvement with resultant impaired bolus formation, difficulty in chewing, and increased propensity for choking with aspiration.

Dysphagia is by far the single most important reason for nutritional impairment and is present relatively early in bulbar than limb-onset ALS due to swallowing dysfunction; with disease progression, it eventually affects almost 75% of patients. Advanced dysphagia is a result of difficulty in chewing and impaired bolus formation; it is associated with prolonged and effortful mealtimes and fear of coughing and choking which all result in decreased food and fluid intake. Anorexia affects many patients with ALS, often with dyspnea and contributes to reduced dietary intake with subsequent weight loss (Jesus et al. 2012). Compounding the effect of dysphagia on nutritional intake are feeding problems due to depression; weakness of the limbs with impaired dexterity and mobility that cause loss of independence; respiratory compromise; cognitive, behavioral, and psychological impairment; and lack of caregiver availability or willingness to help. The combination of these factors leads to difficulties with food preparation, consumption, and ultimately dependence on caregivers. Factors associated with malnutrition are also responsible for dehydration seen in the disease.

Prevalence of Malnutrition and Assessment Techniques

The prevalence and severity of malnutrition vary with the site of onset and stage of the disease, being more common in bulbar-onset patients and in those with advanced disease. The reported prevalence in different studies depends on the method used to study nutritional compromise (Table 1). Nutritional evaluation in ALS has generally adopted several approaches, sometimes in parallel. These include the following assessments:

1. Weight or body mass index (BMI) changes from the premorbid state at the initial visit and after diagnosis.
2. Body composition measured by anthropometry, bioelectrical impedance analysis (BIA)/bioelectrical impedance spectroscopy (BIS), or dual-energy x-ray absorptiometry (DEXA).
3. Daily energy (caloric) intake estimated by dietary analysis.
4. Daily energy expenditure from measured resting energy expenditure or basal metabolic rate.
5. Total daily energy expenditure (TDEE), a reliable surrogate for caloric requirement in humans, measured employing the doubly labeled water (DLW) method.

Based on the method employed, malnutrition is identified in 6% to 100% of patients at the time of first evaluation.

Studies of Nutritional Compromise

Loss of Weight or BMI

Weight

Several studies have examined weight loss and its prognostic value in ALS patients (Table 2). Weight loss is reported in 30 – 85% of patients, being more common in women, with bulbar-onset disease (although it is seen without bulbar involvement), and in advanced disease (Meininger et al. 1995; Korner et al. 2013). The mean loss ranges from 2% to 24% and may be a function of age, duration of disease and follow-up, rapidity of progression, and topography of involvement. The degree of weight loss and the proportion of patients with loss range from >5% in 12 – 50% to 10% in 36 – 48%, >15% in 55%, and >20% in 25% in different series. In general, weight loss of 5–10% from premorbid state is deemed significant for nutritional intervention; cachectic patients typically show loss of >20% of body mass. One study found weight loss to be similar in different BMI groups (Paganoni et al. 2011); in another, there was no difference in loss between normometabolic and hypermetabolic patients (Bouteloup et al. 2009). Weight loss correlates with ALSFRS-R scores and respiratory function, particularly in limb-onset patients. Generally, loss of FFM precedes depletion of FM that might even increase initially (Vaisman et al.

2009) as muscle loss progresses; in one study, loss of FFM and FM was greater in men (Kasarskis et al. 1996). Malnutrition and denervation cause loss of weight, skeletal muscle, and body fat and account for cachexia of the disease and impair muscle function.

Low body weight and leanness in the premorbid state increase the risk of developing ALS by almost threefold (Gallo et al. 2013). Weight loss from the premorbid state, and after diagnosis, can predict survival. At diagnosis, greater weight loss is a predictor of death over the next year; the adjusted risk of death increases by 30% for 5% loss and 45% for ≥10% loss. After diagnosis, the adjusted risk of death increases by 34% for each 5% loss, and for each 2.5 kg higher FFM, the survival increases by 10% (Marin et al. 2011).

BMI

BMI (weight [kg] ÷ √ height^2 [m]) (kg/m^2) is easily measured and has been utilized in several studies of malnutrition in ALS (Table 2). The World Health Organization classifies subjects according to BMI as follows: < 20, malnourished; 20 – <25, normal; 25 – <30, overweight; 30 – <35, obese class I; 35 – <40, obese class II; and 40 or >, obese class III. In other classification systems, a BMI of <18.5 kg/m^2 if age is ≤65 year, or <20 if age is >65 year, denotes malnutrition (Desport et al. 2000). ALS patients showing malnutrition by other indicators, or those requiring gastrostomy, generally show lower BMI (Mazzini et al. 1995; Kasarskis et al. 1999).

Low premorbid BMI carries an increased risk of developing ALS (Gallo et al. 2013). Further, the premorbid BMI reduction rate correlates with total disease duration in some but not all studies and with survival as assessed by the hazard ratio (HR) or relative risk (RR) for death (Table 2). The risk of death increases by 16–24% for each unit of premorbid BMI lost.

In general, malnutrition by BMI criteria at diagnosis occurs in 6–53% of patients and correlates with a general nutritional risk index and respiratory parameters, but not in all studies (Table 3). Other studies show no correlation between BMI and site of onset (bulbar versus limb), neurological disability, measured resting energy expenditure, presence of hyper metabolism, and time to transition from possible/probable to definite ALS by El Escorial criteria. The risk of death is 2.2–7.4-fold higher in patients malnourished at presentation (Desport et al. 1999; Marin et al. 2011; Paganoni et al. 2011), but not in all studies (Shimizu et al. 2012). Several studies report a U-shaped relationship between BMI at first visit and progression of disease as assessed by a decline in the ALS functional rating scale-revised (ALSFRS-R) score or survival, with the best outcome in class I obese patients and the worst in those with malnutrition or class III obesity. In patients with BMI <30 kg/m^2, a higher BMI is associated with slower decline of ALSFRS-R scores (Reich-Slotky et al. 2013). The progression of ALS is about 1/3 slower, and survival is longer, if follow-up BMI is stable or increases by >1 unit versus declines by 1 unit. Conversely, a faster decline of BMI over 2 years portends faster disease progression and lower survival (Jawaid et al. 2010; Shimizu et al. 2012). Malnutrition at the time of insertion of a percutaneous endoscopic gastrostomy (PEG) tube also shortens survival.

Table 3 Studies of change from premorbid body mass index in amyotrophic lateral sclerosis

Reference	Country, # patients	Premorbid BMI	BMI at first visit (kg/m2)	Follow-up (months)	BMI at follow-up (kg/m2)	BMI change (kg/m2)	Comments
Limousin et al. (2010)*	France, 63	25 ± 4 (24 m prior to diagnosis)	24 ± 4	21	22 ± 6	↓ by 2 units	BMI change 2 years premorbid to diagnosis ↑ by 1.0 unit, to final visit ↓ by 3.3 units If premorbid weight loss >10%, BMI ↓ 3.8 at diagnosis and 5.2 at final visit No correlation between BMI or BMI change and disease duration

*BMI < 18.5, **BMI <18.5 if age <70 year, <21 if age ≥ 70 year, *** Median (Q1, Q3)

The inconsistency in the BMI criterion defining nutritional deficiency probably accounts for the wide ranges reported in the prevalence of malnutrition. Further, BMI cannot differentiate between lean and fat components of soft tissue, both of which are affected. For example, BMI did not suggest malnutrition in 70% of patients who were malnourished by other anthropometric criteria (Worwood and Leigh 1998). Caloric deficiency by the DLW method occurred in 10 ALS patients, none of whom had a BMI <20 kg/m^2 (Tandan 2000). Thus, reliance on BMI alone for diagnosing and following undernutrition in ALS is a questionable practice.

Alterations in Body Composition

Skin Folds and Circumferences

Many researchers have developed and validated equations from skinfolds, body circumferences and ratios from different anatomical regions in healthy subjects to estimate body density, and subsequently body fat and fat-free mass, to assess body composition and gleam the nutritional state (Kasarskis et al. 1996; Nau et al. 1997). Several investigators have measured triceps skinfold (TSF) thickness and mid-arm circumference (MAC) to derive mid-arm muscle circumference (MAMC), thus enabling estimation of arm muscle area (AMA), fat mass, and muscle mass to allow determination of age-gender percentiles as compared to normal populations (Table 4). AMA with other indices of muscle mass and disease progression also permit monitoring of muscle atrophy, in addition to establishing the nutritional state (Kasarskis et al. 1997). Generally, anthropometry overestimates FFM and underestimates FM in ALS as compared to DEXA-measured values (Nau et al. 1997).

Moderate malnutrition (TSF below 30th percentile) occurs in 15% and severe malnutrition (TSF below 24th percentile) in 10% of patients, although in 70% dietary inquiry reveals decreased caloric intake compared to RDA values (Slowie et al. 1983). There is a 41% reduction of AMA, denoting loss of muscle, over 50 months prior to death (Kasarskis et al. 1996), and no significant relationship to presence of dysphagia, as reported by others (Jesus et al. 2012). In the United Kingdom (UK), malnutrition (at least one anthropometric measure below the fifth percentile) occurred in 21% of patients irrespective of site of onset, but reduced daily caloric intake as compared to the UK standard was present in all (Worwood and Leigh 1998). Moderate malnourishment by protein-caloric malnutrition scores (PCMS) is evident in Argentinian patients, again unrelated to site of onset (Silva et al. 2008). Increased TSF thickness, an indicator of FM, is also associated with improved survival; in one study, each unit of higher TSF carried a survival advantage of 6% over 28 months of follow-up (Marin et al. 2011).

BIA and BIS

By measuring the resistance, conductance, and impedance of body tissues, single and multiple frequency BIA and BIS estimate body composition and phase angle to assess the nutritional state (Desport et al. 2003; Vaisman et al. 2009) (Table 5). BIS also evaluates the hydration status by measuring total body water and extracellular fluid (ECF) volume and subsequently extrapolates intracellular fluid (ICF) volume.

*=Mean ± SEM, + = Median (inter quartile range)

Generally, FFM and FM are lower in ALS patients than in healthy controls, particularly in those with relatively advanced disease on noninvasive ventilation (NIV) or mechanical ventilation (MV) (Ellis and Rosenfeld 2011), and decrease as the disease progresses. Phase angle (PA) is lower in ALS, especially in malnourished patients, and adversely affects survival (Desport et al. 2005, 2008; Marin et al. 2011). Body composition and hydration status affect survival; thus, each 2.5 unit higher FM has a survival advantage of 10%, and each 0.2 unit increase in ECF/ICF ratio has a favorable survival effect of 67% (Marin et al. 2011).

DEXA

The technique employs electron beams to produce x-rays containing photons, which demonstrate low- and high-energy peaks when passed through a cerium photon "K-edge" filter. Passing through the body causes differential attenuation of the photons dependent upon the mass attenuation coefficient of the tissue – the ratio of attenuation of the two energy peaks describes the tissue property and allows measurement of the mass of three principal body components: fat, bone mineral, and fat-free (lean) soft tissue. The DEXA system acquires and the software analyzes a pixel image of the body components and solves for two components in each pixel: fat and fat-free tissue and bone minerals.

Body composition studies show decreased FFM and FM in ALS patients compared to healthy controls in cross-sectional analyses (Table 5). With progressive disease, there is a 2.0 kg decline over 6 months (Nau et al. 1995); others have noted 5–23% decrease over 6–10 months. This FFM loss is largely due to denervation-induced muscle atrophy (Kasarskis et al. 1996; Desport et al. 2003; Bouteloup et al. 2009; Vaisman et al. 2009), with additional contribution from malnutrition.

Body fat percentage is higher in women with ALS, as in the healthy state. In early or mild disease, when nutrition is relatively unaffected, FM may initially increase by 1–10% during 6–28 months of follow-up as FFM declines (Nau et al. 1995; Bouteloup et al. 2009; Vaisman et al. 2009; Marin et al. 2011). As the disease progresses and nutrition compromises, FM declines by 5–10% over 11–50 months of observation (Kasarskis et al. 1996; Desport et al. 2005, 2008).

Deficiency of Energy Intake

Dietary assessment by the retrospective 24-hour recall or the prospective 3-day food diary estimates daily caloric intake (Kasarskis et al. 2014) using appropriate software; the intake is compared to the recommended daily allowance (RDA) or some other national standard (Kasarskis et al. 1996, 2014; Worwood and Leigh 1998) (Table 6). In patients with early disease without dysphagia, respiratory compromise, or nutritional supplementation, daily caloric intake by the 3-d food diary is similar to that in age- and gender-matched healthy controls (Tandan 2000). In a subsequent study from the United Kingdom, 24-h caloric intake in ALS patients and younger healthy controls was similar (Worwood and Leigh 1998). In contrast, a previous study that included patients with gastrostomy or advanced disease found caloric deficiency by 24-h recall in up to 70% of patients (Kasarskis et al. 1996). In general, some studies report 28–54% lower caloric intake in ALS patients compared to

healthy controls or national standards from several countries; protein intake is relatively normal (Table 6).

In some studies, reduced caloric intake correlates with weight loss and decreased TSF thickness, but not with the presence of dysphagia (Worwood and Leigh 1998; Kasarskis et al. 1996). Recently, no significant difference in caloric intake by 3-d diary was found between bulbar- and limb-onset patients or in patients without or with dysphagia (Kasarskis et al. 2014). Caloric intake is not different between BMI groups (Kasarskis et al. 2014), is higher if hypermetabolism is present (Bouteloup et al. 2009), and progressively decreases by tertiles of ALSFRS-R score (Park et al. 2015). Increased severity of change in eating behavior in ALS-FTD, leading to higher caloric intake, is associated with longer survival (Ahmed et al. 2016).

The use of 24-h intake provides a cheap, convenient, and easy method of assessing caloric intake. Further, intake from 24-h recall and 3-d food diary is not significantly different, thus validating the use of the 24-h recall method to assess intake (Tandan 2000). However, there are several caveats in using the 24-h method for assessing caloric intake: recording intake is prone to recall bias, depends on patient cooperation, can alter eating behavior, and can be imprecise, particularly when caregivers are doing the reporting, as is often the case with many ALS patients.

Enhanced Energy Expenditure

Energy Expenditure Estimated from Harris-Benedict Equation

The Harris-Benedict (H-B) equation is widely used by dieticians to calculate caloric needs in healthy subjects and in disease states (Harris and Benedict 1918). It takes into account gender, age, and height of the subject to calculate resting energy expenditure (REE) in kcal/d; using a factorial approach, the REE value is multiplied by a factor corresponding to the physical activity level of the subject to derive daily caloric requirement. This method does not account for differences in body composition and physical activity levels of subjects, which can be considerable in ALS patients and cause prediction errors. Daily caloric requirement estimated by the H-B equation is imprecise compared to TDEE measured by the gold standard DLW method, with a mean underestimation by 1475 kcal/day or overestimation by 990 kcal/day (Kasarskis et al. 2014) in patients from the USA; underestimation by 244 kcal/d is also noted in Japanese patients (Shimizu et al. 2017). Using a correction factor that accounts for disease severity improves the predictability of the modified H-B equation, resulting in a mean difference of <30 kcal/d (Kasarskis et al. 2014; Shimizu et al. 2017).

Measured and Calculated Resting Energy Expenditure

Several studies have compared the calculated REE (cREE) using the H-B equation with REE measured by indirect calorimetry (measured REE or mREE) using the ventilated hood technique after an overnight fast (Kasarskis et al. 2014) to examine the metabolic state in ALS patients (Table 7); an mREE/cREE ratio of >1.1 denotes hypermetabolism (Desport et al. 2001). Using this method, absolute mREE is higher in ALS patients with early disease as compared to age- and gender-matched healthy

controls (Tandan 2000). In the progressive phase of the disease, mean mREE/cREE ratios of >1.1 are reported in 57–67% of patients with SALS and all patients with FALS. Some researchers (Kasarskis et al. 1996), but not all (Desport et al. 2001), noted a negative correlation between mREE and FVC in proximity to death, implying that effortful breathing from falling FVC could also account for the high mREE/cREE ratio. The fact that the use of NIV in the resting state decreases mREE by an average of 7% (Georges et al. 2014) would confirm at least a partial role for increased respiratory effort in producing hypermetabolism. Other investigators, however, have not found hypermetabolism in ALS patients as compared to matched controls from estimates of the mREE/cREE ratio (Vaisman et al. 2009). In patients with advanced or terminal disease who are immobile, with a PEG tube and on MV, the mREE/cREE ratio becomes <1.0, indicating that these patients are no longer hypermetabolic. In some such patients, the TDEE approximates mREE values (Ichihara et al. 2012; Kasarskis et al. 2014).

Energy Expenditure Measured by Doubly Labeled Water

The DLW technique directly measures TDEE in free-living humans over a 10–14-day period (Kasarskis et al. 2014). Few studies have measured TDEE along with simultaneous estimates of caloric intake and body composition (Tandan 2000; Ichihara et al. 2012; Kasarskis et al. 2014; Shimizu et al. 2017). An earlier study found TDEE up to 30% higher in ambulatory ALS patients with early disease as compared to age- and gender-matched healthy controls (Tandan 2000). The mean TDEE was 339 kcal/d higher in patients than in controls; about 2/3rds of the difference was due to increased caloric use during physical activity and the rest due to hypermetabolism (Tandan 2000). TDEE exceeded daily caloric intake by 24-h recall and 3-d food diary in 90% of patients by a mean of 371 kcal/d indicating negative caloric balance.

In Japanese patients with advanced disease, very low FFM, and nutritional and ventilator support, negative caloric balance occurred in 20%, despite PEG feeding (Ichihara et al. 2012). In the largest DLW study to date in ALS, 73% of patients exhibited negative caloric balance; the mean caloric deficit was 430 kcal/d in men and 466 kcal/d in women. Risk factors for negative caloric balance were lower caloric intake, and higher FVC and TDEE, including an almost fourfold higher physical activity-associated caloric expenditure (Kasarskis et al. 2014). In Japanese patients not using assisted ventilation, 58% showed negative caloric balance (Shimizu et al. 2017). The median daily caloric intake was lower in patients with PEG; TDEE per body weight was higher in patients compared to the healthy Japanese population (Shimizu et al. 2017).

Thus, up to 75% of ALS patients can be in negative caloric balance, particularly in early or progressive phases of the disease, while ambulation is possible. Later in the disease, as nutrition through a PEG and ventilator assistance are required, caloric requirements decline. Greater caloric needs in early ALS are largely due to increased caloric use during physical activity, with a hypermetabolic state contributing particularly as the disease advances. Appropriate nutritional evaluation and management

are therefore paramount and need implementation with other therapies throughout the disease course.

Energy Balance in ALS

Energy homeostasis results from balance of energy intake and energy expenditure. In healthy subjects, the glucose-insulin axis that is intrinsically linked to glucose and lipid metabolism controls energy intake. Energy intake is in balance with basal and activity-dependent energy expenditure, thus leading to stable energy stores, mostly in the form of triglycerides in adipocytes, and a stable BMI (Fig. 1).

Energy Intake

In ALS, energy homeostasis is impaired from a combination of decreased energy intake and increased energy expenditure (Fig. 2). The decreased energy intake as compared to requirements is multifactorial, as discussed previously, and varies between patients due to topographical and disease severity factors (Fig. 3). Another factor with potential effects on the nutritional state in ALS is insulin resistance (Lekoubou et al. 2014). Energy homeostasis depends on the uptake of nutrients,

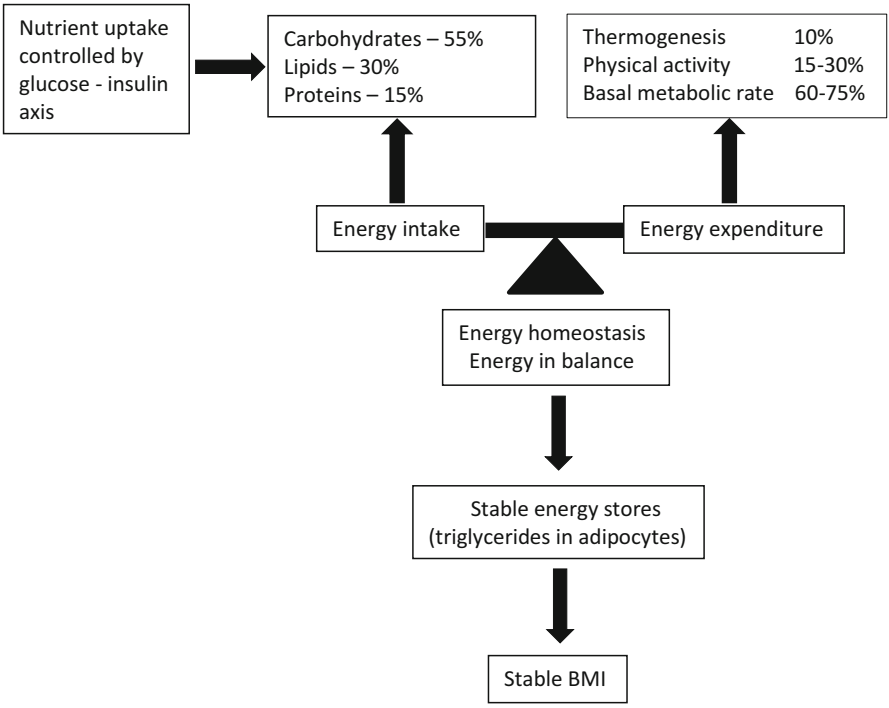

Fig. 1 Energy homeostasis in the healthy state

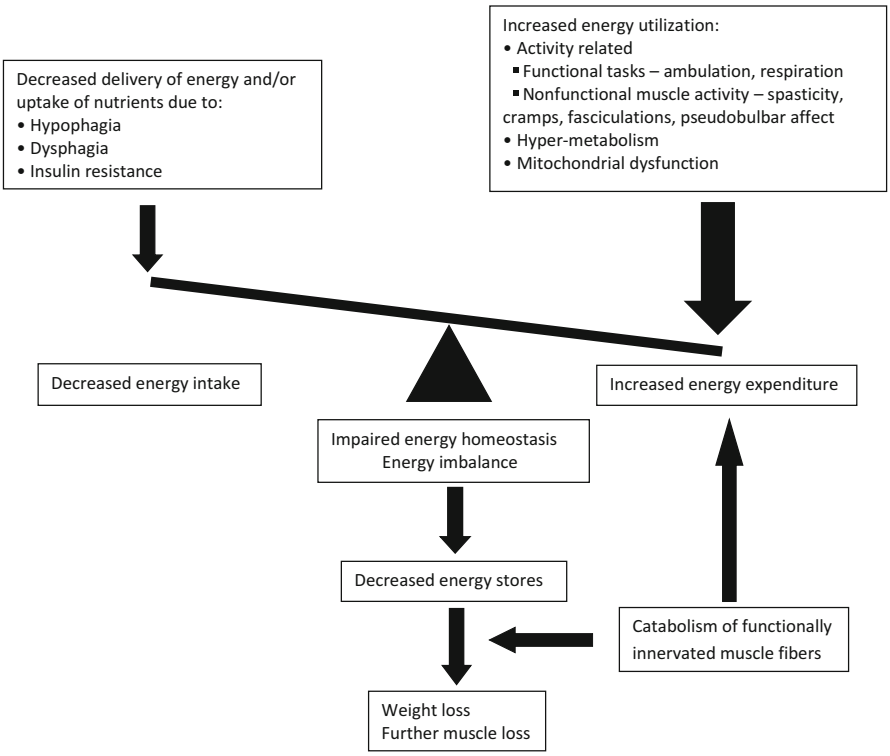

Fig. 2 Energy homeostasis in ALS

including glucose and lipids, controlled by the glucose-insulin axis. Whether the increased prevalence of diabetes and insulin resistance drives the neurodegeneration, or has a neuroprotective effect, remain to be determined.

Energy Expenditure

Compounding the reduced energy intake is the increased energy use due to hypermetabolism (Desport et al. 2005; Muscaritoli et al. 2012), during labored physical activity (Tandan 2000; Kasarskis et al. 2014) and presumably during non-ambulatory muscle use such as with emotional lability, cramps, and fasciculations to overcome spasticity (labeled non-exercise activity thermogenesis or NEATS). Factors potentially causing hypermetabolism include sympathetic over activity, mitochondrial dysfunction, and infections such as aspiration pneumonia; these can potentially exacerbate malnutrition and sarcopenia (Figs. 2 and 3).

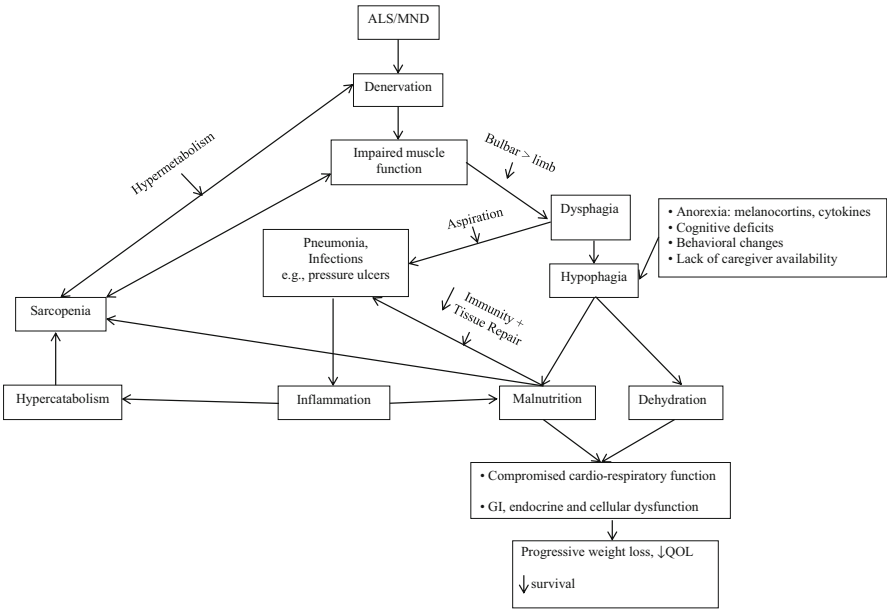

Fig. 3 A schematic representation of the vicious circle of clinical deterioration seen in ALS. See text for details

Consequences of Energy Imbalance and Malnutrition in ALS

Impaired energy homeostasis due to decreased energy intake, increased energy expenditure, or both leads to chronic energy deficiency. This poses excessive metabolic demands and has a catabolic effect on remaining functionally innervated muscles to maintain tasks such as mobility and ventilation, thus further aggravating energy expenditure (Fig. 2). The neuronal degeneration and its consequences result in loss of weight, FFM, and eventually FM, with muscle weakness and atrophy (sarcopenia) and negative consequences on muscle function, including of the diaphragm. Additionally, there is fat redistribution causing loss of subcutaneous and increased abdominal fat that initially correlate with functional status and survival and later explain the proclivity to insulin resistance and hypercholesterolemia (Lindauer et al. 2013).

Malnutrition also links to a series of detrimental consequences, which aggravate the underlying condition in ALS by setting off a vicious cycle of further clinical deterioration (Fig. 3). Dysphagia and multifactorial hypophagia lead to malnutrition, which depresses immunity and impairs tissue repair that make patients susceptible to infections. This sets off an inflammatory response, contributing to excessive energy expenditure that further impairs energy homeostasis, one of the many reasons for the hypermetabolic state. This completes the vicious cycle by worsening sarcopenia. There are multiple interrelated aspects in this cycle: *malnutrition*, largely contributed

by dysphagia; *infections*, most commonly aspiration pneumonia; *inflammation*, which produces a hypermetabolic state and impairs substrate utilization which worsens malnutrition; *denervation-induced sarcopenia*, which is worsened by hypermetabolism and malnutrition; and lastly the two-way relationship between sarcopenia and impaired muscle function.

There are several other potential adverse consequences of malnutrition, in general (Sheard 2014). These include compromised respiratory and cardiovascular functions and endocrine dysregulation that decreases T4 and T3 levels, increases reversed T3 levels, and suppresses gonadotrophins leading to reduced testosterone, estrogen, and progesterone levels. Gastrointestinal dysfunction causes changes in pancreatic exocrine function, intestinal blood flow, villous morphology, and intestinal permeability. General cellular dysfunction results from downregulation of Na^+/K^+ ATPase activity. The clinical consequences of these alterations are fatigue, increased risk of pressure ulcers, poor wound healing, weight loss, and indeed faster disease progression with reduced survival (Desport et al. 1999; Marin et al. 2011).

Metabolic Impairment in ALS

Neural mechanisms and pathways underlying the metabolic impairment in ALS remain elusive. Recent data suggest that perturbations in the hypothalamic melanocortin pathway controlling food intake, energy expenditure, and weight control may be relevant (Fig. 4). The anorexigenic pathway involves release of leptin from adipose tissue, which acts on pro-opiomelanocortin (POMC) and cocaine-related and amphetamine-related transcript (CART) neurons in the hypothalamus. POMC undergoes posttranslational modification to produce peptides such α- and β-melanocyte-stimulating hormone (α- and β-MSH) which act on the MCR3 and MCR4 melanocortin receptors in the paraventricular nucleus (PVN), leading to a decrease in food intake. The orexigenic appetite-stimulating pathway is controlled by the release of ghrelin peripherally, which targets neurons of the arcuate nucleus (ARC) in the hypothalamus that contain neuropeptide Y (NPY) and agouti-related peptide (AgRP); the latter promotes food intake by antagonism of MCR3 and MCR4 receptors.

The failed clinical trial with pioglitazone, an oral antidiabetic agent, when added to riluzole therapy (Dupuis et al. 2012) showed decreased hyperglycemia and liver enzyme levels and increased circulating adiponectin peripherally in ALS patients (Vercruysse et al. 2016). However, a central effect on weight gain mediated through inhibition of the hypothalamic melanocortin system, as reported in prior clinical trials, was lacking. Reduced POMC-positive neuronal counts, and increase in density of AGRP fibers in the hypothalamic arcuate nucleus of multiple transgenic rodents (including SOD1, G86R, TDP-43, and FUS models) carrying human gene mutations, support selective involvement of the melanocortin system. The melanocortin defect is primarily caused by loss of serotonin, a major activator of POMC neurons through the 5HT2C receptor (Wang and Chehab 2006); markers of other stressors which could affect POMC neurons, including oxidative stress,

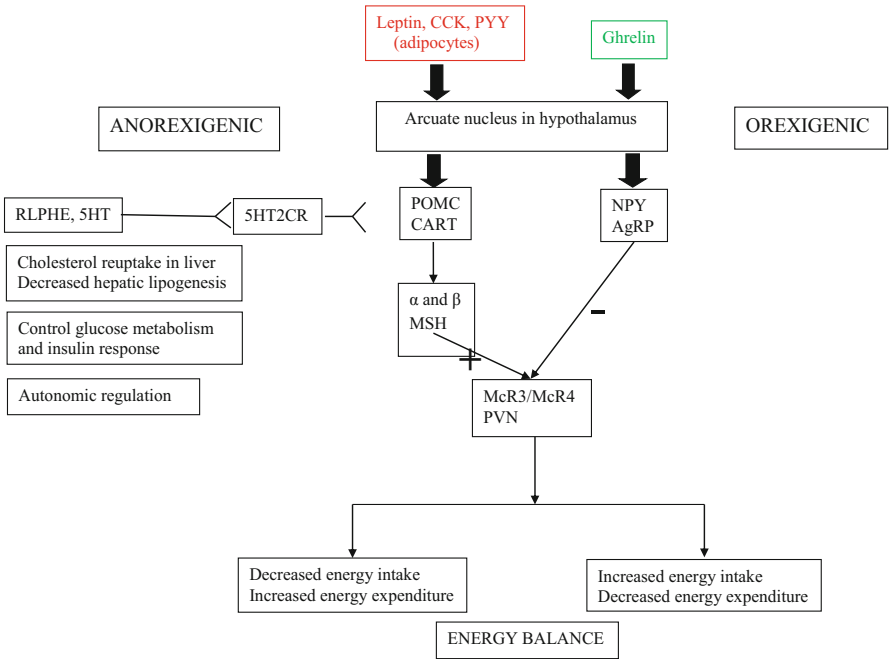

Fig. 4 Central pathways modulating energy intake and expenditure

endoplasmic reticulum stress, defective peroxisome biogenesis, or mitochondrial abnormalities, did not account for the decreased POMC neuronal counts. Nevertheless, other central or peripheral mechanisms of weight loss in human ALS need definition, as the POMC deficiency resulting from the melanocortin defect triggers an increased orexigenic drive to produce a compensatory increase in food intake.

The observed melanocortin defect could potentially explain alterations in other peripheral metabolic pathways in ALS patients. The melanocortin system is important in controlling glucose metabolism and insulin response (Obici et al. 2001), and in regulating peripheral lipid metabolism, by activating cholesterol reuptake in the liver (Perez-Tilve et al. 2010) and reducing hepatic lipogenesis (Leckstrom et al. 2011). Therefore, the observed increased circulating cholesterol (Dupuis et al. 2011) and glucose intolerance in ALS are explained by the melanocortin defect. Moreover, impaired regulation of the autonomic nervous system (Sohn et al. 2013) by the melanocortin defect also explains the dysautonomia sometimes seen in ALS patients (Baltadzhieva et al. 2005).

Taken together, the combined clinical and experimental evidence provides a mechanistic explanation for abnormalities of food intake and weight control in ALS patients. Importantly, these results also show that ALS progression impairs responsiveness to classical drugs, thus leading to weight gain. This has important implications for the pharmacological management of weight loss in ALS, in addition to nutritional supplementation in the disease.

Policies and Protocols

Protocols for Nutritional Management of ALS

In view of the grave consequences of malnutrition and its association with increased morbidity and mortality, nutritional care of patients with ALS is undoubtedly an important element of disease management. The aims of nutritional management are to maintain energy (calorie) balance by optimizing intake and to minimize the effects of weight loss, by both preventative intervention and rehabilitation of weight loss. These goals are best achieved by caring for patients in multidisciplinary clinics with an experienced team of healthcare personnel. Specifically, for nutritional management, patients should undergo regular neurological, nutritional/dietary, and speech and swallowing evaluations. This testing should occur at the time of diagnosis, and then at least every 3 months and occasionally more often, depending on the nutritional status and/or rate of disease progression.

Each clinic visit should include recording of weight, height, and body mass index (BMI) and collection of data from 24-h dietary intake. In addition, assessment of the nutritional state by using other methods should be undertaken, if appropriate equipment is available. Collecting anthropometric data using a Harpenden caliper or measuring tape is simple and cheap to undertake and widely used. TSF is the skinfold thickness most commonly used to assess percent body fat and then derive FM and FFM. When other skinfolds or circumferences are measured, equations published for use in healthy subjects are used. Despite its simplicity, some limitations of anthropometric data include the lack of precision due to asymmetric neurogenic atrophy or uneven fat distribution, dependent edema caused by immobility, inability to accurately distinguish components of body composition (FM and FFM), and the fact that these equations are not validated in ALS.

Other techniques used to measure body composition include BIA, BIS, and DEXA (Desport et al. 2003); BIS also assesses hydration status. However, these methods have some limitations; while BIA and BIS are simple, portable, noninvasive, and inexpensive and are validated in ALS, asymmetrical muscle involvement from denervation influences data. DEXA, while ideal for body composition assessment to differentiate FM from FFM and bone mass (Kanda et al. 1994; Nau et al. 1995, 1997), has limited clinical utility because of high cost, technical difficulties in patients who cannot lie flat, and cannot be used in homebound patients.

Laboratory tests assess the nutritional status, as some correlate with disease progression and survival in ALS. These include serum albumin, prealbumin, total leukocyte count, hemoglobin, magnesium, calcium, phosphorous, serum zinc and copper, retinol-binding protein, creatinine height index, uric acid, lipid profile, and APOE (Lacomblez et al. 2002; Chiò et al. 2014). The relevance of these biochemical indices is not certain in the clinical care of ALS patients. When performed, correlation with other traditional markers of malnutrition should be undertaken; longitudinal studies are required to understand their significance as nutritional markers.

Policies for Nutritional Management of ALS

Energy balance is assessed by utilizing a validated and practical equation, which is a modification of the H-B equation with additional factors relating to disease severity (ALSFRS-6) (Kasarskis et al. 2014). This requires the following actions to be undertaken sequentially:

(1) At home: patient or caregiver will record 24-hour food intake in diary prior to clinic visit.
(2) In the clinic: dietitian will review the 24-h food diary to calculate energy intake using appropriate software.
(3) In the clinic: personnel will obtain ALSFRS-6 score on patient.
(4) In the clinic: dietitian will estimate TDEE using the ALSFRS-6 modification of the H-B equation (Kasarskis et al. 2014).

A web-based calculator, based on the ALSFRS-6 modification of the H-B equation, is available at https://mednet.mc.uky.edu/alscalculator.

The ALSFRS-6 score is the total score of six questions from the ALSFRS-R questionnaire (each rated from 4 = normal to 0 = cannot do; normal score = 24):

Questions 1 (speech), 4 (handwriting with dominant hand as compared to prior to ALS), 6 (dressing and hygiene), 7 (turning in bed and adjusting bed clothes), 8 (walking), and 10a (dyspnea).

The H-B equation and the ALSFRS-6 modification of the H-B equation are below:

H-B equation for men:

Basal metabolic rate (kcal/d) = 66 + (6.23 × weight in pounds) + (12.7 × height in inches)−(6.76 × age in years)

H-B equation for women:

Basal metabolic rate (kcal/d) = 655 + (4.35 × weight in pounds) + (4.7 × height in inches) – (4.7 × age in years)

ALSFRS-6 modification of H-B equation:

TDEE = BMR from H-B equation (kcal/d) + (55.96 × ALSFRS-6 score)− 168 (kcal/d)

A practical example of calculation of TDEE using the ALSFRS-6 modification of the H-B equation is as follows:

Age: 60-year-old ALS patient
Sex: Male
Weight: 180 lbs

Height: 5′ 10″ (70″)
Moderate weakness in upper extremities
ALSFRS-6 score: 19 of 24
Speech: 4
Handwriting: 2
Dressing: 2
Turning in bed: 3
Walking: 4
Calculate Harris-Benedict BMR

$$\text{BMR (kcal/d)} = 66 + (6.23 \times 180 \text{ lbs.}) + (12.7 \times 70'') - (6.76 \times 60 \text{ years}) = 66 + 1121 + 889 - 406 = 1670$$

Adjust for ALS functional status

$$(55.96 \times 19) - 168 = 1063 - 168 = 895 \text{ kcal/d}$$

Calculated TDEE = 1670 kcal/d + 895 kcal/d = 2565 kcal/d

If the combination of these assessments suggests a negative energy balance (daily caloric intake < TDEE), especially during the early stages of the disease, several strategies exist to maintain nutrition in patients who can safely swallow. These involve dietary advice, food fortification with oral nutritional support and prescription of high-caloric supplements, support with safe-swallowing techniques and adaptive eating utensils, and modification of diet texture (Fig. 5).

If these dietary modifications cannot ensure adequate nutrition, then positive energy balance cannot be restored, and significant weight loss progresses making artificial nutrition essential (Shimizu et al. 1991; Kasarskis et al. 2014) (Fig. 6). Artificial nutrition is implemented if weight loss ≥5–10% from premorbid weight, or BMI is <18.5 kg/m^2 if age is 18–65 years and <20 kg/m^2 if age is >65 years

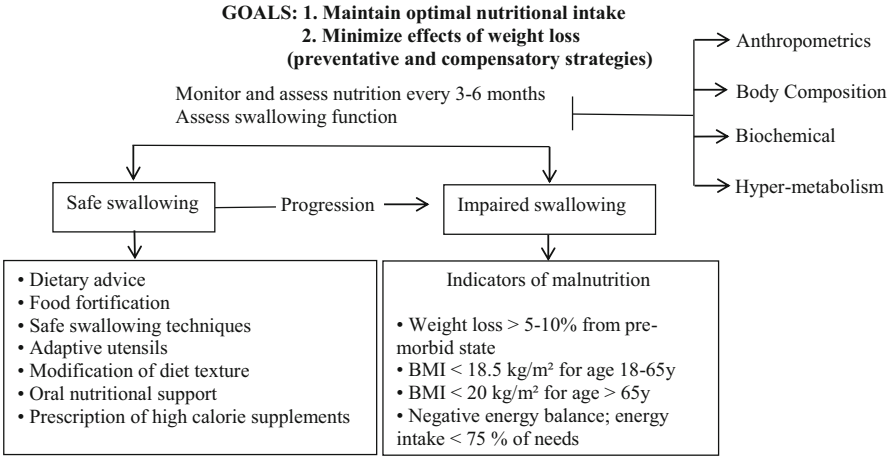

Fig. 5 Suggested algorithm for nutritional care in ALS

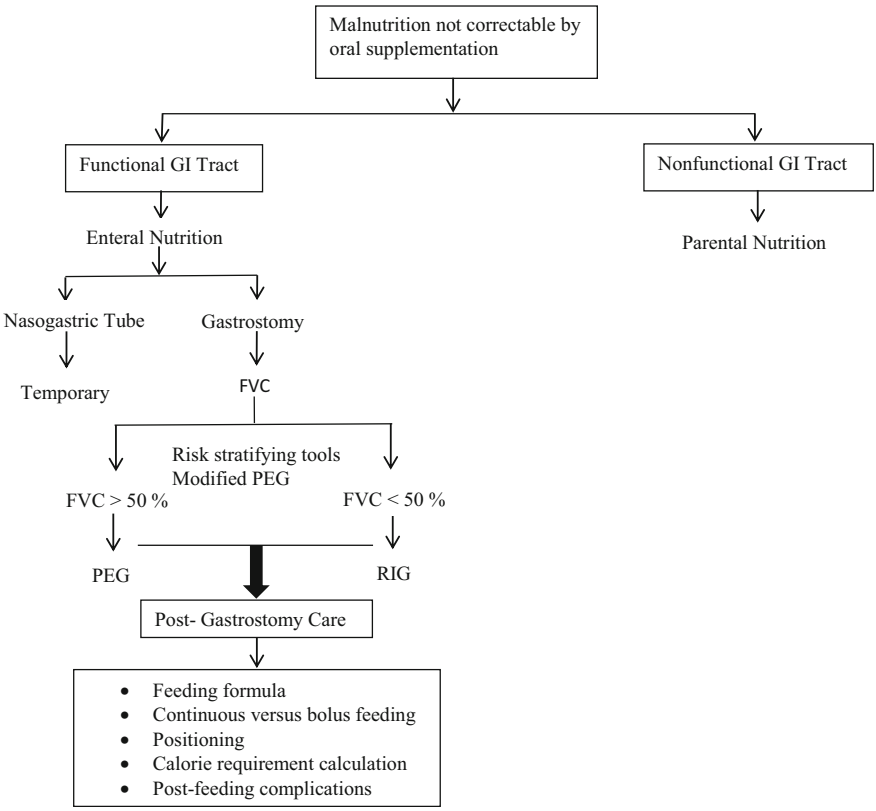

Fig. 6 Suggested algorithm for enteral feeding in ALS

(Desport et al. 2000), or there is persistent negative energy balance, defined as energy intake of <75% of energy needs. For patients who have a functional gastrointestinal tract, enteral tube feeding (ETF) can be delivered either via nasogastric tube (NGT) or gastrostomy insertion, the latter being the recommendation by the American Academy of Neurology (AAN) (Miller et al. 2009) and the European Federation of Neurological Societies (EFNS) (EFNS Task Force on Diagnosis and Management of Amyotrophic lateral Sclerosis 2012).

NGT feedings are indicated only for short-term nutritional support due to the high risk of aspiration, propensity for increasing oropharyngeal secretions, nasopharyngeal discomfort or even ulceration, and social embarrassment. Parenteral nutrition (PN) is rarely indicated in ALS patients and can be considered when consent to ETF is denied or ETF is contraindicated; or there is an inability to access or use the gastrointestinal tract due to malabsorption, dysmotility, or enterocutaneous fistulas. Nasogastric or nasojejunal feeding is not appropriate for long-term ETF due to

Table 8 Comparison of PEG and RIG procedures

	PEG	RIG
FVC requirement	>50%	<50%
Access	Endoscopic	Percutaneous, under fluoroscopic guidance
Sedation	Generalized	Local
Positioning	Recumbent	Upright
Respiratory complications	Higher	Lower
Occlusion risk due to small diameter of tube	Lower	Higher

PEG Percutaneous endoscopic gastrostomy; *RIG* radiologically inserted gastrostomy

patient discomfort, increased likelihood of mechanical complications, and risk of worsening respiratory insufficiency (Verschueren et al. 2009).

Gastrostomy tube insertion uses one of two methods, percutaneous endoscopic gastrostomy (PEG) or radiologically inserted gastrostomy (RIG); differences between the two procedures are highlighted (Table 8). Recent data from a large prospective cohort of ALS patients undergoing gastrostomy found no difference in mortality in patients who underwent PEG versus RIG (overall mortality 4%, 95% CI 2–6%; PEG mortality 3%, 95% CI 1–8%; RIG mortality 3%, 95% CI 1–9%) (ProGas Study Group 2015). In general, both the AAN and EFNS recommend PEG insertion to be performed when FVC is >50% of predicted. However, gastrostomy insertion is successfully undertaken in patients with FVC <50% of predicted, usually with noninvasive respiratory support (Czell et al. 2013). In a recent observational study from a single center, which utilized a "traffic light" risk stratification tool, the authors successfully performed a modified PEG procedure despite respiratory compromise (Thompson et al. 2017).

There is currently scarcity of evidence to guide postgastrostomy feeding in patients with ALS. Even though a handful of observational studies suggest that gastrostomy feeding improves quality of life (QOL) in ALS patients (Mitsumoto et al. 2003), results from a large prospective study indicated that the effect of gastrostomy on QOL was neutral (ProGas Study Group 2015). These results are due to the advancing disease with loss of FFM and its effect on progressively worsening function and to ineffective and non-standardized postgastrostomy care in patients. The lack of standardization may be due to a choice of enteral formula that is not calorically dense to reduce volume, high in fat and low in carbohydrates to minimize carbon dioxide production and possibly slow disease progression, high in omega-3 fatty acids and antioxidants to modify the inflammatory state, and high in fiber to reduce constipation (Muscaritoli et al. 2012). Currently no specific enteral formula confers a benefit to ALS patients; rather, guidance derives from the use in other disease states, such as formulas devised for acute lung injury and acute respiratory failure (Pontes-Arruda et al. 2008). Assessing the effectiveness of specific formulas on disease progression in ALS is an area of needed research.

Several other postgastrostomy feeding logistics need consideration. These include:

1. Bolus feeding versus continuous feeding using a pump, the choice being dependent on resources and patient comfort
2. Patient positioning, to include raising the head end to at least 30 degrees during and for 1 hour after feeding
3. Post-feeding flushing with water to clean the tube, prevent tubal obstruction, and provide adequate hydration
4. Calculation of postgastrostomy calorie requirement
5. Prevention and treatment of postgastrostomy complications, including diarrhea and refeeding syndrome (Hisham et al. 2008)

There is an urgent need to understand the poor nutritional outcomes following gastrostomy in the majority of ALS patients and to further study and develop evidence-based guidance on nutritional management following gastrostomy.

Dictionary of Terms

- **Amyotrophic Lateral Sclerosis** – Also called motor neuron disease (in the United Kingdom), Charcot's disease (in France), or Lou Gehrig's disease (in the USA), this is a neurological condition due to loss of nerve cells in the brain and spinal cord that control muscle function.
- **Body Mass Index** – An index of body size, derived from the ratio between weight and height.
- **Daily Energy Intake** – The number of calories eaten daily through food.
- **Daily Energy Expenditure** – The number of calories spent daily in supporting functions of essential organs (e.g., the brain, heart, lungs, etc.) and physical activity.
- **Fat Mass** – The amount of fat in the body, which can reflect the nutritional state.
- **Fat-Free Mass** – The amount of lean tissue, usually muscle, in the body.
- **Gastrostomy** – An artificial "hole" in the stomach to facilitate delivery of nutrition in individuals who are unable to swallow.
- **Harris-Benedict Equation** – An equation that utilizes a person's weight, height, age, and gender to estimate the number of calories needed daily for bodily functions, found to be inaccurate to predict calories needed daily in ALS subjects.
- **Hypermetabolism** – Excessive use of calories to support the functions of essential organs.
- **Modified Harris-Benedict Equation** – A valid equation using some ALS severity measures to modify the Harris-Benedict equation and correctly estimate the number of calories needed daily for bodily functions.

- **Malnutrition** – A deviation from the normal nutritional state (could be undernutrition that results in excessive thinness or overnutrition that produces obesity).
- **Marasmus** – A state of undernutrition resulting from decreased intake of calories.

Summary Points

- This chapter reviews the frequency, causes, and approach to management of malnutrition in amyotrophic lateral sclerosis (ALS).
- Depending on the method uses, malnutrition is identified in from 6 to 100% of patients.
- Malnutrition is primarily due to energy or caloric deficiency; protein deficiency is uncommon.
- Dysphagia reduces energy intake; labored physical activity and hypermetabolism produce excessive energy expenditure, which alone or in combination result in negative energy balance.
- Regular nutritional care is best provided in multidisciplinary clinics where patients are evaluated by a team of experienced providers.
- At clinic visits, the team members identify the causes of malnutrition, chart energy intake from food diaries, and estimate energy needs based upon disease severity and topography of involvement.
- A validated published tool, which is a modification of the commonly used Harris-Benedict equation, is used to assess energy needs and incorporates disease severity measures.
- At clinic visits, energy balance is critically examined, and appropriate oral dietary modifications with regard to food type, food consistency, and energy supplementation are recommended.
- At subsequent clinic visits, if energy balance is not met, then a recommendation is made for an alternative route for feeding, which is typically a percutaneous or radiologically inserted gastrostomy.

Hydration in Amyotrophic Lateral Sclerosis 53

Connor Scagnelli, Waqar Waheed, and Rup Tandan

Contents

Abstract

Water is essential for health and survival. Water needed for health exceeds the amount the body produces through metabolic activity. Although water intake is predominantly as free water or in liquid drinks, about a quarter comes from solid foods such as meats and vegetables. Water exists as total body water (TBW) that constantly replenishes and occurs in intracellular and extracellular compartments. Recommended daily water intake is 3.0 L in men and 2.5 L in women and decreases with normal aging; inadequate intake in healthy elderly results in

increased morbidity and mortality. Amyotrophic lateral sclerosis (ALS), a neurodegenerative disease of middle age, causes diffuse weakness with dysfunction in the limbs and bulbar muscles accompanied by erosion of quality of life and early death from respiratory failure. Although often discussed in ALS circles, the assessment and management of dehydration are frequently overlooked. Dehydration assessed by the gold standard-labeled water method to examine daily water turnover, a surrogate for water intake, occurs in 20% of ALS patients at first evaluation; its degree increases as the disease progresses. TBW and water turnover are 1,200 ml (3.4%) and 260 ml/day (8.6%) lower, respectively, in ALS patients compared to age- and gender-matched healthy controls. Risk factors for poor hydration are female gender, bulbar-onset disease, malnutrition estimated by body mass index, and low lung function measured by incentive spirometry. As in the healthy elderly population, decreased water intake adversely affects survival in ALS patients. Equations used to estimate daily water requirement, recommended by the US Centers for Medicare and Medicaid Services in healthy elderly, are inaccurate for use in ALS patients. Validated equations are now available to accurately estimate hydration using endpoints routinely assessed in ALS clinics. As with nutrition, hydration should be regularly examined at ALS clinic visits using these equations to assess water requirements and improve clinical care.

Keywords

Amyotrophic lateral sclerosis · Dehydration · Doubly labeled water · Harris-Benedict equation · Hydration status · Total body water · Total daily energy expenditure · Water intake · Water turnover · Survival

List of Abbreviations

ALS	Amyotrophic lateral sclerosis
ALSFRS-6	Summed scores for speech, handwriting, dressing & hygiene, turning in bed and adjusting bedclothes, walking and dyspnea components of ALSFRS-R (normal = 24)
ALSFRS-R	Amyotrophic lateral sclerosis functional rating scale-revised
BMI	Body mass index
DLW	Doubly labeled water
FVC	Forced vital capacity
H-B	Harris-Benedict
OR	Odds ratio
TBW	Total body water
TDEE	Total daily energy expenditure

Introduction

Water is an essential component of the diet and vital for health and sustenance of life. Total body water (TBW) is present in intracellular and extracellular compartments and accounts for 75% of body weight in infants and 55% in the elderly

(Nicolaidis 1998). TBW turns over continuously; the amount required for maintaining normal hydration and health needs supplementation from external sources (Kleiner 1999). The average daily water consumption to maintain normal hydration is determined to be 3.0 L in males and 2.5 L in females (Raman et al. 2004). Dehydration results from depleted TBW due to inadequate intake or excessive loss in the healthy state or due to illness (Begum and Johnson 2010). Dehydration and associated morbidities are reversible; however, if left untreated the risk of mortality is significantly increased.

Amyotrophic lateral sclerosis (ALS) affects middle- to late-age subjects (Li et al. 1990) who already have an increased risk of dehydration (Phillips et al. 1984; Silver and Morley 1992; Phillips et al. 1993). Malnutrition is frequent in the disease; the multiple causes of malnutrition in ALS are also relevant in producing dehydration. Contributory factors include poor oral intake due to bulbar dysfunction, weakness of arms that interferes with feeding, anorexia, depression, cognitive impairment, impaired mobility, and lack of caregiver availability (Scagnelli et al. 2017). Additionally, impaired thirst and fear of incontinence also contribute to poor hydration. Dehydration is a chronic concern in ALS but is often overlooked in the management of patients (Scagnelli et al. 2017).

Prevalence of Dehydration in the Elderly and in ALS

Preformed water intake decreases by 15 mL/decade in healthy men and women between the ages of 40 and 79 years (Raman et al. 2004). This decrease with normal aging also occurs in TBW (Lesser and Markofsky 1979; Weitzman and Kleeman 1999). Dehydration is the most common cause of electrolyte abnormality in the elderly (Lavizzo-Mourey et al. 1988), and estimates are that 1.5% of elderly subjects living in institutions undergo hospitalization annually for dehydration (Warren et al. 1996). In the early 1990s, dehydration was the principal diagnosis in 6.7% of all hospitalized Medicare patients (Warren et al. 1994). Dehydration occurs in 31% of nursing home subjects by using urine-specific gravity, urine color, bioelectrical impedance analysis, and dietary records when hydration is tracked for 6 months (Mentes 2006).

There is no prior epidemiological data on the prevalence of dehydration in ALS. Data on prevalence is now available from a recent multicenter study in the USA (Scagnelli et al. 2017). In this study, 80 patients with “definite” or “probable” ALS from 5 academic centers (Kasarskis et al. 2011, 2014; Scagnelli et al. 2017) underwent 250 observations for measurement of hydration status using the gold standard doubly labeled water (DLW) method over a 10-day period (Scagnelli et al. 2017). Data were compared to that in age- and gender-matched healthy subjects from a Clinical Research Center Database from the Robert Larner, MD College of Medicine at the University of Vermont, Burlington, VT, USA. Daily water turnover, a surrogate for water intake in weight stable subjects, was less than two standard deviations below the healthy control mean in 20% of patients. Among hospitalized patients in a Center for Medicare and Medicaid Services (CMS) national inpatient

database, dehydration and malnutrition were the most frequent concurrent diagnoses, affecting 36% of ALS patients (Lechtzin et al. 2001).

Hydration in ALS

Water Turnover

The average daily water turnover by DLW is 9% or 260 mL lower in ALS patients than in age- and gender-matched healthy controls (Scagnelli et al. 2017) (Table 1). Water intake in ALS patients from this study is also lower than that reported in healthy controls from intake questionnaires (Zizza et al. 2009) and by DLW in another study of a larger number of healthy subjects (Raman et al. 2004). Risk factors for lower water intake are bulbar-onset disease and values below the median in the groups for amyotrophic lateral sclerosis functional rating scale-revised (ALSFRS-R) (Table 2), body mass index (BMI), and percent predicted forced vital capacity (FVC) (Fig. 1). The odds ratio (OR) for low water turnover in the below median groups ranged between 2.03 and 3.75 and was the highest for BMI.

Total Body Water

In the multicenter study from the USA (Scagnelli et al. 2017), TBW was 1,200 ml (3.5%) lower in ALS patients as compared to that in matched healthy controls (Table 2). Although there are no data from other studies in ALS, in an isotopic dilution study using tritiated water, TBW was not significantly different in groups of patients with muscular dystrophy, myasthenia gravis, and neurogenic atrophy (Delwaide et al. 1972). This study only had one ALS patient in the neurogenic atrophy group.

Table 1 Total body water and water turnover by the doubly labeled water method in ALS patients and matched healthy controls ($n = 57$ in each group)

	ALS (mean ± SD)	Healthy controls (mean ± SD)	p-value (paired t-test)
Age (y)	64.1 ± 9.4	64.8 ± 10.0	0.07
Height (cm)	168.0 ± 10.2	167.8 ± 8.9	0.99
Weight (kg)	76.2 ± 15.9	73.1 ± 14.4	0.53
BMI (kg/m2)	26.9 ± 4.5	25.9 ± 4.2	0.20
Fat-free mass (kg)	45.7 ± 10.4	49.3 ± 10.1	0.003
Fat mass (kg)	31.3 ± 11.2	24.0 ± 11.0	0.004
TBW-DLW (L)	34.6 ± 7.7	35.8 ± 7.5	0.15
Water turnover-DLW (L/d)	2.75 ± 0.83	3.01 ± 0.66	0.05

Table 2 ALS functional rating scale-revised

Questions
1. Speech
4 = Normal speech processes
3 = Detectable speech disturbances
2 = Intelligible with repeating
1 = Speech combined with nonvocal communication
0 = Loss of useful speech
2. Salivation
4 = Normal
3 = Slight but definite excess of saliva in mouth, may have nighttime drooling
2 = Moderately excessive saliva, may have minimal drooling
1 = Marked excess of saliva with drooling
0 = Marked drooling, requires constant tissue or handkerchief
3. Swallowing
4 = Normal eating habits
3 = Early eating problems – occasionally
2 = Dietary consistency changes
1 = Needs supplemental tube feeding
0 = NPO (exclusively parenteral or enteral feeding)
4. Handwriting
4 = Normal
3 = Slow and sloppy, all words are legible
2 = Not all words are legible
1 = Able to grip pen but unable to write
0 = Unable to grip the pen
5a. Cutting food and handling utensil (patients without gastrostomy)
4 = Normal
3 = Somewhat slow and clumsy but no help needed
2 = Can cut most foods, although clumsy and slow; some help needed
1 = Food must be cut by someone but can still feed slowly
0 = Needs to be fed
or
5b. Cutting food and handling utensils (alternate scale for patients with gastrostomy)
4 = Normal

10. Breathing
4 = Normal
3 = Shortness of breath with minimal exertion (e.g., walking, talking)
2 = Shortness of breath at rest
1 = Intermittent (e.g., nocturnal) ventilatory assistance
0 = Ventilator dependent
R-1. **Dyspnea**
4 = None
3 = Occurs when walking
2 = Occurs with one or more of the following: eating, bathing, dressing
1 = Occurs at rest, difficulty breathing when either sitting or lying
0 = Significant difficulty, considering using mechanical ventilatory support
R-2. **Orthopnea**
4 = None
3 = Some difficulty sleeping at night due to shortness of breath, does not routinely use more than two pillows
2 = Needs extra pillows in order to sleep (more than two)
1 = Can only sleep sitting up
0 = Unable to sleep
R-3. **Respiratory insufficiency**
4 = None
3 = Intermittent use of NIPPV
2 = Continuous use of NIPPV during the night
1 = Continuous use of NIPPV during the night and day
0 = Invasive mechanical ventilation by intubation or tracheostomy

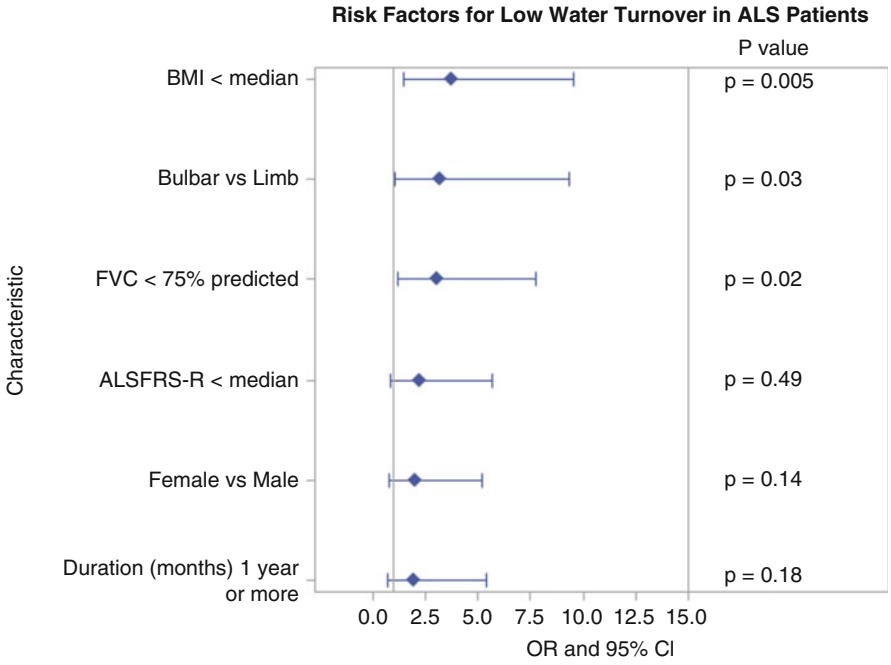

Fig. 1 Risk factors for low water turnover in ALS patients using the doubly labeled water method ($n = 79$)

Hydration Parameters with ALS Progression

With progressive worsening of clinical measures over a year, decreases in average daily water turnover by 14% or 40 mL, and in TBW by 6% or 210 mL, are seen (Fig. 2). This rapid worsening of hydration is largely a consequence of declining intake and can account for several adverse biological effects.

Consequences of Dehydration in Elderly

Poor hydration has several health-related adverse consequences in normal subjects. In the elderly, reduced water intake, resulting in dehydration, is the most frequent cause of electrolyte disturbances (Lavizzo-Mourey et al. 1988), particularly hypernatremia, and produces increased mortality and morbidity (Borra et al. 1995). In the elderly, dehydration alone has serious consequences, including an increased likelihood of pneumonia, urinary tract infections, bowel obstruction, vomiting, fever, delirium, and cardiovascular complications. Dehydration in the elderly increases the risk of morbidity and mortality not only in of itself but also when it

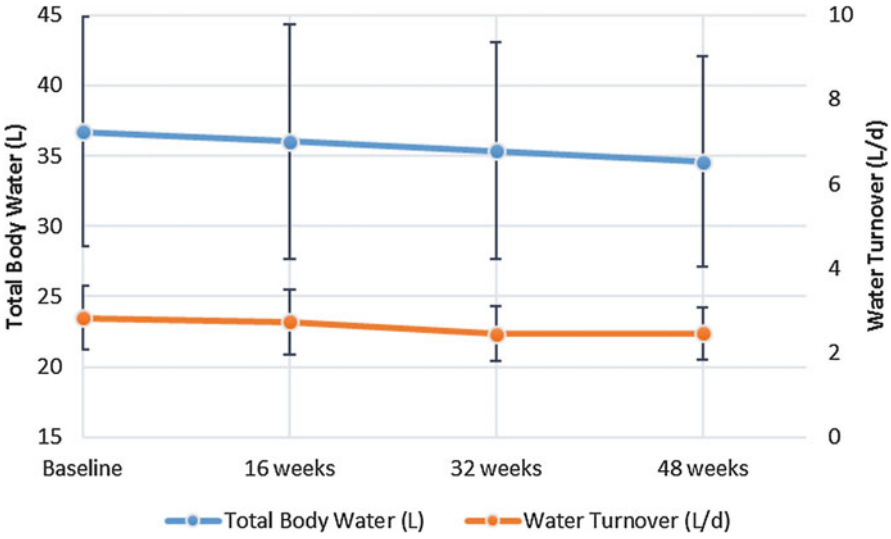

Fig. 2 Change in total body water and water turnover measured by doubly labeled water over 48 weeks in ALS patients ($n = 49$)

co-occurs with several diseases, including cancer, diabetes, urinary infections, and respiratory illnesses (Warren et al. 1994).

Consequences of Dehydration in ALS

The effect of dehydration on mortality in ALS has been studied recently. Poor hydration is associated with increased mortality in ALS patients, as shown by the multicenter study from the USA (Scagnelli et al. 2017). The median Kaplan-Meier survival in a clinic cohort is reduced by 16 months in patients with estimated daily water intake values below the median as compared to above the median (Fig. 4). By quartiles of water intake, patients in the lowest quartile show reduced median survival by 21 months as compared to that in the highest quartile (Fig. 5). Mortality 12 months after the first clinic visit is 45% in the lowest quartile compared to 9% in the highest quartile (Fig. 6); after adjusting for the known prognostic factors in ALS, the hazard ratio for increased likelihood of death from reduced water intake is still significant at 12 months. These data suggest that lower water intake is an independent risk factor for survival.

In dichotomous groups separated at median values of estimated daily water intake and BMI, median Kaplan-Meier survival was 14, 18, 31, and 29 months, respectively, in groups with low BMI/low water intake, high BMI/low water intake, low BMI/high water intake, and high BMI/high water intake (Fig. 7) (Scagnelli et al. 2017). The proportion of patients in the above median and below median groups

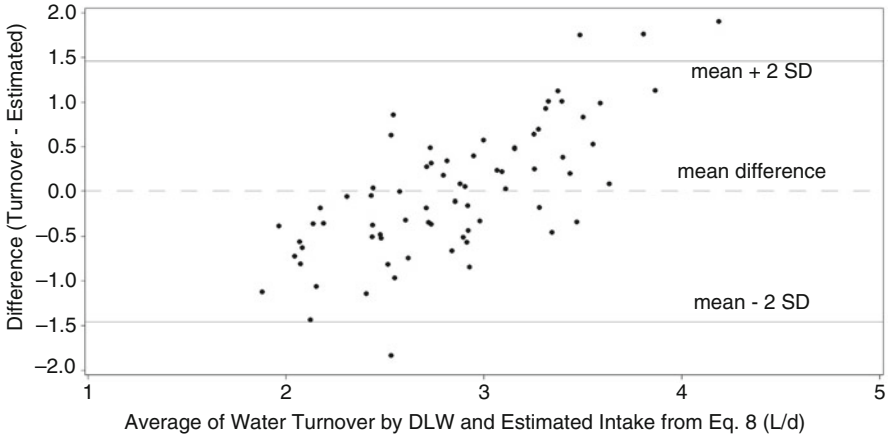

Fig. 3 Bland-Altman plot of water turnover from doubly labeled water and water intake estimated from *Equation 8* in ALS patients ($n = 79$)

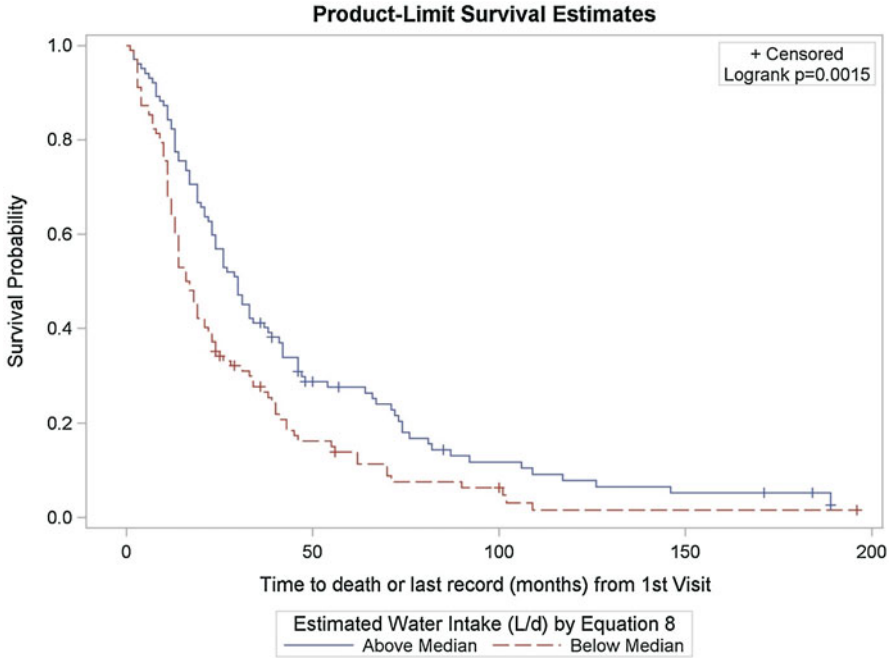

Fig. 4 Kaplan-Meier survival curves for baseline daily water intake estimated from *Equation 8* in patients seen at University of Vermont ALS Center clinic ($n = 208$) with intakes above and below median value of 2.88 L/d. Proportional hazards regression, hazard ratio (HR) = 1.59 ($p = 0.002$)

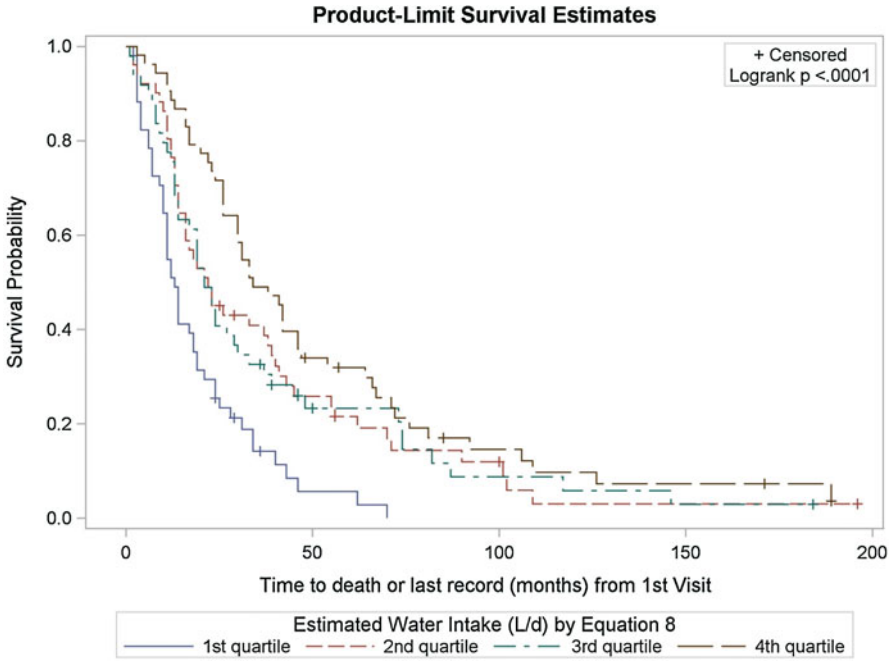

Fig. 5 Kaplan-Meier survival curves for baseline daily water intake estimated from *Equation 8* in patients seen at University of Vermont ALS Center clinic ($n = 208$), by quartiles

for BMI and water intake is comparable (Fig. 8), showing concordance between the nutritional state and dehydration based on water intake employing *Equation 3*. These data demonstrate that low water intake can have a more significant negative impact on survival than low BMI. Daily water intake, water intake relative to TBW, and TBW corrected for body weight and lean body mass are for the first time shown to be significant predictors of survival in ALS (Fig. 9). Taken together, these data indicate that both water intake and TBW are probably chronically low in ALS patients and add to the adverse risk conferred by the other known prognostic factors toward shortened survival.

Equations for Estimating Water Intake and TBW

Scagnelli et al. (2017) have shown that the two equations published in the USA by CMS (Recommended Daily Allowances 1989; Chidester and Spangler 1997) for estimating daily water intake in healthy adults are inaccurate in predicting water requirement in ALS (*Equations 1 and 2*, Table 2). Using DLW data for validation, they created equations to estimate daily water intake and TBW using variables easily obtained at routine ALS clinic visits (*Equations 3–5*, Table 2).

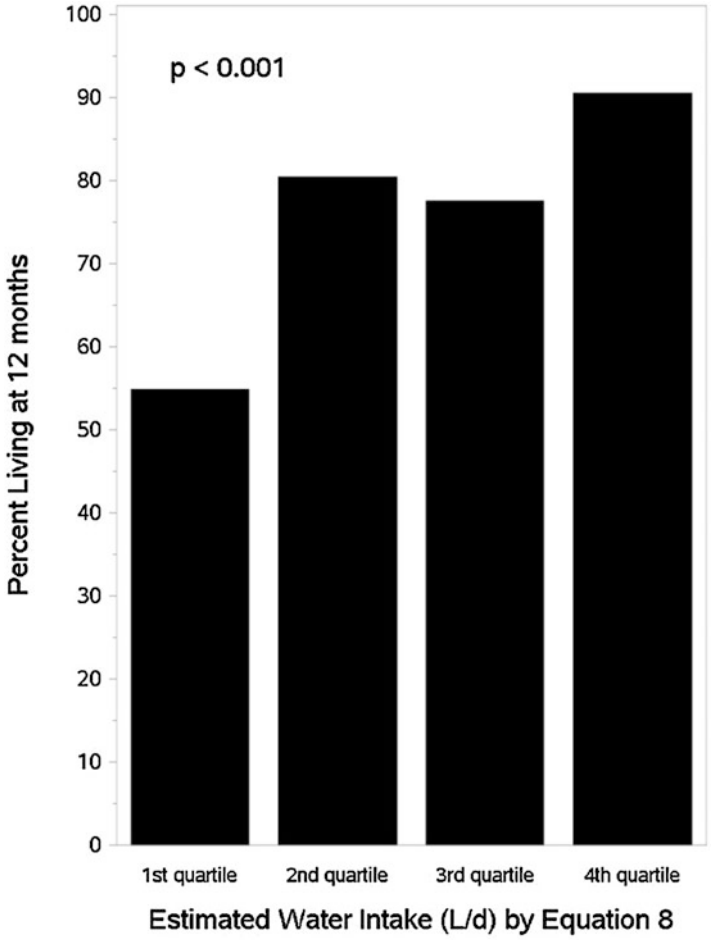

Fig. 6 Bar graph of survival at 12 months in quartiles of clinic patients ($n = 204$) based on daily water intake estimated by *Equation 8* at first visit in patients seen at University of Vermont ALS Center clinic (p-value is for Kendall's Tau correlation)

The validated *Equations 3* and *4* accurately estimate TBW in men and women with ALS.

An accurate estimate of total daily energy expenditure (TDEE) is a prerequisite for using *Equation 1* to predict water intake. The Harris-Benedict (H-B) equation, when used to predict daily energy requirements, significantly underestimates TDEE in ALS patients. However, the predictability is much more accurate if an ALS disease-specific modification (the ALSFRS-6 modification) of the H-B equation (*Equation 5*, Table 2) is utilized (Kasarskis et al. 2014) to estimate TDEE. Thus, TDEE obtained from *Equation 5* provides an accurate estimate of daily water intake in ALS patients (Scagnelli et al. 2017).

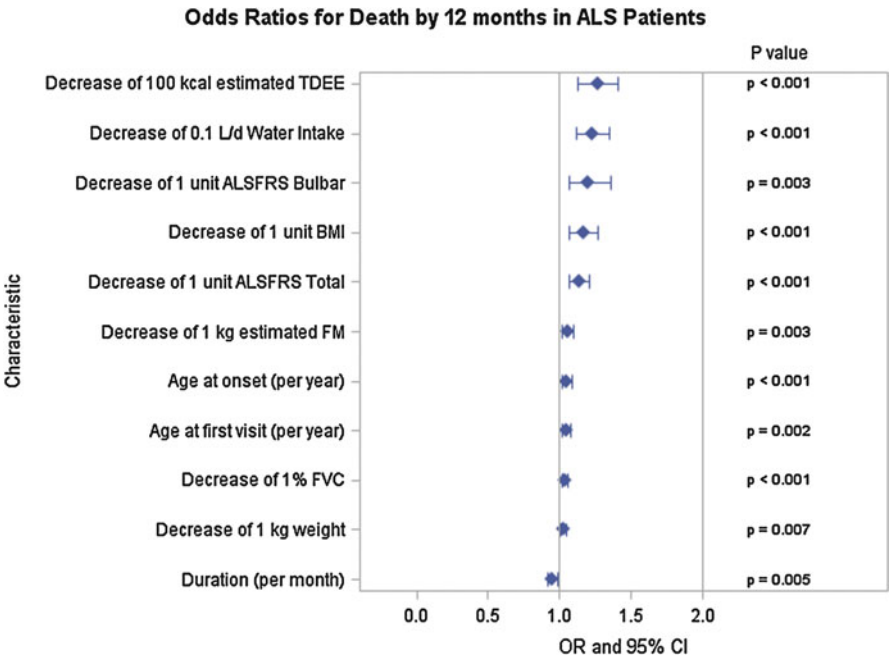

Fig. 9 Odds ratio for mortality at 12 months from first visit based on baseline demographic and hydration measures in patients seen at University of Vermont ALS Center clinic ($n = 208$)

Policies and Protocols

Protocols

At each ALS clinic visit, the following tools are essential to provide accurate estimates of hydration status:

1. *Equations 3* and *4* to estimate TBW
2. Basal metabolic rate using the H-B equation
3. Total ALSFRS-6 score
4. *Equation 5* to estimate TDEE
5. *Equation 8*, using the TDEE value from *Equation 5*, to estimate daily water intake

Policies and Recommendations

Figure 10 is a flow diagram of the recommended course of action to estimate TBW and water intake in ALS patients. The individual steps to predict nutrition and hydration requirements in ALS patients at each clinic visit, therefore, are:

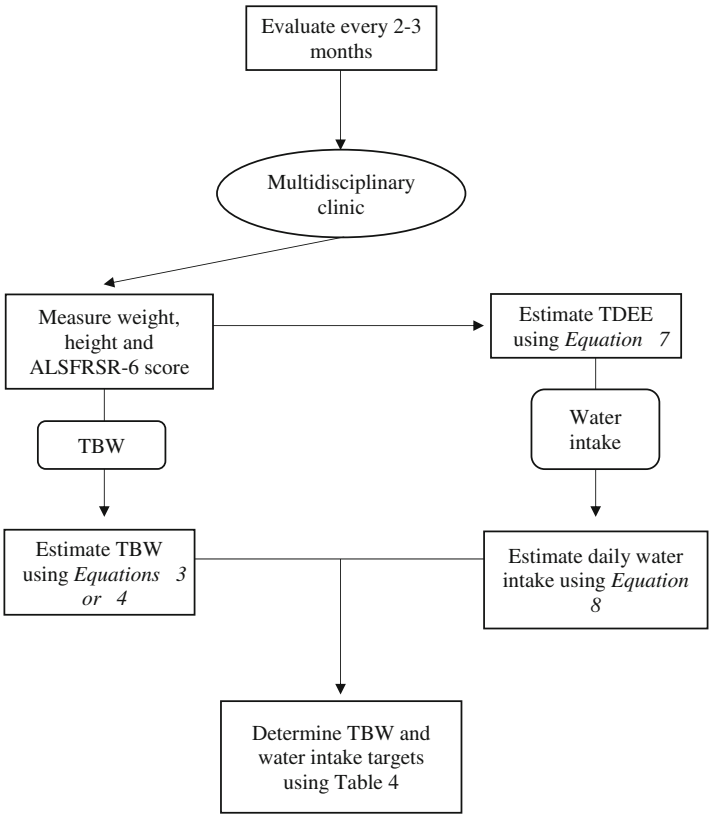

Fig. 10 Suggested algorithm for assessment of hydration in ALS patients

1. Measure, not estimate, body weight.
   (i) Record height.
2. Record the consensus responses (from the ALS patient, family members, ALS clinician) to the ALSFRS-6 (Questions 1, 4, 6, 7, 8, and 10 from the ALSFRS-R questionnaire) (Table 2).
3. Calculate the total daily energy (calorie) needs according to the ALSFRS-6 modification of the H-B equation to provide energy intake targets for the ALS patient (Kasarskis et al. 2014).
4. Calculate the daily water needs according to *Equations 3–5* to provide TBW and water intake targets (Table 3).
   (i) Recommendations from the dietician and speech pathologist can help the patient achieve the goals set forth in #3 and #4.
5. Consult Table 4 to determine recommended values of TBW and water turnover in men and women by age.

Table 3 Equations for estimating total body water, daily water intake, basal metabolic rate, and total daily energy expenditure (modified from Table 1, Scagnelli et al. (2017))

	Equation	Comment
Equation 1 (CMS)	**Water requirement** (L/d) = 0.001* total daily energy expenditure	Total daily energy expenditure estimated from H-B equation and factorial approach
Equation 2 (CMS)	**Water requirement** (L/d) = 100 mL/kg body weight for first 50 kg + 50 mL/kg for remainder of body weight	From body weight
Equation 3 (TBW)	**Total body water** (L) (men) = [0.209* weight (kg)] + [0.140* height (cm)] − 1.809	From body weight and height
Equation 4 (TBW)	**Total body water** (L) (women) = [0.209* weight (kg)] + [0.140* height (cm)] – 8.064	From body weight and height
Equation 5 (H-B equation)	**Basal metabolic rate** (kcal/d) = 66 + (6.23 × weight in pounds) + (12.7 × height in inches) − (6.76 × age in years)	For men
Equation 6 (H-B equation)	**Basal metabolic rate** (kcal/d) = 655 + (4.35 × weight in pounds) + (4.7 × height in inches) − (4.7 × age in years)	For women
Equation 7	**Total daily energy expenditure** (kcal/d) = BMR + (55.96 × ALSFRS-6 score) − 168	From ALSFRS-6 modification of Harris-Benedict equation
Equation 8	**Water requirement** (L/d) = 0.087 + 0.001151* total daily energy expenditure (Fig. 3)	Total daily energy expenditure estimated from ALSFRS-6 modification of Harris-Benedict equation

6. Reassess at subsequent clinic visits.
7. If the patient fails to achieve the goals for energy and water intake, then recommend a gastrostomy for an alternative route for nutrition and hydration.

Dictionary of Terms

- **Amyotrophic lateral sclerosis** – Also called motor neuron disease (in the UK), Charcot's disease (in France), or Lou Gehrig's disease (in the USA), this is a neurological condition due to loss of nerve cells in the brain and spinal cord that control muscle function.
- **Amyotrophic Lateral Sclerosis Functional Rating Scale-Revised** – A 13-item questionnaire completed by patients, caregivers, or clinic staff that evaluates activities of daily living and the functional state of patients.

Table 4 Water turnover and TBW in healthy men and women by decade

		Age	40–49	50–59	60–69	70–79

* = L/d; ** = L

- **Amyotrophic Lateral Sclerosis Functional Rating Scale-6** – A six-item subcomponent of the ALS Functional Rating Scale-Revised that evaluates the summed scores for speech, handwriting, dressing and hygiene, turning in bed and adjusting bedclothes, walking, and dyspnea and helps to accurately estimate daily water intake needs.
- **Daily Energy Requirement** – The number of calories needed in the daily diet through food to maintain a healthy state.
- **Daily energy Expenditure** – The number of calories spent daily in supporting functions of essential organs (e.g., the brain, heart, lungs, etc.) and in carrying out physical activities.
- **Dehydration** – A state of water deficiency in the body.
- **Gastrostomy** – An artificial "hole" in the stomach to facilitate delivery of nutrition and hydration in individuals who are unable to swallow.
- **Harris-Benedict Equation** – An equation that utilizes a person's weight, height, age, and gender to estimate the number of calories needed daily for bodily functions.
- **Hydration** – A measure of the body's water status.
- **Modified Harris-Benedict Equation** – A valid equation using some ALS severity measures to modify the Harris-Benedict equation and correctly estimate the number of calories and amount of water needed daily to maintain nutrition and hydration and also bodily functions.

- **Total Body Water** – The volume of water, in liters, contained in the body inside the tissues and in the circulation.
- **Water Intake** – The volume of water consumed largely as liquids; some are also available from solid foods.
- **Water turnover** – The volume of water that is added daily to the body's water compartments to maintain normal hydration.

Summary Points

- This chapter reviews the prevalence, consequences, and approach to management of dehydration in amyotrophic lateral sclerosis (ALS).
- Dehydration is identified in 20% of patients using the gold standard doubly labeled water method.
- Dehydration is an independent risk factor for early death in patients and is probably responsible for increased morbidity.
- Reduced oral intake due to dysphagia is the principle cause of dehydration; however, also contributory are anorexia, depression, cognitive dysfunction, weakness of arms, lack of caregiver availability or support, and decreased thirst associated with normal aging.
- As with nutritional care, attention to proper hydration is best provided by education of patients and caregivers in multidisciplinary clinics by a team of experienced providers.
- At clinic visits, team members can identify malnutrition and dehydration using validated published tools.
- It is essential to assess daily energy needs correctly so as to appropriately determine hydration requirements.
- If appropriate oral dietary modifications with regard to food type, food consistency, and energy supplementation cannot correct malnutrition and dehydration, then a recommendation is made for an alternative route for feeding, which is typically a percutaneous or radiologically inserted gastrostomy.

Surgical Treatment for Severe Protein-Calorie Malnutrition After Bariatric Surgery

54

Reginaldo Ceneviva and Wilson Salgado Junior

Contents

Abstract

Obesity is a chronic and universal disease that has reached global epidemic proportions and is one of the ten greatest health risks that can be prevented. Medical treatment results in a limited and usually transitory weight loss, especially among the more obese patients. The frequent failure of conservative therapy, coupled with worsening of quality of life and possible reduction of survival, favors the indication of surgical treatment.

Bariatric surgeries are an efficacious treatment for morbid obesity, but they are not free of early or late complications, including severe protein-calorie malnutrition. Although few evidence-based studies are available to instruct decisions about strategies and managements, emphasis was placed on the description of

Introduction

Nutrient deficiencies constitute the most important long-term complications of bariatric procedures (Tack and Deloose 2014, 741; Nett et al. 2016). Protein-calorie malnutrition (PCM) may develop after bariatric surgery, and diagnosis should be made early before complications establish and physical conditions deteriorate, with medical treatment and dietary adjustment being promptly initiated. The demand for revision bariatric procedures increases with the increasing number of primary bariatric surgeries (Ma et al. 2016).

For a successful revision, it is essential to evaluate data about the previous surgical procedure and perform a careful preoperative clinical-laboratory study, including the assessment of nutritional status and other parameters such as imaging examinations and the behavioral and dietary habits of the patients (Salgado et al. 2014; Santarpia et al. 2014; Ma et al. 2016).

The proposition of revision surgery should be made preferably by a health multi-professional team, when there is an obstructive problem not solved by endoscopy or when there is a recognized failure of the appropriate conservative treatment.

According to Topart and Becouarn (2015), revision surgery should be indicated when there is failure of medical treatment for excessive and continuous weight loss (>100% excess weight loss) or biological and laboratory signs of SPCM (severe protein-calorie malnutrition), risk of liver failure, persistent hypoalbuminemia (<3.5 g/dL), and persistent hypoprealbuminemia (<0.02 g/dL).

The selection of a particular surgical revision procedure for the treatment of SPCM after each type of primary surgery has not been standardized in the literature. There is limited evidence due to the small number of studies published which are usually retrospective and involve small patient series. Furthermore, most studies on the treatment of malnutrition after bariatric surgery do not specify the type and severity of malnutrition, making it difficult to identify the PCM, particularly in its severe form. Revision surgeries are usually more complex and pose higher risk than the previous surgical procedures (Brethauer et al. 2014). Thus, it is desirable that they should be performed by experienced surgeons (Buchwald 2015; Ma et al. 2016).

Kellogg (2011) showed that the overall incidence of surgical revision after a primary bariatric operation is of 5–50%, including other indications besides PCM. According to Nesset et al. (2007), out of 1584 patients submitted to bariatric surgery, 218 (14%) underwent revision procedures, of which 97 (44%) for unsatisfactory weight loss and 26 (12%) for severe nutritional/metabolic problems.

Reoperations for treatment of SPCM involve three kinds of procedures:

Reversals – restoration to original anatomy

Conversions – which consist of another kind of procedure, considered to be better than the previous one, regarding the potential improvement of the nutritional status

Corrections – which solve complications or complement the treatment effect of the primary bariatric surgery

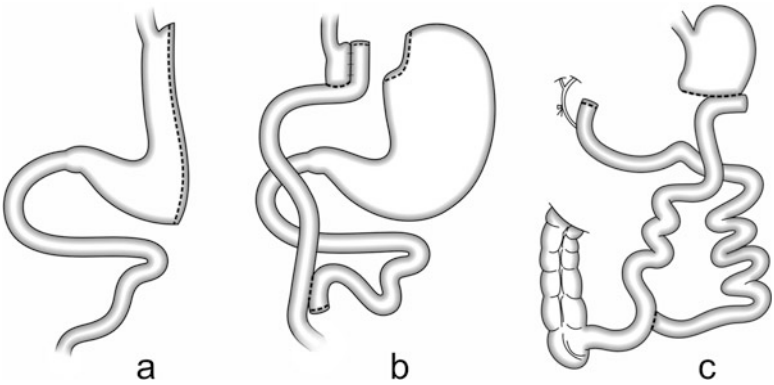

Fig. 1 Bariatric surgeries. (**a**) Sleeve gastrectomy. (**b**) Roux-en-Y gastric bypass. (**c**) Biliopancreatic diversion

Knowledge about the primary bariatric surgery and the anatomical features is essential for the surgeon to perform the therapeutic revision procedure efficaciously (Ma et al. 2016). Figure 1 shows schemes of three bariatric operations which represent three different groups: purely restrictive, mixed with predominant restrictive component, and mixed with predominant malabsorptive component.

Surgical Revision Techniques

For Purely Restrictive Surgeries

In general, reversal and conversion after restrictive surgeries are only indicated in the rare cases of occurrence of SPCM. Stenosis or obstructions are usually resolved by therapeutic methods involving an endoscopic or surgical approach to revise the complication itself, such as endoscopic dilatation of the stenosis and removal of the band (Brethauer et al. 2014). Milone et al. (2014) found, in a systematic review, that persistent vomiting was the major determinant of Wernicke encephalopathy in patients undergoing restrictive weight loss surgery.

For Purely Malabsorptive Surgeries

Revision of the jejunoileal bypass should be considered to prevent cirrhosis, oxalate nephropathy, renal failure, and chronic malnutrition (Singh et al. 2009; Chousleb et al. 2012).

For Mixed Surgeries with a Malabsorptive Component

Roux-en-Y Gastric Bypass

Hypoalbuminemia is uncommon after RYGB (Pajecki et al. 2007). Anatomical causes of malnutrition are usually indications for reoperation. PCM may result from complications of RYGB due to stenosis of the gastrojejunostomy accompanied by vomiting and, not infrequently, by dysphagia and psychological disorders such as fear of eating. Stenosis of the gastrojejunal anastomosis should be preferentially treated by endoscopic dilatation, and when this treatment fails, the therapeutic alternative is reoperation with a direct approach to the cause of obstruction (Kushner 2000), as is the case with other causes of mechanical obstruction of the alimentary tract. Chronic or intermittent pain during late postoperative period may result from intestinal obstructions of several types: internal hernia, stenosis of the jejunojejunal anastomosis and adhesions, or, more rarely, intussusception of the enteral loop (Kassir et al. 2016). Image exams may fail to confirm the hypothesis of obstruction due to adhesions or to an internal hernia, mainly if those exams are performed outside the episodes of pain. An early surgical intervention may be crucial because of the possibility of ischemia of the bowel loops involved.

Diarrhea and excessive weight loss are causes of PCM (Malinowski 2006) but are infrequent after RYGB. Crohn's disease, celiac disease, and lactose intolerance manifested before or after RYGB involve a particularly conservative treatment (Janczewska et al. 2011; Cuenca-Abente et al. 2013) but may indicate a revision procedure if marked malabsorption attributed to bariatric surgery occurs.

No established directives are available to guide the choice of the type of revision procedure for the treatment of PCM after RYGB (Fig. 2a). The choice between reversal and revision is frequently difficult.

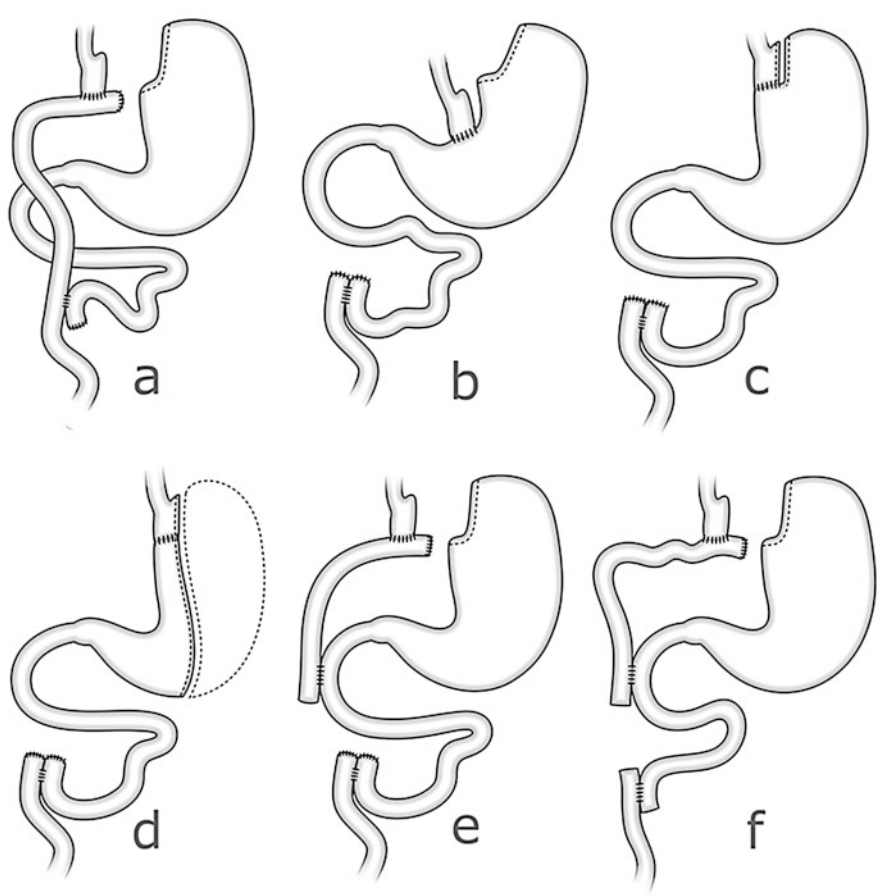

Fig. 2 Revision surgeries for Roux-en-Y gastric bypass. (**a**) Standard RYGB. (**b**) Reversal with an end-to-side anastomosis between the pouch and the body of the stomach. (**c**) Reversal with an end-to-side anastomosis between the pouch and the fundus of the stomach. (**d**) Conversion to sleeve gastrectomy. (**e**) Short jejunal interposition. (**g**) Jejunal interposition of the entire AL

Reversal of RYGB

In a systematic review of 175 articles selected, Brethauer et al. (2014) observed that the indications to reverse RYGB were rare and based, among other disorders, on severe intractable nausea, vomiting, excessive weight loss, psychological issues, recurrent anastomotic ulceration, malnutrition, and extensive bowel resections. Shoar et al. (2016) selected 100 patients in a systematic review of 35 papers. Although weight regain was the main reason for revision surgery after RYGB, malnutrition was the most common indication for reversal (12.3%), followed by severe dumping syndrome (9.4%), postprandial hypoglycemia (8.5%), and excessive weight loss (8.5%).

Reversal of RYGB involves the reconstruction of the stomach by means of anastomosis of the gastric pouch with the body (Fig. 2b) or with the fundus (Fig. 2c) of the remnant stomach, in addition to reconstruction of the small bowel continuity (Himpens et al. 2006). Measurement of the total length of the small bowel is obligatory, and the AL must be preserved, especially if longer than 100 cm (Vilallonga et al. 2016).

Reports of RYGB reversal include resection of the primary gastrojejunal anastomosis, what may eliminate or reduce the restrictive component of the operation, and reconstruction of the small bowel continuity, what abolishes the malabsorptive component. However, some related articles do not mention the extension of the AL and the CC in the primary operation nor whether intestinal restoration was associated with reconstruction of the stomach.

Results of reviewed studies evaluating procedures for PCM after RYGB are shown in Table 1.

The indications of RYGB revision procedures to treat PCM had an ample variation rate, from 4% (Zaveri et al. 2016) up to 58% (Chen et al. 2016). This difference was probably due to the variations in the series of patients studied or in the criteria adopted to establish the need for reoperation. Most of the articles do not make any reference to the severity of malnutrition. Several authors stressed the need for gastrostomy feeding in the preoperative and occasionally postoperative nutritional support. The reversal was the most common revision operation performed for the treatment of malnutrition reported in those publications, except for two cases in which the reoperation was an SG and one case which was a jejunal interposition. On some occasions, when weight regains were anticipated, reversal was complemented by an SG during the procedure, although this may increase the possibility of complications (Vilallonga et al. 2013). No mortality was referred after the revision procedures as treatment for PCM, and they generally involve short follow-up. These results favor the surgical revision procedures to treat selected cases of PCM. General results showed malnutrition and short gut syndrome resolution after the RYGB revision surgery. Jejunal interposition and intestinal restoration can also be efficacious to treat PCM after RYGB (Ceneviva et al. 2016). The significant variation of follow-up duration seems to explain different outcomes, mainly related to complications. Early postoperative assessment may fail to show complications, such as weight regain. In a recent review evaluating 100 reversals of RYGB to normal anatomy, followed up to 48 months, Shoar et al. (2016) reported a significant rate

of unfavorable results: weight regain (28.8%), severe gastroesophageal disease (10.2%), and abdominal pain (6.8%). RYGB reversal to normal anatomy, as with the reversal of other bariatric procedures, may result in weight regain and recurrence of obesity-related comorbid conditions (Pernar et al. 2016). However, there are particular circumstances in which the reversal of RYGB cannot be avoided (Chousleb et al. 2012). Judicious patient selection must be considered, due to the high incidence of weight regain after RYGB reversal (Shoar et al. 2016). RYGB reversal should be performed especially by experienced bariatric surgeons (Park and Kim 2014).

Conversion of RYGB to Sleeve Gastrectomy

The conversion to SG (Fig. 2d) associated with the restoration of intestinal continuity has the objective of reversing the malabsorptive effects of the partial exclusion of the intestine while maintaining the restrictive effect of the SG. As shown by Chen et al. (2016), the main reasons for conversion to SG in 49 of 2382 patients submitted to RYGB and miniRYGB were malnutrition (58%), weight regain (10%), food intolerance (18%), and others (14%). The conversion resulted in the improvement of malnutrition with no mortality, however with a high rate of early complications such as leakage (6.8%) and internal bleeding (5.1%) (Shoar et al. 2016).

Interposition of a Jejune Loop Between the Gastric Pouch and the Duodenum

Sometimes it is not easy to clarify the cause of PCM after RYGB, what explains the difficulty surgeons often have in choosing which revision process should be used in cases of SPCM refractory to medical treatment.

Many surgeons perform gastric bypass surgery in a conventional manner with a BPL of 50–70 cm and an AL of 100–150 cm, usually without worrying about how much of the CC should remain. This happens because with the small bowel with a length of more than 500 cm or 600 cm, as is usually the case, the expectation is that at least 280 cm of the CC will remain to prevent excessive malabsorption. The small bowel, however, may be shorter than 500 cm, and, depending on its length, standard RYGB can result in a CC length close to 100 cm or less, thus exacerbating malabsorption and favoring the development of PCM. Furthermore, if the small bowel is very short, for example, with a jejunoileal length of less than 300 cm, RYGB can result in short bowel syndrome and consequent PCM (Malinowski 2006), even when a CC of more than 150 cm is constructed (Ceneviva et al. 2016). The interposition of a jejune loop between the proximal gastric pouch and the duodenum was proposed for a patient with SPCM after RYGB, with a CC length of 180 cm and a total jejunoileal length of only 300 cm. The aim was to maintain the restrictive component and to increase the absorptive area by including the duodenum and proximal jejunum, as they are significant intestinal segments in the alimentary tract for nutrient absorption (Ceneviva et al. 2016). The surgical technique with interposition of a shorter jejune loop (Fig. 2e) involves the section of the AL of RYGB at 20–30 cm from the gastrojejunal anastomosis, with the jejunojejunal anastomosis being reversed by a section of the BPL and food transit being reinstated with a jejunoduodenal anastomosis and a jejunojejunal anastomosis. When the AL is

relatively short, jejunal interposition may be performed by sectioning that loop close to the jejunojejunal anastomosis and then anastomosing it to the second portion of the duodenum (Fig. 2f). Jejunal interposition and intestinal restoration eliminate almost the entire malabsorptive component of RYGB and have the advantage of maintaining the restriction conferred by the gastric capacity reduction and the gastrojejunal anastomosis.

Distal Roux-en-Y Gastric Bypass

Malnutrition, more frequently associated with malabsorptive procedures (DRYG, BPD, and BPD/DS), is the late complication of bariatric surgery that most requires revision. The appropriate revision procedure is performed either to increase the length of the common limb or reverse the intestine to its original anatomy. Reversal is rarely indicated because of the consequent regain of lost weight and resumption of the previous comorbidities. Distal RYGB, performed with different lengths of the AL (150 cm or more) and of the CC (120 cm or less from the ileocecal valve), with the objective of adding malabsorption to standard RYGB, has been demonstrated to result in long-term weight loss in the super obese and morbidly obese patients. However, there has been a high incidence of protein malnutrition and deficiency of various micronutrients requiring revision in a significant number of cases (Fox et al.1996; Fobi et al. 2001; Ciovica et al. 2008; Pitt et al. 2016). Results of reviewed studies evaluating revision procedures for PCM after malabsorptive bariatric surgeries are shown in Table 2.

Several articles have shown the relationship between common channel length, weight loss, and malnutrition rate. Sugerman et al. (1997) found that all 5 patients submitted to DRYGB with 50 cm long CC developed PCM requiring revision procedure, whereas out of 22 patients with 150 cm long CC, only 3 (13.6%) developed PCM needing reoperation. Kellum et al. (2011) cited that out of 23 patients with a 50 cm long CC, 13 (56.5%) required revision as compared with 8 out of 25 (32%) with CC $\geq$ 100 cm. Stefanidis et al. (2011), in an evidence-based review, demonstrated a significant positive impact to exist on weight loss when the length of the CC approaches 100 cm. Based on their findings, these authors recommended that to obtain the benefit of malabsorption for weight loss after RYGB, surgeons should focus rather on CC length than on AL or BPL length. BPD/SS $\geq$ 200 mL and BPD/DS/CC = 100 cm decrease the risk of revision surgery. No consensus has been observed to exist about the optimal length of the limbs of RYGB (Tacchino 2015), probably because other factors are participating. One example is the association between patient height and total small bowel length demonstrated by Tacchino (2015), what suggests that those measurements can also be of help in deciding on the appropriate length of the loops.

In the treatment of PCM after DRYGB (Fig. 3a), the aim with the revision procedures is to increase the absorptive area of the intestine, by means of lengthening the common channel (Fig. 3b, c) or by performing a proximal enteroenterostomy (Scopinaro 2008; Appresai and Murr 2012) (Fig. 3d).

Some conclusions concerning DRYGB are common in the studies shown in Table 2: a short CC (= or < 100cm) DRYGB results in an increase in weight loss but at the

expense of an increased incidence of PCM and revision procedures requiring close monitoring and follow-up (Fox et al. 1996; Sugerman et al 1997; Kellum et al. 2011); results of CC lengthening revision to treat PCM are good. According to Sugerman et al. (1997), a 50 cm long CC results in unacceptable morbidity and mortality, and according to Kellum et al. (2011), DRYGB should not be the choice of primary operation for morbid or super obese patients.

Biliopancreatic Diversions

The prevalence of PCM after BPD or BPD/DS depends on the length of the common loop and ranges from 1% to 6% of the cases (Sudan and Jacobs 2011; Scopinaro 2006; Gagner 2010; Currò et al. 2015). Even though biliopancreatic diversion is one of the most efficacious surgical procedures for obesity, it is not very widespread because of the fear of long-term nutritional complications, besides complexity of the operation and lack of knowledge (Anderson et al. 2013; Ballesteros-Pomar et al. 2016). Despite the relatively small number of biliopancreatic diversions performed, the rates of revision surgery due to excessive protein malabsorption after those operations are relatively high. Topart and Becouarn (2015) found, in a review of 18 articles selected, a PCM rate of 10%; PCM was the cause for revision procedures up to 40–60% of the patients in 2 years after BPD and BPD/DS (Table 2). These authors also observed an incidence of those revision procedures to occur due to protein malabsorption of 3.0–18.5% after BPD and of 0.5–4.9% after BPD/DS. The prevalence of reversal surgeries is frequently reported to be in the 0.2–7.0% range after BPD. These rates are similar to those reported by other authors cited in Table 2. The prevalence of PCM after BPD or BPD/DS depends on the size of the stomach left and mainly on the length of the common loop and ranges from 1,4% (BPD/DS) to 21,7% (BPD) (Scopinaro et al. 2005; Scopinaro 2006; Marceau et al. 2009).

The revision procedures usually are common channel lengthening or enteroenterostomy and technically similar for BPD and BPD/DS. The length of the AL and of the CC has been, respectively, 200 cm and 50 cm for BPD and 200 cm and 100 cm for BPD/DS, although varying with the characteristics of the patient (Scopinaro 2008, 2012). Common channel lengthening is the revision procedure of choice for these diversions, usually with a 150 cm length for BPD and a 100 cm choice for BPD/DS, so that the length of the bowel in contact with food becomes 400 cm or longer with both techniques. The extension of CC lengthening reported in the literature varies among authors (Table 2), usually according to the severity of diarrhea and the occurrence or absence of associated PCM. Lengthening of the CC of the BPD (Fig. 4a) should be performed by proximally advancing the junction between AL and CC along the BPL as this will promote a greater increase of the absorptive area (Fig. 4b). The lengthening along the AL may be restricted to the rare cases of diarrhea due to excessive reduction of ileal absorption of bile salt (Fig. 4c) (Scopinaro 2008). The proximal enteroenterostomy is a simple and efficacious technique (Hamoui et al. 2007) (Fig. 4d). The longer the common channel, the greater the absorption capacity and the potential for PCM correction, but also the greater the possibility of weight regain.

The most frequently performed revision procedure for the treatment of PCM after standard RYGB is the reversal (Table 1) and for biliopancreatic diversions is the correction (Table 2). The term reversal of biliopancreatic diversion has been applied at times indistinctively to surgical revisions removing the malabsorptive component partially (proximal enteroenterostomy) or totally (anatomical continuity). It seems logical to restrict reversal or intestinal restoration after BPD to recover the entire absorptive area of the intestine, also including the duodenum in the food transit

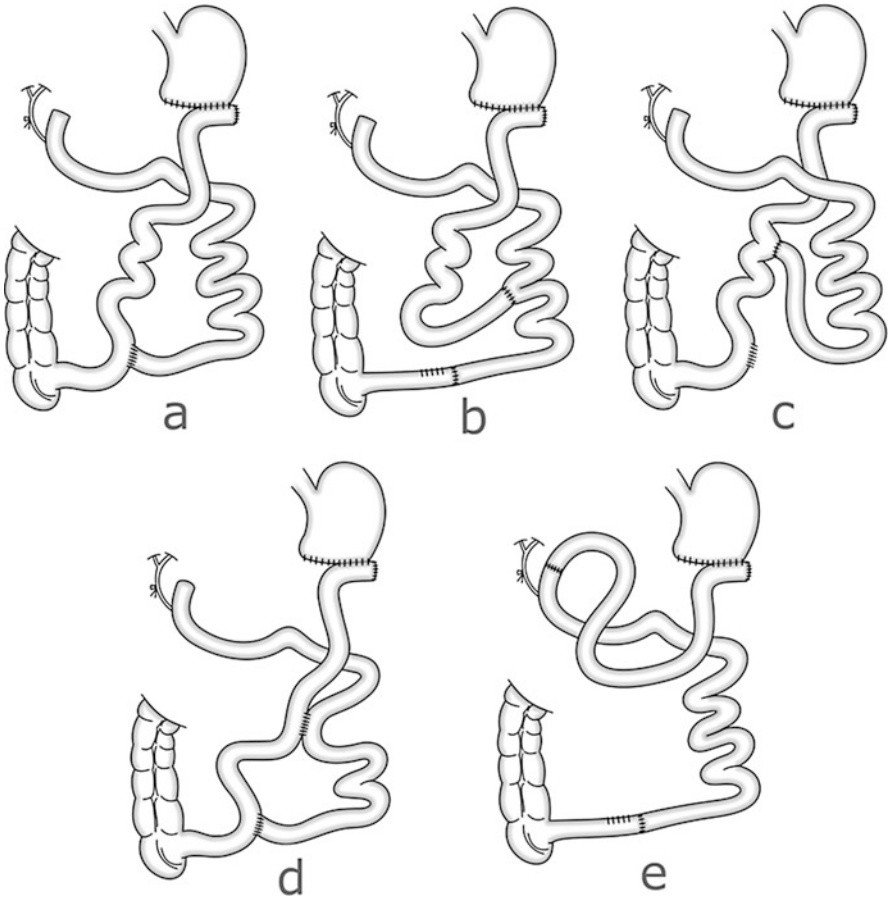

Fig. 4 Revision surgeries for biliopancreatic diversion. (**a**) BPD. (**b**) Elongation of about 150 cm of the common channel along the biliopancreatic limb. (**c**) Elongation of about 100 cm of the common channel along the alimentary limb. (**d**) Proximal enteroenterostomy close to angle of Treitz. (**e**) Restoration of the intestinal continuity

(Fig. 4e). The indications of reversal of biliopancreatic diversion are rare and usually performed after failure of revision (Scopinaro 2008). The procedure of choice for patients in hazardous physical condition is enteroenterostomy, which is faster to perform and less liable to postoperative complications. When malabsorption is serious, the enteroenterostomy should be performed close to the angle of Treitz. Some conclusions concerning BPD and BPD/DS have been drawn: BPD is a very efficacious surgery (Ballesteros-Pomar et al. 2016), and according to Scopinaro (2006), it is necessary to tailor the operation to the patient's characteristics, in order to achieve the best results with the minimum of complications; the BPD/DS is efficacious for all categories of morbidly obese patients, including the super obese (Hess et al. 2005); the DS improves the BPD, and according to Marceau et al. (2009)

and Sethi et al. (2016), it yields better results related to weight loss, revision, side effects, and absorption of nutrients.

Metabolic complications, including protein-calorie malnutrition, micronutrient deficiencies, and anemia, after bariatric procedures with a predominant malabsorptive component, can be fully reversed after appropriate lengthening of CC (Scopinaro 2008) and also after proximal enteroenteroanastomosis (Clare 1993; Appresai and Murr 2012) and reversal (Clare 1993).

Policies and Protocols

Policy

Prevalence of obesity is high and increasing worldwide, and in many countries, the supply of bariatric surgeries has not been enough to meet the existing demand. Patients who underwent bariatric surgery generally require medical follow-up throughout life, with more rigorous control in the first postoperative years. It should be advisable that the public health hospitals where bariatric surgeries are performed should be in charge of the postoperative control in the 1st years. However, it is not possible, due to the ever-increasing number of patients operated, to offer all necessary periodic follow-up. Thus, a scheme that has been followed at our Bariatric Centre provides clinical and hospital laboratory control at 1, 2, 3, 6, 12, 18, 24, and 36 months after surgery or at shorter intervals if needed. Then, if evolution is favorable, patients with good progress are counter-referred to the doctors who first referred them, instructing them through standard protocols containing guidelines on necessary follow-up, medication to be maintained, and exams to be requested in periodic checks. Those patients return to the hospital where they had been operated on at every 5 years after surgery or any time if the general practitioner deems it necessary. Schemes like this favor a better and sensible postoperative assistance to the patients and a standard survey of results.

Protocols

1. The preoperative preparation for bariatric surgery aims at improving the physical and psychic conditions of the patient. To reduce postoperative morbidity and mortality rates, the preoperative care should involve the treatment of frequent functional and metabolic disorders, such as severe sleep apnea and diabetes, as well as the improvement of the cardiorespiratory functional capacity through specific medical therapy, physiotherapy, and weight loss. By means of controlled diet and physical exercises, we aim, in the preparation for surgery, to reach, according to Tarnoff et al. (2008), a weight loss of about 10% and for the super obese (BMI > 50 kg/m^2) of 15%. This preparation is expected to result in several advantages: facilitation of surgical access, reduction in operative time, number and degree of complications, and length of hospitalization, besides contributing

to more rapid recovery and greater weight loss. Preoperative preparation may include the use of intragastric balloon to promote weight loss, particularly in patients with BMI $>$ 60 kg/m^2 and having uncontrolled comorbidities and/or difficulty to lose weight. The obese usually have inadequate eating habits, almost always eating hyper caloric diets and leading a sedentary lifestyle. It is important that they introduce the lifestyle changes already in the preoperative period, ingesting qualitatively and quantitatively correct food and doing regular physical activities, which should persist after surgery. The preparation time varies according to the patient's physical and psychic conditions and degree of engagement and may last a few to many months. Few patients, due to their bad health conditions, need a closer control with the use of the physiotherapeutic services of the Bariatric Centre itself.

2. The importance of adopting a healthy lifestyle before and after bariatric surgery has already been stated. Several schemes devised for losing and maintaining weight have been proposed. The WHO recommends doing moderate physical activity for 30–60 min a day, three times a week to maintain, and five or more times a week to lose weight. We follow a protocol for weight loss that includes physical exercises under the guidance of a physiotherapist and that has the following characteristics:
   - Frequency: 3 days a week up to 5–7 days a week.
   - Type of exercise: aerobic at least for 30 min and at most for 60 min, continuous or accumulated (walking, cycling, swimming, and/or water aerobics and treadmill, among others). Endurance exercises can be added to aerobic exercises.
   - Intensity: mild to moderate.
   - The exercise session should be divided into three stages: 5 min of warm-up, 50 min of constant intensity exercise, and 5 min of cooldown, plus stretches.
   - Wearing of loose clothes and comfortable shoes, preferably trainers, with soft soles and good impact absorption. Walking on stable surfaces.
   - Hydration before and during exercise.
   - The program should begin by doing a minimum of 30 min a day and increasing the session gradually up to the recommended 60 min.

The recommendation of rigid physical activity regimens for maintenance of weight loss is frequently difficult to follow by patients. It is important to know the limitations patients have to adapt their physical activity scheme, including by changing incidental and/or leisure activities.

Dictionary of Terms

- **Stenosis of the gastrojejunal anastomosis after gastric bypass** – a narrowing of the passage from the stomach pouch to the small intestine (gastrojejunal anastomosis). It is called anastomotic stenosis, also known as anastomotic stricture.

- **Laparotomy** – a surgical incision in the abdominal wall aiming at opening the peritoneal cavity, which offers surgeons a view inside the cavity, and being usually performed under general or regional anesthesia, with a therapeutic or exploratory purpose.
- **Gastroplasty** – any plastic surgery performed to reshape the stomach or repair any stomach defect or deformity. With respect to obesity, it is a surgical procedure to change the shape of the stomach aiming at limiting the gastric capacity and, therefore, reducing food ingestion. It is used in cases of severe obesity.
- **Gastrectomy** – a surgical procedure performed to remove all or part of the stomach.
- **Sleeve gastrectomy** – removal of the left portion of the stomach, performed typically in weight loss surgery, alone or combined with duodenal switch.
- **Distal gastrectomy** – removal of the distal portion of the stomach (the lower portion) in the biliopancreatic diversion (Scopinaro technique), used in cases of severe obesity.

Summary Points

- The demand for revision bariatric procedures increases with the increasing number of primary bariatric surgeries performed.
- Bariatric surgeries are an efficacious treatment for obesity, however are not free of early or late complications, including severe protein-calorie malnutrition.
- This chapter focuses on the surgical treatment of severe protein-calorie malnutrition (SPCM) after bariatric surgery, mainly on indications and surgical techniques used for revision.
- PCM after bariatric surgery may occur as a consequence of the restricted food ingestion and/or the malabsorptive effects of the bariatric surgery itself and also of other less frequent causes.
- The proposition of revision surgery should be made preferably by a health multidisciplinary team when there is an obstructive problem not solved by endoscopy or when there is a recognized failure of appropriate conservative treatment.
- An overview was given on the main surgical revision techniques.
- An attempt was made to describe the most accepted procedures by analyzing relevant published studies and the types of surgical treatment for SPCM after bariatric surgery.
- Surgical treatment has some particularities related to the type of primary surgery performed and mainly to the causes of the PCM.
- There are few clinical indicators or studies that guide strategies for the treatment for SPCM after standard Roux-en-Y gastric bypass.
- For malabsorptive surgeries, however, it is well established that the revision procedure of choice is the elongation of the common channel.

Abstract

Undernutrition is a consequence of an unbalance between supply of nutrients/energy and the demand of the body to ensure its functions and growth. It has deleterious effects on the development of organs and growth, generating stunting and underweight in childhood. Globally, about 159 million children (<5 years of age) have stunting, and more than 50 million are underweight.

Undernutrition undermines economic growth, perpetuates poverty, and is associated with the development of noncommunicable diseases in the long term. Several studies have demonstrated that fetuses and infants under a limited supply of nutrients program their metabolism to ensure their survival by sparing energy and selectively preserving tissues and organs. This strategical programming results in specific metabolic and endocrine changes that remain throughout the life span and in the next generations. The aim of this chapter is to describe the major endocrine changes in undernutrition and, in addition, to present some results of an adequate recovery in height and weight in the first 5 years of life.

Keywords

Cortisol · IGF-1 · Thyroid hormones · Insulin · Leptin · Reproductive hormones · Undernutrition · Stunting · Low birth weight · Metabolic programming · Nutritional recovery

List of Abbreviations

ACTH	Adrenocorticotropic hormone
α-MSH	Alpha-melanocyte stimulating hormone
CART	Cocaine amphetamine-regulated transcript
CREN	Center for nutrition education and recovery
CRH	Corticotrophin-releasing hormone
FSH	Follicle stimulating hormone
GH	Growth hormone
GnRH	Gonadotropin-Releasing Hormone
GR	Glucocorticoid receptor
HOMA	Homeostasis model assessment
HPA	Hypothalamus-pituitary-adrenal
HPT	Hypothalamus-pituitary-thyroid
IGF	Insulin-like growth factor
LH	Luteinizing hormone
POMC	Proopiomelanocortin
T3	3,5,3′-Triiodothyronine
T4	3,5,3′,5′-Tetraiodothyronine (or thyroxine)

TNF	Tumor necrosis factor
TRH	Thyrotropin-releasing hormone
TSH	Thyroid stimulating hormone

Introduction

Undernutrition in the critical windows of body development promotes endocrine and metabolic changes to guarantee immediate survival that seems to have long-term deleterious effects (Martins et al. 2011). Some of these adaptations have programming effects that are being progressively clarified. Undernourished children and adolescents, for example, show metabolic and endocrine alterations that increase the risk of noncommunicable diseases (Reynolds 2013). Moreover, studies in short stature adults have demonstrated higher prevalence of diabetes, cardiovascular diseases, and obesity; and significantly lower labor capacity (Florêncio et al. 2008).

The aim of this chapter is to describe the major endocrine changes in undernutrition and, in addition, to present some results of an adequate recovery in height and weight in the first 5 years of life.

Hypothalamus-Pituitary-Thyroid Axis

3,5,3′-triiodothyronine (T3) and 3,5,3′,5′-tetraiodothyronine (T4) are the major hormones produced by the thyroid gland and have a significant role in several physiological processes such as linear growth, neural development, metabolic rate, and body temperature (McAninch and Bianco 2014). The thyroid produces T4 in higher concentrations than T3, but in peripheral tissues, T4 can be converted to T3, by deiodinases. T3 is the major active thyroid hormone. The production of these hormones is controlled by the hypothalamus-pituitary-thyroid (HPT) axis.

The hypothalamic arcuate nucleus integrates signals that originate in peripheral tissues, such as the hormones ghrelin, leptin, insulin, and the metabolites glucose and fatty acids. It responds to different conditions such as hunger or satiety by activating orexigenic neurohormones such as neuropeptide Y and agouti-related peptide, or anorexigenic hormones such as proopiomelanocortin (POMC), alpha-melanocyte stimulating hormone (α-MSH), and cocaine amphetamine-regulated transcript (CART), respectively (Joseph-Bravo et al. 2015). When orexigenic neurons are active, there is a decrease in TRH expression, while anorexigenic neurons activate TRH expression. In animals submitted to fasting, the central administration of α-MSH or CART avoids inhibition of TRH gene expression and can maintain or increase TRH release (Fekete and Lechan 2014). Fasting can also accelerate the inactivation of T4 and T3 by conjugation with glucuronic acid (McAninch and Bianco 2014). Lower concentrations of T4 and T3, such as observed in severe hypothyroidism, can decrease the total energy expenditure about 50% (McAninch

and Bianco 2014). These data together show the importance of the HPT axis in response to energy deficits.

Children with kwashiorkor, a severe form of undernutrition, show a decrease in circulating concentrations of T4 and T3 due to the decrease in the carrier proteins, thyroid hormone binding globulin and thyroid hormone binding prealbumin and albumin (Kumar et al. 2009).

The duration of undernutrition appears to be important in determining alterations in the HPT axis (Brown and Brasel 1990). In acute undernutrition, there is a reduction in total T3 and T4 concentrations secondary to the reduction on plasma proteins, with maintained euthyroid status, whereas prolonged and severe undernutrition damage the adaptive mechanisms resulting in hypothyroidism with low concentrations of free T3 and an increase of reverse T3 (inactive form) (Waterlow et al. 1992). The lower T3 reduces thermogenesis and oxygen consumption, which allows a better conservation of energy across the insufficiency of energy. In addition, the decrease in peripheral level (liver and kidney) of the enzyme activity that converts T4 to T3, 5′- deiodinase (which promotes the hormone action at the target cell) can contribute to the lower concentrations of thyroid hormones in undernutrition (Waterlow et al. 1992). Another physiological adaptation in undernourished children can be the inhibition of the thyroid function caused by higher activity of hypothalamus pituitary adrenal axis (HPA) (Joseph-Bravo et al. 2015).

It has been described that undernutrition during gestation programs thyroid status in adulthood. Women with low birth weight and low stature show increased risk of spontaneous hypothyroidism (Kajantie et al. 2006). One study with offspring rats undernourished during gestation and lactation found normal T4 and TSH but lower T3 at weaning, indicating normal thyroid status but decreased function in target tissues (Ayala-Moreno et al. 2013). The weaning animals then received ad libitum access to food and on the 90th day normal concentrations of T3, but lower free T4 and higher concentration of TSH were found compared to controls, indicating persistent thyroid impairment.

Stunting in less severely undernourished children promotes changes in thyroid status as well. Normal concentrations of TSH and free T3, but lower free T4, were found in stunted children when compared to nonstunted controls (Martins et al. 2016). Similar findings were observed in short stature Brazilian women (but not men) with overweight/obesity, since it was found lower T3 concentrations in these short stature women in comparison to overweight/obese women with normal stature (Sawaya et al. 2009).

Hypothalamus-Pituitary-Adrenal Axis

The adrenal gland produces the stress hormone cortisol through stimulation of HPA axis. Undernourished individuals have higher cortisol concentration (Romero et al. 2009). The production of cortisol depends on the release of corticotrophin-releasing hormone (CRH) by paraventricular nucleus in hypophyseal portal system that stimulates synthesis and secretion of adrenocorticotropic hormone (ACTH) by

adenohypophysis. ACTH then acts in the zona fasciculata of adrenal gland stimulating cortisol production (Gunnar and Quevedo 2007).

Cortisol has catabolic effects that are important during undernutrition, as it promotes the increase of gluconeogenic activity, proteolysis, and lipolysis. These effects are responsible to maintain normal glycemia and to ensure energy supply to the brain. Glucose is the major energetic substrate of the nervous system. Cortisol interacts with glucocorticoid receptors (GR) located in the cytosol and nucleus of the target cells to promote its effects. Marasmic children without infection show higher nuclear GR in leukocytes in comparison to well-nourished children with infection (Manary et al. 2006). However, cortisol concentrations in these children were lower than in those with marasmus and infection. This is important because it demonstrates that infection is a strong stimulus to increase cortisol concentrations. Moreover, the higher number of GR demonstrates that nutritional status modulates glucocorticoid receptor action, in addition to the increase in circulating glucocorticoid concentrations (Manary et al. 2006).

Changes in the epigenetic status of the GR were found in the liver of offspring rats that were fed a protein-restricted diet during the intrauterine period (Stevens et al. 2011). These animals showed a decreased GR methylation, with a 200% increase in GR expression in comparison to controls. Furthermore, these changes persisted in the offspring even though the dietary restriction had stopped, suggesting that the methylation status of genes is potentially permanent.

Epigenetic effects in cortisol response have also been described in human fetus that suffered intrauterine undernutrition (Weaver 2009). Children born at term but with low birth weight, for example, show higher cortisol concentration at 10 years of age (Cianfarani et al. 2002). Another example of the reprogramming of HPA axis is the change in the activity of the 11 Beta-hydroxysteroid dehydrogenase type 2 enzyme. This enzyme converts cortisol to cortisone and constitutes a placental barrier that protects the baby from the higher maternal cortisol concentration during stress conditions. Undernutrition promotes a down regulation of this enzyme and a fetal overexposure to maternal cortisol (Draper and Stewart 2005).

Higher maternal cortisol concentrations present in undernourished pregnant animals in the latter half of pregnancy contribute to change the set point of HPA axis in the offspring, making this axis more reactive to stress (Reynolds 2013). Thereafter, many studies have pointed out cortisol as one of those hormones responsible for the higher risk of noncommunicable diseases in adult life among undernourished individuals (Reynolds 2013).

Growth Hormone and Insulin-like Growth Factor-1 Axis

One of the most evident consequences of undernutrition is the restriction on linear growth. This is mainly a result of a disruption on the growth hormone (GH) –insulin-like growth factor-1 (IGF-1 or somatomedin C) axis. Children with marasmus or kwashiorkor have higher GH concentration, whereas the hepatic IGF-1 production is reduced when compared to normal children (Kilic et al. 2004). This can be explained

by a decreased negative feedback at the pituitary level due the lower concentration of IGF-1. IGF-1 acts in hypothalamus and pituitary decreasing secretion of growth hormone releasing hormone and GH, respectively. In addition, the lower IGF-1 concentrations, despite of higher GH, seem to be due to three factors: (1) lower expression of the hepatic GH receptor or defect in intracellular mechanisms postreceptor such as found in animal models of starvation and protein deficiency, respectively; (2) lower blood insulin and T3 concentrations (Fazeli and Klibanski 2014); and (3) lower essential amino acid concentrations (Thissen et al. 1999). This GH resistance allows the increase of lipolysis and gluconeogenesis and, consequently, brain energy availability (Fazeli and Klibanski 2014). The lower IGF-1 concentration, on the other hand, is an important determinant for the decrease in linear growth. For this reason, IGF-1 is considered a biomarker of nutritional status in children (Hawkes and Grimberg 2015).

Insulin and Glucose Metabolism

Changes in insulin concentration are common in undernourished individuals. Severe hypoglycemia is a signal commonly found in terminal cases, but in general, undernourished individuals show low or normal fasting glycemia concentrations accompanied by low insulin. The production of insulin by the pancreas appears to be particularly affected. Lower insulin release following oral glucose tolerance test was observed among undernourished children (Das et al. 1998). In addition, a decreased activity of beta-cell function was found in stunted adolescents (Martins and Sawaya 2006) (Fig. 1).

The alterations in glucose and insulin metabolism seem to have a programming effect as well. Higher insulin sensitivity was observed in small for gestational age newborns (Soto et al. 2003). A study in Brazilian stunted adolescents found higher insulin sensitivity (HOMA-S) as well as lower insulin production (HOMA-B) (Fig. 1). Other studies found that undernutrition in the first year of life independent of the birth weight was associated with higher insulin concentration and lower insulin sensitivity, which worsened as BMI increased in adult life (González-Barranco et al. 2003). Brazilian adult women with short stature and obesity showed higher insulin resistance, together with altered glycemic and lipid profile, in relation to obese normal height women (Florêncio et al. 2007). Although an increase in total body mass was associated with a moderate decline in peripheral insulin sensitivity, abdominal obesity showed a much steeper decline in insulin sensitivity and was accompanied by reduced peripheral glucose stimulation and insulin production. In addition, compared to women of medium height, women with short stature had higher concentrations of glycated hemoglobin, total cholesterol, and LDL, whereas HDL cholesterol concentrations were significantly lower. Stature was identified as the main factor associated with insulin resistance. These findings demonstrate that undernutrition when associated with overweight generates worst metabolic consequences in comparison to normal height individuals with overweight.

Changes in the metabolism of glucose and insulin may also be observed in subjects with mild stunting (height for age between −2 and −1 Z score). Overweight

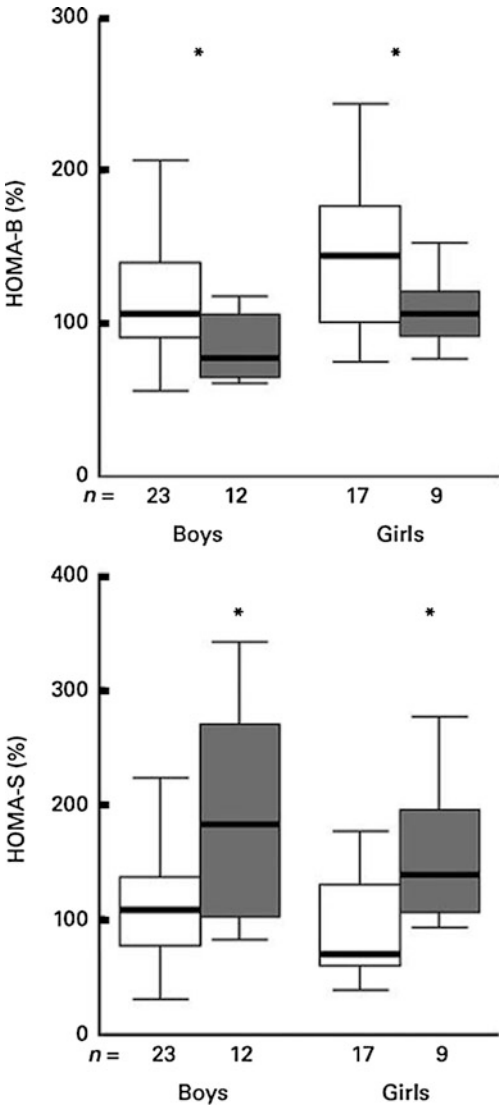

Fig. 1 Insulin production and sensitivity in stunted and well-nourished children. Homeostasis model assessment for pancreatic beta-cell function (*HOMA-B*) and for insulin sensitivity (*HOMA-S*) values of stunted (*black box*) and nonstunted (*white box*) boys and girls. The box represents the interquartile range which contains 50% of the values, the vertical bars indicate the highest and lowest values (excluding outliers) and the line across the box indicates the median. Significant difference between groups: $*P < 0.05$. Lower HOMA-B means lower insulin production and higher HOMA-S show higher insulin sensitivity, both in stunted children (Reprinted with permission from British Journal of Nutrition (2006), 95, 996–1001)

Brazilian adolescents with mild stunting showed higher blood glucose, insulin resistance, and lower insulin production (da Luz Santos et al. 2010). Moreover, adolescents with mild stunting presented elevated insulin concentration at a lower waist circumference deciles compared with nonstunted subjects (Fig. 2) (Clemente et al. 2014). The authors suggested that the increase in plasma insulin is one of the primary metabolic deviations that occur in stunted individuals and may be associated with the elevated risk of insulin resistance and diabetes found in short stature adults.

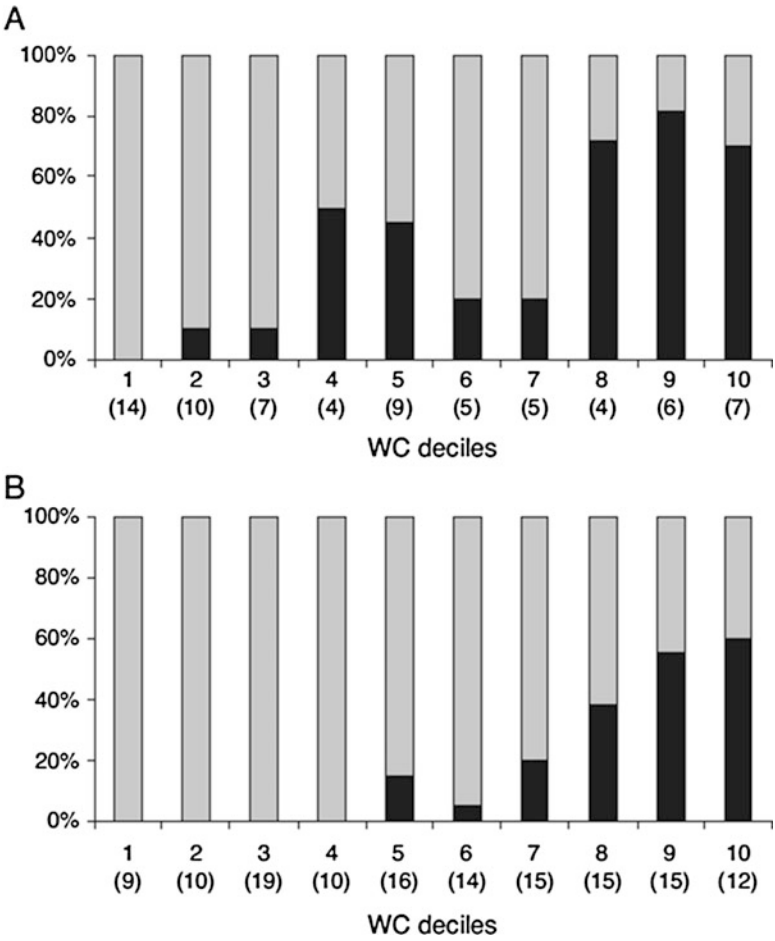

Fig. 2 Relationship between waist circumference and elevated insulin in stunted and well-nourished children. Distribution of stunted (**a**) and nonstunted (**b**) individuals according to waist circumference (*WC*) deciles and their respective prevalences of elevated insulin concentrations: (*black box*) > 75th percentile; (*gray box*) ≤75th percentile. The WC deciles correspond to the following absolute values of stature of studied population: (*1*) 53 cm, (*2*) 55.90 cm, (*3*) 57.50 cm, (*4*) 59.50 cm, (*5*) 62 cm, (*6*) 65 cm, (*7*) 68 cm, (*8*) 71 cm, (*9*) 76.74 cm. The numbers between parentheses represent the number of individuals of the sample in each decile of WC (Reprinted with permission from J Pediatr (Rio J). 2014;90(5):479–485)

Leptin

The use of fat stores is essential in situations of food restriction and undernutrition. Adipose tissue is the local synthesis of many hormones such as leptin, adiponectin, plasminogen activator inhibitor-1 (PAI-1), and others, which are collectively referred

to as adipokines. Leptin is considered an adipostat signal because it provides a good measure of the volume of the adipose tissue (Park and Ahima 2015).

Leptin is regulated by peripheral factors such as insulin, cortisol, estrogens and tumor necrosis factor alpha (TNF-alpha) (Park and Ahima 2015). It acts particularly at the hypothalamic level through binding to the ObRb receptor (Park and Ahima 2015); and its main action is to regulate (stimulatory effect) the expression of the anorexigenic peptides and inhibit orexigenic hormones in the nucleus arcuate. Leptin acts synergistically with the peripheral hormonal signals to influence the release or inhibition of these peptides and, consequently, the regulation of energy expenditure and eating behavior.

Leptin is considered a "starvation hormone" because of its strong signaling action in the central nervous system in energy deficit and the activation of counterregulatory mechanisms to conserve energy as the reduction of thyroid hormones, basal metabolic rate, and protein turnover (Prentice et al. 2002). Leptin also plays an important role in the control of linear growth, pubertal development, cardiovascular and immune function (Soliman et al. 2012).

Studies in children with kwashiorkor or marasmus have demonstrated lower leptin concentrations compared to healthy children (Soliman et al. 2000). Similar findings have also been observed in Brazilian children with mild to moderate undernutrition (Martins et al. 2014).

Reproductive Hormones

Undernourished children have delayed puberty and lower concentrations of FSH (Follicle Stimulating Hormone) and LH (Luteinizing Hormone) (Iwasa et al. 2015). The decrease in these hormones contributes to a delay in the menarche. It is well established that the organism has to reach a critical weight and body size for the initiation of puberty, regardless of the age at which started the spurt of adolescence growth, and leptin plays a key role in this mechanism (Iwasa et al. 2015). As the leptin concentrations are lower in undernourished individuals, the excitatory effect of leptin in the GnRH expression is impaired. In this condition, the activity of hypothalamus pituitary gonadal axis is decreased, explaining at least in part the delay in pubertal developmental in undernourished adolescents (Iwasa et al. 2015).

The major endocrine changes in undernutrition are summarized in Figs. 3 and 4.

Metabolic Programming

Changes in Body Composition

Undernutrition promotes long-term changes in body composition, by increasing central fat mass, and therefore, ensuring fast availability of energy (Martins et al. 2004; Hoffman et al. 2007). Undernourished children have also lower resting metabolic rate associated with lower lean mass and this decrease in energy expenditure helps the

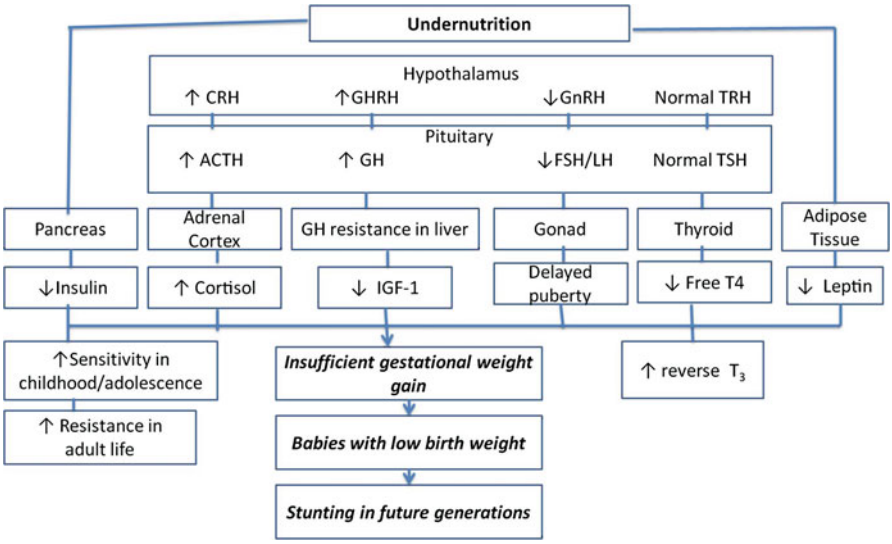

Fig. 3 Major endocrine changes found in undernutrition. These changes are associated with increased risk of development of noncommunicable diseases in adulthood and may impact next generations

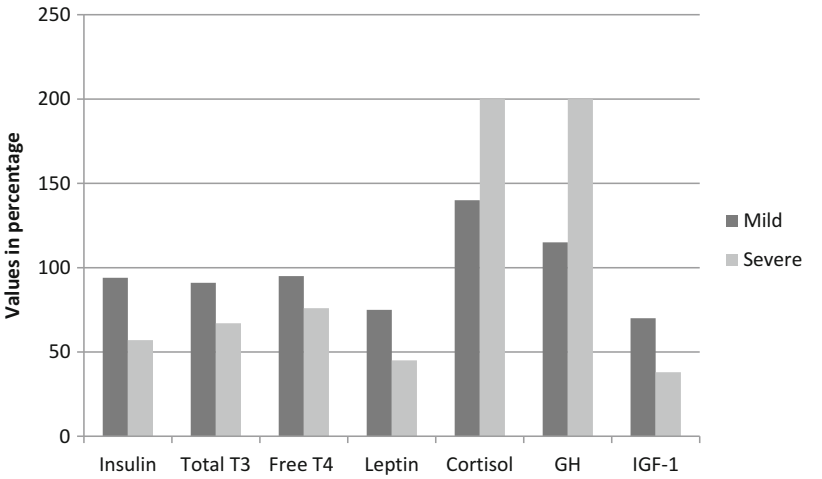

Fig. 4 Changes in hormonal concentrations in children that suffer mild or severe undernutrition. Hormonal concentrations are presented in percentage of normal hormone concentration (100%). Leptin, GH, and IGF-1 concentrations are influenced by age and gender. Cortisol concentration is positively associated to the degree infection. The increase or decrease in hormone concentrations depends of the degree of undernutrition, energy balance and protein intake. For example, acute severe undernutrition (72 h) can promote wide hormonal changes such as 75% decrease in leptin (accompanied by a weight loss). Children with kwashiorkor have high GH concentration and when treated with protein during 3 days show 50% decrease on GH concentration. This decrease does not occur when the children are treated with carbohydrate only

increase in fat mass (Soares-Wynter and Walker 1996; Sawaya et al. 2003). In addition, smaller increments in bone mineral density were described in undernourished adolescents of both sexes during prospective studies (Martins et al. 2011). A decrease in fat oxidation was also identified (Hoffman et al. 2000). These findings demonstrate that in environmental conditions where the consumption of energy and nutrients is insufficient or inadequate, the organism prefers to reduce growth and energy expenditure, while at the same time activating mechanisms of energy conservation.

Hypertension

High prevalence of hypertension has been found in children, adolescents (Fernandes et al. 2003), and adults (Florêncio et al. 2004) that suffer undernutrition. Intrauterine development of the kidney is particularly affected by maternal undernutrition due to the lower number of nephrons formed (Hinchliffe et al. 1992). The renal structure and specifically the number of nephrons are some of the main determinants of blood pressure and renal function, so that individuals with low numbers of nephrons have a predisposition to hypertension.

Maternal short stature is independently associated with obesity, abdominal obesity, and increased blood pressure and is an important determinant of children's health, as it is associated with low birth weight and stunting (Ferreira et al. 2009).

Some mechanisms have been proposed to explain the development of hypertension in this population. A deficit in elastin synthesis of the aortic wall and large vessels was described, and this deficiency may cause changes in the mechanical properties of the vessel (Martyn and Greenwald 2001). Changes in the renin-angiotensin-aldosterone and sympathoadrenal system also have been found. Girls born small for gestational age showed increased noradrenaline concentration when compared to those born with adequate weight for gestational age (Franco et al. 2008). The boys, on the other hand, showed increased activity of the angiotensin-converting enzyme and higher angiotensin II activity.

Diabetes

It is known that poor countries with accelerated urbanization have shown an increase in the prevalence of type 2 diabetes (Yajnik 2004). Diabetes among Ethiopian adults, for example, was shown to be associated with a history of undernutrition and lack of basic sanitation in childhood, reinforcing the importance of adequate postnatal development for long-term health maintenance (Fekadu et al. 2010). Adults who suffered intrauterine growth restriction have also higher risk of development of diabetes (Forsén et al. 2000).

Nutritional Recovery

One of the biological variables that have the greatest impact on the long-term health is stature. Special attention to the quality of the diet is then essential during nutritional recovery, especially in the quality of the protein intake, to allow the

gain in stature without an exaggerated increase in the energy supply. As an example, undernourished school-aged children treated with high-protein diet showed an increase in height directly related to the amount of protein supplementation compared to a group fed an oil-added diet (Kabir et al. 1998). Refeeding these children with normocaloric and normoprotein diet increased IGF-1 concentrations after 5 days by up to 70% of the basal levels before feed restriction, whereas refeeding with isocaloric but hypoprotein diet delayed recovery in IGF-1 for 2 days, and the concentrations of these hormones did not reach 50% of the prerestriction values (Thissen et al. 1999).

One strategy to adequate recovery in height and weight of undernourished children is the investment in the creation of rehabilitation centers with outpatient and day-hospital services. Few decades ago, some rehabilitation centers were established in Brazil in Southeast area in the city of São Paulo, and later in Northeast area, in the city of Maceió, one of the poorest areas of the country. These centers are called Centers for Nutrition Education and Recovery (CREN). They offer treatment to thousands of undernourished children living in urban slums every year. In the box, there is a detailed description of the methodology of the treatment developed at CREN in Brazil, aiming the recovery of height as well as weight.

Policies and Protocols

CREN Treatment Protocol at day Hospital

Active search is an important aspect of the CREN methodology to find undernourished children directly at the community level (Fig. 5). After identifying children with underweight and/or stunting by anthropometric census, families are visited at home and invited to CREN for treatment.

Any child under 5 years of age with weight-for-height and/or height-for-age Z score < -2.00 is eligible for day-hospital treatment. Children that present diseases which potentially could affect linear growth (e.g., hypothyroidism, deficiency of growth hormone, congenital cardiac diseases, genetic syndromes, or cystic fibrosis) are referred to other health services.

The daily follow-up aims at providing an overall improvement of the nutritional, cognitive, motor, psychological, and social status. The children stay at the center, from Mondays to Fridays, from 7:30 to 17:30. During the day, they engage in educational activities and are divided into groups of approximately 15 children, according to their ages. Pediatricians, nurses, dieticians, social workers, psychologists, and teachers participate in the treatment. The intervention included treatment of all diagnosed infections and other conditions, such as anemia and a diet that rotated daily every 11 weeks, as follows:

7:30–8:30: Patients are admitted. Breakfast (one serving of dairy and carbohydrates, such as bread, biscuits, or cake).
9:00: Snack (one serving of fruit).

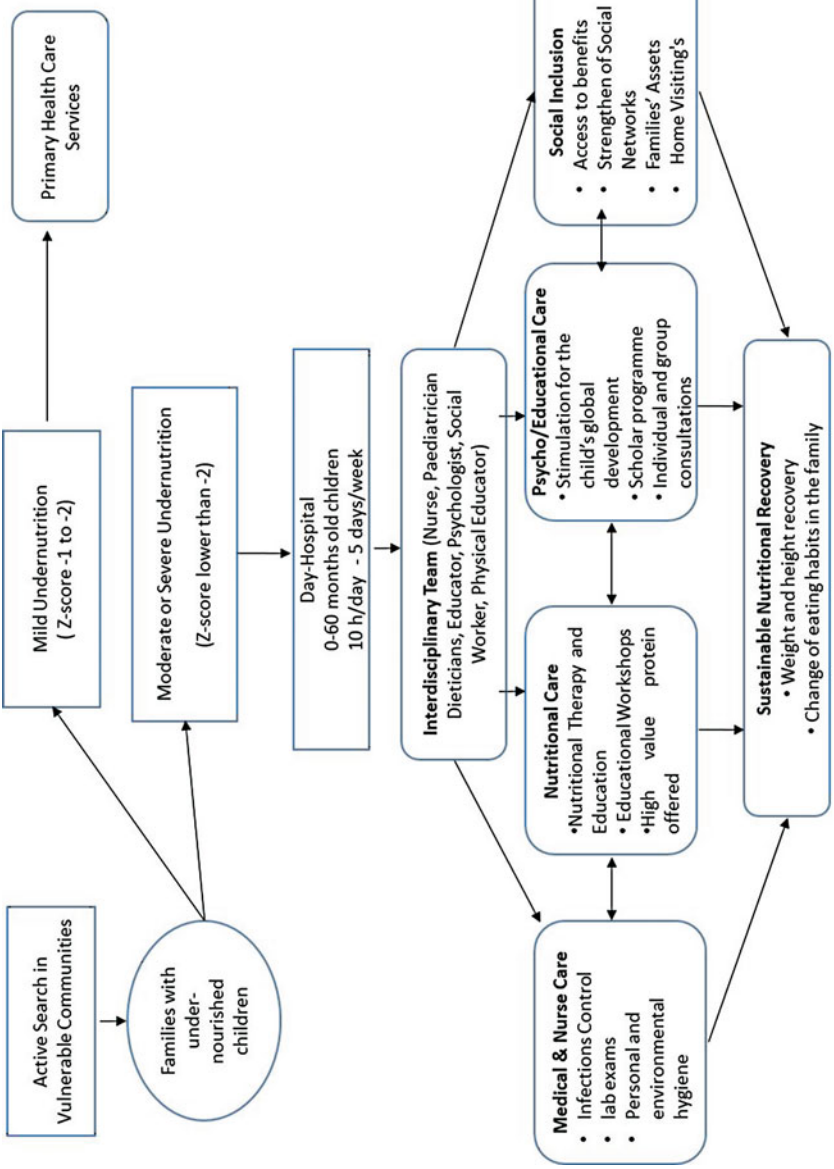

Fig. 5 Flow of day hospital treatment for undernourished children at CREN. For adequate treatment of undernourished children, an interdisciplinary team is necessary

11:30: Lunch: Rice, beans, meat or eggs, salad, and cooked vegetables with a dessert of fruit.
12:00: Nap.
13:30: Afternoon activity period.
14:00: Snack (one serving of dairy).
16:00: Afternoon meal: Rice, beans, protein (fish, beef, chicken, or pork), salad, and cooked vegetables with a dessert of fruit.
17:30: Return to home.

All children receive five meals each weekday using traditional Brazilian food such as: rice, beans, meat, fruit, and vegetables. Ultraprocessed foods are excluded. Meals are provided to meet 70% of daily energy requirements, 100% of daily dietary protein using biological high-value protein (meat, eggs, and milk), and recommended fiber intake according to the Dietary Reference Intake (Trumbo 2002). The meals provided to children supply approximately the following macronutrient composition as percent of total calories for children 6–12 months, 1–3, and 4–8 years of age, respectively: 45% carbohydrates, 15% protein, and 40% fat; 55% carbohydrates, 15% protein, and 20% fat; and 57% carbohydrates, 17% protein, and 18% fat. The family of each child is instructed to offer two more meals at home. Infant formulas are used for children less than 1 year of age who are no longer breastfed. Food supplements or special formulas are not used.

Micronutrient supplements like iron (Wayhs et al. 2012), zinc (Trumbo et al. 2001), and vitamins are used in prophylactic doses. Higher doses are used in cases of deficiency, with clinical or laboratory evidence, according to the recommendations of the Brazilian Pediatric Society (Wayhs et al. 2012; de Paula et al. 2016).

A pediatrician monitored the clinical status, laboratory results, and anthropometric progress of each child on a daily basis during their treatment at CREN as follows:

7:30–8:30: Patients are admitted and undergo a preliminary exam by nurses and are referred to the attending pediatrician for a physical exam. When health problems are detected, antibiotics, bronchodilators, and/or other necessary medications are prescribed.
9:00: Micronutrient supplementation: Vitamin complexes (A, B, C, and D) and Zn are provided to all children. Iron is provided according to age and laboratory test results. Administration of medications to patients as needed.
12:00: Oral hygiene and nap.
13:00: Monitoring of vital signs during sleep (i.e., temperature, pulse, and respiratory rate) and bathroom break (monitoring and recording of bowel movements and urination).
15:00: Administration of medications to patients as needed.
16:45: Oral hygiene and bathroom break (monitoring and recording of bowel movements and urination).
17:15: Consulting period with nurses to determine follow-up of medication protocol and continuation of basic health care at home for patients receiving medications.

Nutritional Education

An important aspect of CREN's intervention is nutritional education. The children participate in nutrition education workshops according to the psychomotor and cognitive readiness with the objective of facing the feeding problems. The contents of these workshops aim at the knowledge of the varieties of fruits and vegetables, to promote the neuropsychomotor development, improving the relationship between child and food, enhancing palatability, and promoting the development of good eating habits. Parents are also involved in treatment in frequent activities through the participation in regular nutrition education workshops for reinforcement of nutrition, for the expansion of its social networks and for health advice. Novel foods are also displayed during these meetings.

Monitoring and Treating Infectious Diseases

Children are monitored for infections on daily basis. Parents and caregivers are required as to the presence of symptoms such as fever, cough, runny nose, dyspnea, vomiting, diarrhea, or presence of worms in the stool. Positive responses are recorded. Diagnosis is recorded along with notation of medications prescribed. Intestinal parasites are confirmed by testing of stool sample or by maternal report of occurrence of intense anal itching or elimination of worms in feces. All children admitted at the Day Hospital receive deworming medication.

Discharge

Discharge from the day-hospital occur when the child reaches the weight and height for age greater than −1.64 Z scores or when they reach the age to enter regular school (6 years). Following discharge, the child continues to receive treatment using an established outpatient regimen.

A description of the nutritional and health outcomes of a sample of children treated at CREN showed that 92.5% of the children recovered at least one anthropometric index and 67.9% recovered weight and height (Alves Vieira et al. 2010). Almost half of the children presented nutritional recovery of more than 0.50 Z score in height for age (46.2%) and about 40% in weight for age (38.7%). The mean age at admission was 23.7 months, with an equal proportion of boys and girls. The mean duration of treatment was 16.4 months for all children, and the longer treatment time was associated with higher weight for age and height for age increases. The mean birth weight was 2563 g, and approximately 40% of the children were classified as low birth weight. The gain in stature was statistically different according to the birth weight, being greater among those who were born smaller. The most prevalent diseases during treatment were upper respiratory infections, and 82% of children showed at least one episode, 44% had diarrhea, and 18% had lower respiratory tract infections.

Recovered children at CREN present increase in height for age greater than weight for age, in general. Past studies showed normalization of body composition

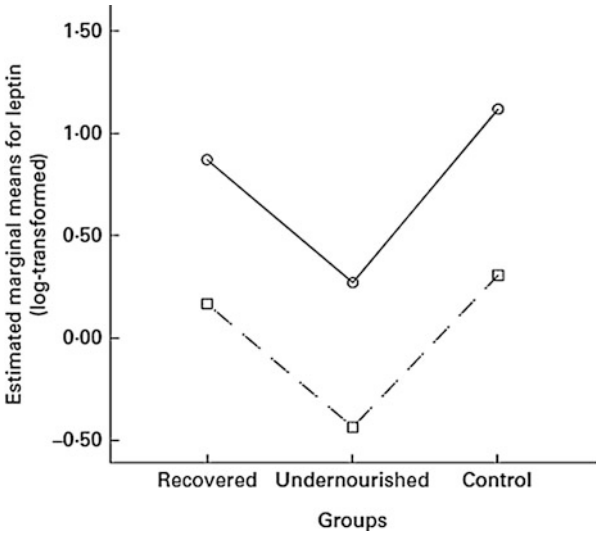

Fig. 6 Serum leptin concentrations in children recovered from undernutrition, undernourished, and well-nourished children. Boys (*dotted line*) have significantly lower leptin concentrations than girls (*continuous line*). Leptin concentrations in both sexes in the undernourished group were significantly lower than those in the other two groups. The scale is in logarithms (Reprinted with permission from British Journal of Nutrition (2014), 112, 937–944)

and bone mass (das Neves et al. 2006). In terms of food consumption, a study found higher protein intake in recovered children, compared to a control nontreated group of children living in the same poor communities, even after 6 years of discharge. Moreover, recovered children demonstrated normalization of insulin and glucose metabolism (Martins et al. 2008), and normal leptin concentrations in both sexes (Fig. 6) (Martins et al. 2014).

A study performed with the objective of determining cortisol activity found lower cortisol response after recovery comparing to undernourished children, but similar to that of well-nourished controls, indicating a normal HPA response after treatment (Martins et al. 2016). The daily cortisol response was also measured after an unpleasant stimulus (immersing the right hand in cold water for 1 min, at 10:00 h) (Fig. 7) and a pleasant stimulus (watching a video with pictures of nature at 14:00 h) (Fig. 8). After the application of the unpleasant stimulus, there was an increase in cortisol for all children (controls, stunting, and underweight) with exception of the recovered ones. No significant differences were found between groups in terms of response to the pleasant stimulus, with exception of a slight elevation in cortisol concentrations among undernourished children.

Another interesting result was lower free T4 concentrations in the recovered children in comparison to controls (Martins et al. 2016). This can indicate a programming effect that may lead to future accumulation of body fat, and this justifies the maintenance of a continuous observation of anthropometric and clinical indicators as well as encouragement for healthy lifestyles in these children.

In conclusion, programs and policies should be designed to prevent undernutrition taking into account the findings on its long-term effects on the health of the world's low-income population.

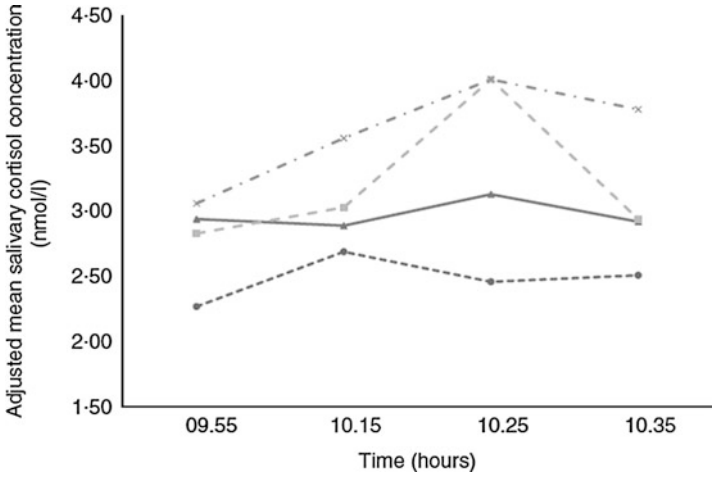

Fig. 7 Salivary cortisol concentrations in children recovered from undernutrition, undernourished, and well-nourished children submitted to unpleasant stimulus (cold pressor test). Salivary cortisol concentrations were similar in all groups before the application of the stimulus and increased after the unpleasant stimulus in the control, stunted, and underweight groups but not in the recovered group. Control; stunted; underweight; recovered (Reprinted with permission from Br J Nutr. 2016 14;115(1):14–23)

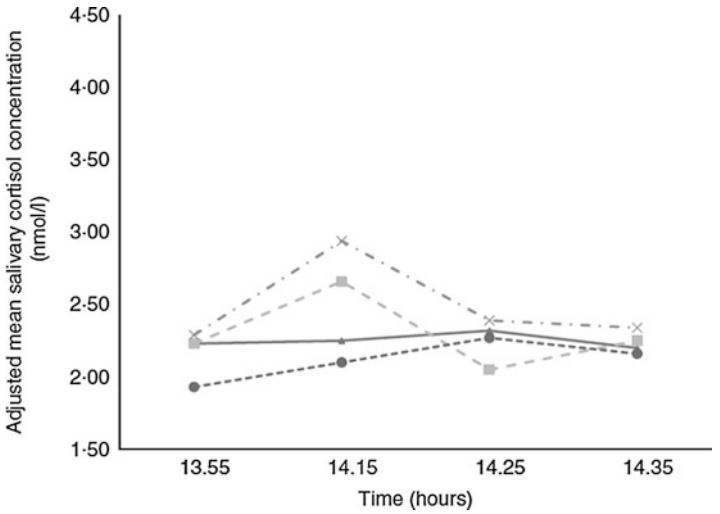

Fig. 8 Salivary cortisol concentrations in children recovered from undernutrition, undernourished, and well-nourished children submitted to pleasant stimulus (pictures of nature). No differences were found between groups in terms of response to the pleasant stimulus; however, the undernourished groups showed an increase of salivary cortisol after the pleasant stimulus in comparison with the recovered and control groups. Control; stunted; underweight; recovered (Reprinted with permission from Br J Nutr. 2016 14;115(1):14–23)

Dictionary of Terms

- **Undernutrition** – Refers to children with low weight for age, short stature for age or stunting.
- **Basal metabolic rate** – Oxygen consumption in total rest, refers to basal energy expenditure (after 12 h of fasting and 8 h of sleep).
- **Resting metabolic rate** – Oxygen consumption measured in recumbent position. This value is higher than basal metabolic rate.
- **Programming** – Adaptation to any kind of biological or psychological insult (low supply of nutrients and energy, for example) that occurs during critical periods of body development (intrauterine or postnatal period). This metabolic adaptation, at one hand, allows the individual to survive, but at the cost of permanent changes in the morphology and physiology of organs.
- **Z-score** – Can be positive or negative, with a positive value indicating the score is above the mean and a negative score indicating it is below the mean. Positive and negative scores reveal the number of standard deviations; the score is either above or below the mean.

Summary Points

- Undernutrition in early life promotes morphological and physiological changes associated with programming effects and noncommunicable diseases in adulthood.
- Undernourished children, adolescents, and adults show lower thyroid hormone activity.
- There is a marked decrease in IGF-1 in undernutrition, although higher GH concentrations can be observed.
- Undernutrition is a major form of stress and, therefore, shows higher cortisol concentrations.
- Undernourished children have normal/low glucose concentrations, lower insulin production, and higher insulin sensibility. This condition is associated with the development of insulin resistance in adulthood and diabetes.
- Lower concentrations of leptin can be observed in undernourished children.
- Undernourished children have delayed puberty and lower concentrations of FSH and LH.
- Undernutrition in early life is associated with the development of hypertension in adult life.
- Undernutrition in children promote changes in body composition. Higher fat mass and lower lean mass can be observed in stunted children.
- Adequate treatment is important to ensure recovery of height and weight. Recovered children show normal insulin, leptin, and cortisol concentrations.

Contents

Abstract

Research on animals has revealed multiple mechanisms, brain circuits, and peripheral signals that coordinate energy homeostasis. This review summarizes information relevant to the hypothalamic-pituitary-thyroid axis, one of the outputs that the central nervous system uses to control energy utilization. It is hierarchically organized and controlled by paraventricular nucleus hypophysiotropic thyrotropin-releasing hormone neurons integrating central and

peripheral information. These neurons regulate thyrotropin secretion from anterior pituitary and thyroid hormone production. Tissue concentrations of thyroid hormones depend in addition on transporters and deiodinases expressed by target tissues. Thyroid hormones control basal metabolic rate, thermogenesis, lipolysis, and glycolysis, as well as the development and performance of immune and nervous systems; they exert feedback control on the axis at multiple levels. Fasting, food restriction, malnutrition, stress, and disease downregulate the activity of the thyroid axis, an adaptation that minimizes energy utilization. In contrast, diet-induced obesity activates the axis, although deiodinase activities limit its capacity to compensate for energy excess. Maternal nutritional status or stress during gestation, and/or lactation, programs offspring's body weight, neuroendocrine axes, and energy metabolism in the adult. Studies in animals contributed to identify pathophysiological events of the thyroid axis associated with human diseases.

Keywords

Thyroid axis · Energy balance · Thyrotropin · Thyroid hormone · Thyrotropin-releasing hormone · Arcuate nucleus · Paraventricular nucleus · Adrenal axis · Stress · Deiodinase · TRH-degrading ectoenzyme · Programming · Diet · Tanycytes

List of Abbreviations

Note	Italics are used for gene or mRNA names, i.e., *Trh* for animals and *TRH* for humans, and capital letters, i.e., TRH, for peptides/proteins (HUGO Gene nomenclature Committee; Mouse genome informatics)
11-β-HSD	11-β hydroxysterol dehydrogenase
3V	third ventricle
Abd	abdominal
AC	adenylyl cyclase
Act	activity
ACTH	adrenocorticotropin hormone
AgRP	agouti-related peptide
Apit	anterior pituitary
AR	adrenergic receptor
Arc	hypothalamic arcuate nucleus
ATP	adenosine triphosphate
Avp	arginine vasopressin
BAT	brown adipose tissue
BBB	blood–brain barrier
BDNF	brain–derived neurotrophic factor
BP	blood pressure
BW	body weight
CART	cocaine- and amphetamine-activated transcript

CAs	catecholamines
Ch	cholesterol
Cort	corticosterone
CREB	cAMP-response element-binding protein
CRH	corticotropin-releasing hormone
Cx	cortex
d	days
db	diabetes mice
Dio1	deiodinase type 1
Dio2	deiodinase type 2
Dio3	deiodinase type 3
DMN	hypothalamic dorsomedial nucleus
E	embryonic
F	female
FA	fatty acids
FFA	free fatty acids
FR	food restriction
FT3	free triiodo-L-thyronine
FT4	free thyroxine
G	gestation
GABA	γ-aminobutyric acid
GC	glucocorticoids
GH	growth hormone
GR	glucocorticoid receptor
Gs	signal-transducing G protein
Hc	hippocampus
HFD	high-fat diet
HOMA-IR	homeostatic model assessment for insulin resistance
HPA	hypothalamic-pituitary adrenal axis
HPT	hypothalamic-pituitary-thyroid axis
Ht	hypothalamus
I− excess + LP	iodine excess plus a low protein diet
I	iodine
Ins	insulin
InsR	insulin receptor
JAK2	janus kinase 2
KO	knockout
L	lactation
LC	locus coeruleus
LDL-c	low-density lipoprotein cholesterol
LH	lateral hypothalamus
LP	low protein diet
Lpl	lipoprotein lipase
LPS	lipopolysaccharide

M	male
MBH	mediobasal hypothalamus
Mc4R	melanocortin 4 receptor
Mct10	monocarboxylate transporter 10
Mct8	monocarboxylate transporter 8
ME	median eminence
mo	months old
Mr	mineralocorticoid receptor
MS	maternal separation
NE	norepinephrine
NEFA	non-esterified fatty acids
NPY	neuropeptide Y
Nr3c1	GR gene
NTIS	non-thyroidal illness syndrome
NTS	nucleus tractus solitarius
OATP1C1	organic anion transporter family member 1C1
Ob	obese mice
ObRb	leptin's receptor b isoform
PD	postnatal day
Pepck	phosphoenolpyruvate carboxykinase
Pit	pituitary
PKA	protein kinase A
POMC	proopiomelanocortin
Ppargc1a	peroxisome proliferator-activated receptor gamma coactivator 1-alpha
PPit	posterior pituitary
PTU	propylthiouracil
PVN	hypothalamic-paraventricular nucleus
RMR	resting metabolic rate
SCh	suprachiasmatic nucleus
SOCS3	suppressor of cytokine signaling 3
STAT3	signal transducer and activator of transcription 3
T-^{131}I uptake	thyroid ^{131}iodine uptake
T3	triiodo-L-thyronine
T4	thyroxine
TBG	thyroxine-binding globulin
Tg	thyroglobulin
TG	triglyceride
TH	thyroid hormone
TPO	thyroid peroxidase
TR or Thr	thyroid hormone receptor
TRE	thyroid response element
TRH	thyrotropin-releasing hormone
TRHDE	TRH-degrading ectoenzyme
TRHR1	TRH receptor-1

TSH	thyrotropin
TSH-R Tshr	TSH-receptor
TT3	total triiodo-L-thyronine
TT4	total thyroxine
UCP1	uncoupling protein 1
VMN	hypothalamic ventromedial nucleus
W	weight
WAT	white adipose tissue
wk	week
Y1/Y5R	NPY receptor-1/5

αMSH	α-melanocyte-stimulating hormone

Introduction

Most anatomical and functional studies on the relationship between HPT axis and energy balance have been performed in rodents, due to their short gestation time and half-life. Molecular mechanisms are dilucidated in cell cultures or in mice with modified genomes. Research on ovine is also included as many temporal patterns of fetal tissue and organ development are similar to humans (Johnsen et al. 2013).

Energy balance relies on the adequate access of fuel, for metabolic and physical activity, provided by food intake or metabolism and mobilization of endogenous reserves (glycogen, adipose tissue, and protein in pathological circumstances) and modulated by the sympathetic system, GC, and TH. TH controls basal metabolic rate regulating enzymes of metabolic pathways in almost all cells and tissues; they are crucial for thermogenesis, mitochondrial biogenesis, various aspects of metabolism, development and performance of immune and nervous systems, central regulation of sympathetic outflow, and expression of adrenergic receptors at target organs. Symptoms caused by dysfunctions of the thyroid axis overlap with many found in the metabolic syndrome (Fliers et al. 2014; Mullur et al. 2014).

The hypothalamus is recognized as the "site" of homeostasis regulation. Circulating metabolites and hormones are sensed by hypothalamic structures involved in sensing energy status such as the Arc, ventromedial, dorsomedial, and PVN nuclei, as well as the LH (Fig. 1). Among them, the Arc, localized at the base of the brain with a loose blood-brain barrier, acts as an integrator of peripheral and central cues involved in feeding and energy status (Sutton et al. 2016). Two groups of neurons control food intake, and one synthesizes POMC and CART; POMC is processed to several active neuropeptides including αMSH, which acts through the Mc4R. The other is formed by neurons expressing *Agrp*, *Npy*, and GABA. AgRP binds to Mc4R opposing the actions of αMSH. This set of neurons, and their targets, form the arcuate-melanocortin system as their actions converge on the Mc4R receptor. POMC/CART neurons are activated in conditions of energy surfeit by leptin (hormone synthesized and secreted by adipocytes), insulin, and a variety of metabolites; they have anorexic actions and stimulate energy expenditure (Webber

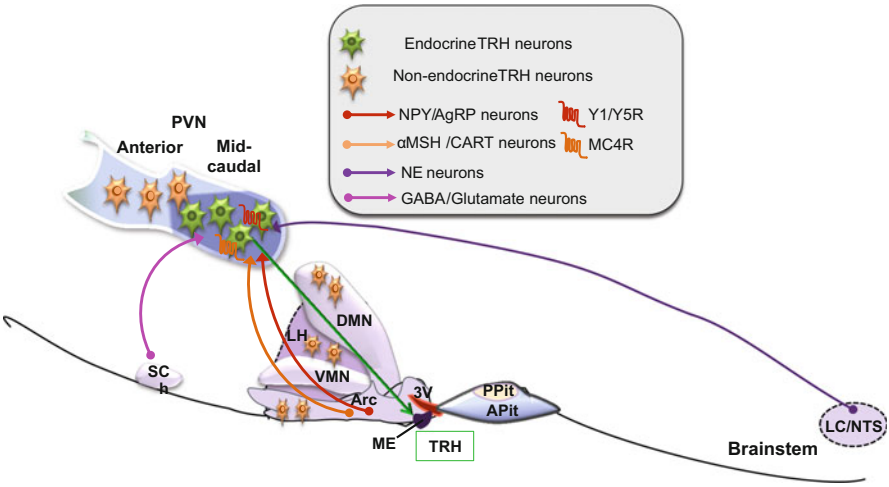

Fig. 1 Major hypothalamic nuclei involved in energy homeostasis and PVN-TRH neurons innervation. Innervations of mid-caudal paraventricular nucleus hypophysiotropic TRHergic neurons arising from the arcuate nucleus, suprachiasmatic nucleus, and brainstem (Modified from Joseph-Bravo et al. (2015a). Copyright © 2015, Society for Endocrinology)

et al. 2015). AgRP/NPY/GABA neurons promote hunger and lower energy expenditure and are activated by ghrelin, a hormone secreted by empty stomach. *Mc4r* KO mice are hyperphagic and obese (Sutton et al. 2016). Another crucial nucleus is the PVN that controls the HPT and HPA axes and is the principal hypothalamic output to brain stem nuclei controlling the sympathetic and parasympathetic nervous system (Fliers et al. 2014; Joseph-Bravo et al. 2015a).

The Hypothalamic-Pituitary-Thyroid Axis

The HPT axis is coordinated by PVN hypophysiotropic TRH neurons that project to the median eminence where TRH is released in the vicinity of portal vessels and β2-tanycytes (Fig. 2). Tanycytes express *Dio2* that transforms T4 to T3 and the *Trhde*, which inactivates released TRH. Together with TRH secretion rate, TRHDE sets the levels of TRH that enter the portal vessels communicating with the pars distalis of the pituitary. When TRH reaches thyrotrophs, it binds to TRHR1 and stimulates the synthesis of TSH, its glycosylation, and release to the systemic circulation; TSH secretion is also regulated by other hypothalamic and peripheral signals, including TH and GC (Mullur et al. 2014). TSH binds to TSH-R in the thyroid inducing the synthesis and secretion of T4 (Fekete and Lechan 2014; Joseph-Bravo et al. 2016). T4 is transformed to T3 in thyroid but mainly in target tissues by Dio1 and Dio2 (Fig. 2). TH travels in the bloodstream bound to proteins (transthyretin, thyroxine-binding protein, and albumin), leaving a low proportion of free hormones. The concentration of T3 is exquisitely modulated by deiodinases

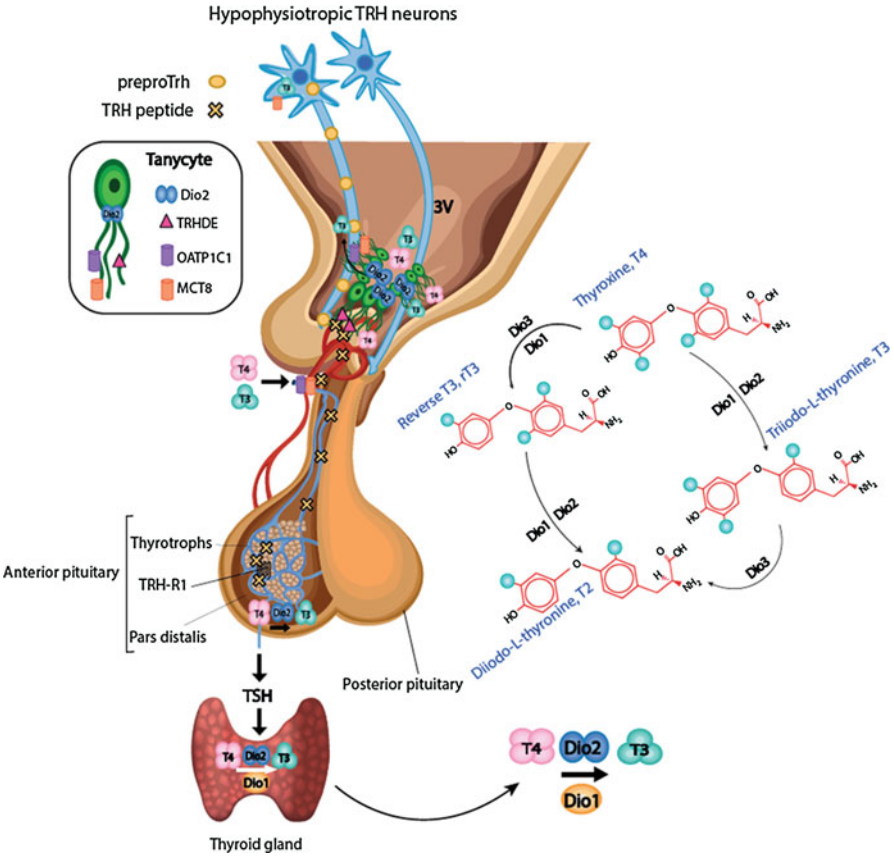

Fig. 2 Hierarchical organization of the HPT axis. Critical cells of the axis include the TRH neurons of the paraventricular nucleus, tanycytes, thyrotrophs, and follicular cells of the thyroid. Deiodinases 1, 2, and 3 can transform T4 to other thyronines in many cell types (Modified from Joseph-Bravo et al. (2016))

differentially regulated by the sympathetic system and by several hormones including TH, in a tissue-specific manner (Gereben et al. 2015). TH enters the cell through MCT8 (higher affinity for T3 than T4), MCT10, and OATP1C1 (more selective for T4 than T3) (Mendoza and Hollenberg 2017). The availability of TH also varies due to modulation of their clearance (Bianco et al. 2014).

In rodent hypothalamus, circulating T4 passes from blood vessels into tanycytes through OATP1C1, where it is deiodinated to T3, which is then transported to the extracellular space by MCT8. It has been hypothesized that T3 is then taken up by TRHergic nerve terminals that contain MCT8, retrogradely transported to the nucleus where it negatively regulates *Trh* transcription (Fekete and Lechan 2014). T3 in anterior pituitary inhibits transcription of *Tshb*. T3 binds to TR-α, TR-β1, or TR-β2 that recognizes TH-response elements in target genes; tissue and gene

specificity is provided by the type of TR and by the set of coregulators required for T3-regulated transcription. T3 or T4 acts also through membrane receptors (integrin αυβ3) and kinase transduction pathways (Mullur et al. 2014).

The activity of TRHergic hypophysiotropic neurons and, hence, of the HPT axis coincides with its active role in metabolism; they are regulated at different levels and in multiple conditions that drive acute or chronic metabolic changes. Understanding this multifactorial regulation aids to the comprehension of the role this axis plays in energy homeostasis, in the development and function of different organs, and in related diseases. HPT activity is modulated by circadian and nutritional status. PVN-TRH neurons are stimulated by αMSH through the Mc4R receptor and by leptin whereas inhibited by AgRP and NPY (Fekete and Lechan 2014). PVN-TRHergic neurons receive neuronal inputs from the suprachiasmatic nucleus which is the central sensor of light changes and by hormones modulated by day-night cycles which directly or indirectly influence HPT activity; plasma concentrations of TSH and TH are highest during the inactive period of animals (Fliers et al. 2014).

Finally, albeit a major role of TSH is to control TH secretion, TSH-R is also present in other organs where TSH activates Dio2 in BAT and affects membrane potential of cardiac cells or development of T cells (Fröhlich and Wahl 2016).

Hypothyroidism

In hypothyroid situations, TSH and TRH concentrations are elevated by lack of T3-negative feedback and the opposite occurs in hyperthyroidism. T3 feedback occurs at different levels of HPT axis (Fig. 3). Central hypothyroidism is produced in *Trh* or *Trhr1*-KO mice, whereas hyperthyroidism in *Tr*-KO mice (Mendoza and Hollenberg 2017).

Inhibition of the HPT axis leads to decreased metabolic rate, impaired thermogenesis, and altered lipid metabolism and cardio and muscle-skeletal systems. The activity of HPT axis is decreased in chronic situations as fasting, food restriction, malnutrition (Table 1), stress, and disease. Fasting or food restriction diminishes serum TH levels but, contrary to primary hypothyroidism when TSH levels are high, TSH and TRH (protein and mRNA) are decreased causing tertiary hypothyroidism. Fasting-induced inhibition of *Trh* expression involves decreased circulating leptin concentration, stimulation of AgRP/NPY/GABA and inhibition of POMC/CART neurons, upregulation in tanycytes of *Dio2* and of *Trhde* (Fekete and Lechan 2014), as well as inhibition of *Dio3*, the enzyme that degrades T3 (Fig. 2).

Stress activates HPA axis, which functions similarly to HPT axis: PVN neurons that synthesize and release CRH activate pituitary adrenocorticotropin synthesis and release which in turn regulates that of GC from the adrenal cortex (cortisol in humans; Cort in rodents). The HPA axis is activated by either physical or psychological stress-releasing GC within minutes. Physical stress (infection, cold, heat, pain) activates neurons in brain stem nuclei that connect directly with the PVN, whereas psychological stress activates limbic areas (amygdala, hippocampus, frontal cortex) that influence directly or indirectly PVN-CRHergic neurons (Herman and

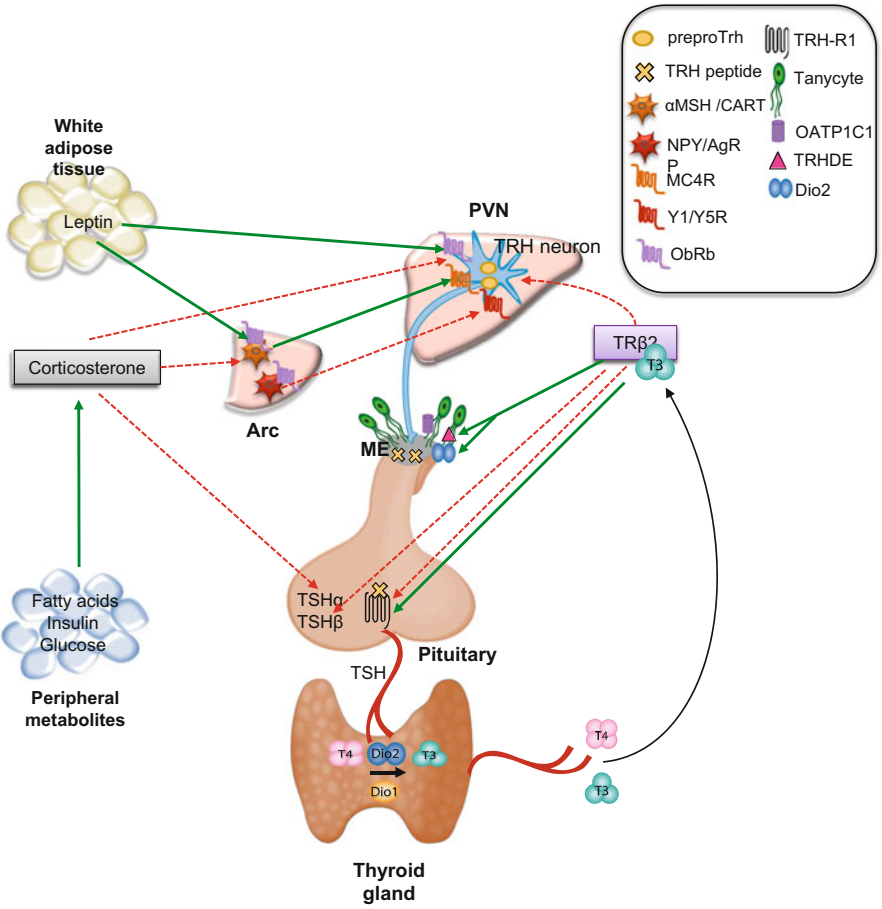

Fig. 3 Regulation of the central arm of the HPT axis by thyroid hormone feedback and energy balance signals. Thyroid hormones inhibit *Trh* and *Tsh* synthesis through TR-β2, stimulate the expression of *Trhde* and *Dio*2 in tanycytes, inhibit that of *Trhr1* in pituitary, and regulate either positively or negatively TRs and deiodinases, acting thus at many levels to set the activity of the HPT axis. Hormones and metabolites control the activity of TRH neurons directly or indirectly through Arc neurons (Modified from Joseph-Bravo et al. (2015b). Copyright © 2015, Society for Endocrinology)

Tasker 2016; van Bodegom et al. 2017). Several rat models of chronic psychological stress demonstrate HPT axis inhibition (decreased expression of PVN-*Trh*, pituitary *Tsh,* and serum concentrations of TSH and of TH). Administration of Cort for several days decreases PVN-*Trh* expression in male rats, as well as circulating TSH and TH concentrations, whereas the activity of Dio2 increases in tanycytes (Joseph-Bravo et al. 2015a; Moog et al. 2015). Stress affects HPT axis activity likely indirectly because chronic stress or Cort administration alters neuronal plasticity, dynamics of HPA responses, food intake, adiposity (high leptin serum levels), and increase Arc-*Npy*

Table 1 Effects of nutritional status on HPT axis in adult animals. The nutritional status of adult animals exerts profound effects on the hypothalamic-pituitary-thyroid axis; effects vary depending on the intensity and/or duration of the energy or micronutrient deficiency

Model	Duration and sex	Body W	HPT axis	Metabolic parameters

and *Agrp* expression (Morris et al. 2015), which by themselves affect HPT activity (Joseph-Bravo et al. 2015a).

Infection induces, as chronic illness, a NTIS in humans characterized by low TH and low or normal TSH. LPS injection to rats, which mocks infection, diminishes *Trh* and *Tshb* expression, TSH and TH, while *Dio2* expression and activity in tanycytes rapidly increases even after interfering with variations in serum concentrations of T4 or Cort (Fekete and Lechan 2014). LPS also affects TH levels at the periphery altering hepatic and muscle metabolism. LPS injection to steers depresses TSH, T3, and T4 serum levels, and the effect is exacerbated if animals are kept at high ambient temperatures (32–40 °C vs. 19 °C) that also decrease HPT activity (Kahl et al. 2015). A rabbit model of NTIS caused by chronic inflammation of the limb reduces *Trh* expression in the PVN and T3 circulating levels; these animals have increased expression of *Dio2* (but not activity), of *Mct10* and *Oatp1c1*, and of T4 concentration in hypothalamus, but local T3 does not increase. As rabbits are parenterally fed, these effects are not due to negative energy balance (Fliers et al. 2014). Cytokines, secreted in inflammatory conditions, regulate pituitary expression and activity of *Dio1*, *Dio2*, and *Thrb* (depending on the species) liver *Dio1*, thyroid iodide transport, thyroglobulin, and peroxidase (de Vries et al. 2015a).

Hyperthyroidism

Hyperthyroidism and thyrotoxicosis are characterized by high TH and low TSH serum concentrations, causing symptoms such as palpitations, tremor, fatigue, anxiety, heat intolerance, polydipsia, risk of osteoporosis, and cardiac failure; these are accompanied by increased energy expenditure, loss of body weight, decreased gluconeogenesis, lipolysis, and cholesterol, many of which are reproduced in experimental animals (Mullur et al. 2014).

In male rodents, HFD starting at weaning, or in young adults, promotes central activation of HPT axis, as demonstrated by increased PVN-*Trh* mRNA and TRH levels, serum TSH levels, thyroid iodide uptake, and TH levels; however, small changes in Dio1 and Dio2 activities in the periphery limit the capacity of the HPT axis to compensate for energy excess (Araujo et al. 2010; Perello et al. 2010). Enhanced circulating leptin levels, induced by HFD, are likely causative for upregulation of TRH neurons (Perello et al. 2010), but leptin also regulates other aspects of TH metabolism, including deiodinases activity in various tissues, and TH hormone production (Fontenelle et al. 2016). The critical role of leptin is consistent with the hypothyroid phenotype of Ob/Ob or db/db mice (Myers and Leibel 2015). It should be noted that HFD duration, diet composition, development of leptin resistance, production of inflammatory cytokines, and sex and genetic propensity to obesity likely impact on HPT axis adjustments (Xia et al. 2015; Fontenelle et al. 2016).

Response of the HPT Axis to Acute Stimuli

Homeostasis requires rapid and efficient neuroendocrine responses to a threat. HPT axis is activated by energy demanding situations as cold exposure and physical activity. Within minutes, TRH and TSH are released followed by T4. Simultaneously, synthesis of TRH and of TSH increases transiently, contributing to replenish the depleted pools provoked by release. T4 and the sympathetic system activate BAT, an active thermogenic organ (Fig. 4); hypothyroid mice may die at low temperatures (Mullur et al. 2014; Joseph-Bravo et al. 2015a). Moderate exercise, or increased physical activity, activates the HPT axis at all levels: PVN-*Trh* and serum T4 concentrations increase proportionally to exercise performed. TH regulates mitochondrial muscle biogenesis, cardiac and respiratory fitness, as well as

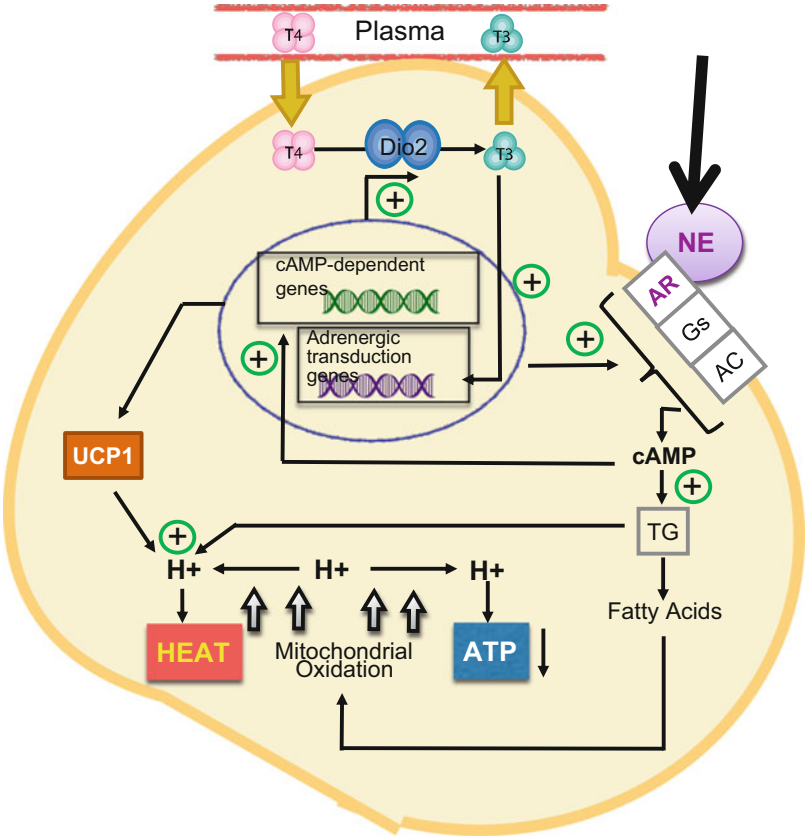

Fig. 4 Control of thermogenesis in brown adipose tissue. Adrenergic inputs activate Dio2 that transforms T4 to T3; T3 binds TR-β2 and stimulates synthesis of UCP1 and Dio2. UCP1 is activated in the mitochondrial membrane and uncouples the respiratory chain, resulting in heat production instead of ATP

lipid and glucose metabolism, mobilizing energy substrates to active tissues. Hypothyroid rats decrease their physical performance and show signs of fatigue. Exercise done to exhaustion or at high intensity decreases circulating TH serum concentrations as the organism detects negative energy balance (Joseph-Bravo et al. 2015a).

Acute stress inhibits the response of the HPT axis, but the magnitude of this inhibition depends on how strong or how long the stressor is perceived (Joseph-Bravo et al. 2015a; Moog et al. 2015). Stress or Cort injection blunts activation induced by cold or physical exercise: neither TRH, TSH, nor TH shows the cold-induced increase, nor Dio2 activation in BAT. The characterization of *Trh* gene promoter helped to unravel mechanisms by which hormones, neurotransmitters, and transduction pathways modulate transcription (Joseph-Bravo et al. 2015a, b, 2016). *Trh* transcription is activated by noradrenaline (via PKA), an effect inhibited by cotreatment with GC; the mechanism involves interaction between activated GR and PKA impeding phosphorylation of CREB and its binding to *Trh* promoter. This interaction (also shown for *Crh* transcriptional regulation) explains the fast interference of GC on the neuronal activation produced by cold that constrains the activation of HPT axis (Sotelo-Rivera et al. 2017 and references therein), although other unidentified mechanisms by which stress exerts inhibitory effects, at diverse levels and dynamics, likely exist. Fast inhibitory Cort effects on TRH neurons may contribute to the negative effects of stress on metabolism. Glucocorticoids also inhibit TSH release, as well as the activities of deiodinases.

Programming of the HPT Axis

HPA and HPT axes activities depend on the history of the animal. Interferences during development can produce deleterious outcomes that prevail until adulthood. The HPT axis of altricial mammals, as rodents, matures during the first 10 postnatal days, whereas in precocial species as lamb or human, most elements are fully expressed at birth (Forhead and Fowden 2014; Préau et al. 2015). The temporal expression profile of the elements involved in HPT activity varies in a tissue-dependent manner. Transporters, deiodinases, and TR appear early in development, but thyroid maturation is attained at midterm in sheep and human, whereas in rat it is delayed to the last gestation quarter. Maternal TH hormones are important for human and rat development during the first two thirds of fetal life; sheep, pigs, and horses are, in contrast, independent of maternal thyroid status (Moog et al. 2015; Forhead and Fowden 2014). TH bioavailability is controlled during gestation in rodents and humans, by regulating the amount of T4, T3, and iodine; for example, Dio3 presence in placenta prevents excess of T3 passing to the fetus (Moog et al. 2015). PVN-*Trh* expression increases to adult levels by the end of lactation, and feedback regulation of HPT axis appears postnatal; connections between Arc and PVN that regulate the activity of HPT axis are formed between the eighth and tenth PD in rat (Dearden and Ozanne 2015; Joseph-Bravo et al. 2016). Long-term effects of perturbations depend on the time window of development of the various participants (Préau et al. 2015).

THs are essential for adequate fetal metabolism (oxygen and glucose consumption), mitochondrial biogenesis, and differentiation and maturation of many organs and systems; timing of TH deficit or excess affects adequate development at various levels. Brain development involves TH-regulated genes for cell migration, proliferation, and maturation of neurons and glia (Préau et al. 2015). Deleterious effects on cognition in children from hypothyroid mothers have been long recognized and now characterized in several animal models; rats show deficiency in spatial learning tasks and decreased expression of nerve growth factor in hippocampus. TH effects on neuroplasticity occur even during adulthood (Moog et al. 2015; Raymaekers and Darras 2017). Congenital hypothyroidism in humans occurs with a single nucleotide polymorphic mutation in various elements of HPT axis; for example, MCT8 mutations produce psychomotor and brain retardation (Allan-Herndon-Dudley syndrome). Similar defects occur in double mutant *Mct8/Oatp1c1* (mice compensate MCT8 defect with OATP1C1, expressed lightly in humans and primates) (Mendoza and Hollenberg 2017). Offsprings from hyperthyroid dams show thyroid and brain developmental defects, increase in oxidative damage, and deformed neurons and glia in various brain regions of rats (Ahmed et al. 2012). Cardiac performance is impaired after an ischemic insult in adults whose mothers became hyperthyroid during the last half of gestation (Lino et al. 2015).

Mother Nutritional Status

Maternal protein or calorie restriction during gestation and/or lactation programs the offspring's body weight, causes dysfunction to various neuroendocrine axes, and alters energy metabolism and parameters regulating energy homeostasis as the melanocortin system in the adult; effects on thyroid function of the offspring vary depending on the severity of the restriction, the timing of gestation and/or during lactation, and the offspring's age and sex. As malnutrition evokes a hypothyroid condition in the mother, this probably adds up to the response of the offspring to nutrient deficiencies or other insults. Table 2 depicts the principal effects reported on HPT axis and associated metabolic variables. Food restriction decreases HPT activity, whereas protein restriction induces high TH levels in rat offspring due to higher transfer by milk (de Moura et al. 2008). Offsprings from 50% energy/protein-restricted mothers, raised on a high-carbohydrate/high-fat diet, are predisposed for hyperphagia and obesity (Wattez et al. 2013).

Maternal protein restriction during gestation and/or lactation and early weaning affects the structure of hypothalamic nuclei, energy expenditure, and body composition in the offspring, becoming susceptible to develop obesity and metabolic syndrome as adult; HPA development is affected, as well as adipocyte metabolism leading to fat accumulation later in life. Maternal undernutrition increases Cort secretion which reduces placental 11-β-HSD. Fetal Cort exposure affects vasculature and maturation of brain cells, while HPA tone is hyperactivated until adulthood, and GR methylation patterns are disturbed depending on the time of nutrient deficiencies (Correira-Branco et al. 2015; Wattez et al. 2013). As discussed below, stress affects HPT function, and

Table 2 Maternal nutritional status programs offspring's body weight, HPT axis, and energy homeostasis. Maternal caloric or protein restriction during gestation and/or lactation programs the offspring's body weight, energy metabolism, and hypothalamic and thyroid axis parameters regulating energy homeostasis. Effects are dependent on type, duration, and time period during which dams are exposed to the restriction, as well as on offspring age

therefore, the effects of malnutrition on HPA axis may contribute to altered HPT development.

In rodents and nonhuman primates, maternal overnutrition before and/or during gestation and/or lactation can modify hypothalamic sensing and HPT axis activity at birth or weaning and leads to adult obesity and adaptations of the HPT axis that differ from those observed earlier (Table 3).

The thyroid axis is very susceptible to alcohol and nicotine that cause long-term HPT inhibition in the offspring and metabolic alterations (Portolés et al. 1988; Ramadoss et al. 2008; Lisboa et al. 2015). Research during the last decade has demonstrated the danger of endocrine disruptors, which are present in plastics, insecticides, flame retardants, and cosmetics to name a few; due to space limitations, it is not possible to cover this issue but comprehensive reviews are available (Duntas 2015; Préau et al. 2015).

Stress

The HPA develops in rodents during the first 2 weeks of gestation. During pregnancy, GC participate in the development and maturation of multiple organs, including the brain, pituitary, and thyroid. This occurs at defined time windows, and administration of high doses of GC at other times, as used in many therapies, may alter normal development. Furthermore, mother stress is sensed by the fetus that shows, in several species, similar changes in GC concentration as the mother (Moisiadis and Matthews 2014; van Bodegom et al. 2017).

GC administration, at an equivalent anti-inflammatory dose, at day 16 of gestation (when the thyroid is rapidly growing and maturing) diminishes the number of thyrotrophs in pituitary and inhibits thyroid growth but promotes its maturation which may affect their response as adults (Manojlović-Stojanoski et al. 2014). Dexamethasone injection to pregnant rats from day 18 to 21 decreases core body temperature as well as *Trh* mRNA levels, number of expressing cells, and stained fibers in the PVN of adult rat females, although males have normal to reduced postnatal TH levels with a tendency to remain low in adulthood (Carbone et al. 2012). In sheep, GC treatment near term modulates activities of Dio1 and Dio3 increasing T3 serum concentrations; variations in TH concentrations also affect the HPA axis supporting a dual regulation of both hormones for adequate development (Forhead and Fowden 2014; Moog et al. 2015).

Perturbations at postnatal critical periods like lactation or adolescence affect programming with long-term consequences in the adult. Meaney and his group elucidated the mechanism involved in the effect of inadequate caring by the mother during lactation that induces in pups an overreactive HPA axis when exposed to stress as adults. These animals present diminished hippocampal expression of GR (important for negative feedback of HPA), due to epigenetic changes on the promoter of *Nr3c1* which has been detected in several paradigms of early-life stress in animals and humans (Turecki and Meaney 2016). A model of MS of the pups for a few hours a day during the first 2 or 3 weeks of lactation reproduces these findings;

Table 3 Effects of maternal overnutrition on the offspring's HPT axis and energy homeostasis. Maternal overnutrition before and/or during gestation and/or during lactation programs the offspring's body and white adipose tissue weights, hypothalamic-pituitary-thyroid axis, and energy homeostasis

this and other models of early-life stress allowed identification of several hypo- or hyper-methylated gene promoters pertaining to HPA axis and other brain regions (van Bodegom et al. 2017).

MS causes gender-specific changes in HPT, and male rats have increased basal Cort levels as adults and secondary hypothyroidism (low TSH and T3 serum concentrations); *Trh* expression is not modified but that of *Trhde* increased, which explains HPT inhibition only at pituitary and thyroid levels. In contrast, female rats have increased expression of *Trh* and high white adipose mass, which points for a subclinical hypothyroidism. MS blunts the response of HPT axis to threats as fasting only in males (Jaimes-Hoy et al. 2016) or to cold exposure (unpublished). Males seem to be more susceptible to the stress induced during lactation, and, since stress diminishes the HPT response of adults, the effects of MS could be combined with the higher stress response of MS males, together with possible effects on *Trhde* programming.

Conclusion

The HPT axis is submitted to multilevel regulation and integrates environmental, emotional, endocrine, and metabolic signals. It is programmed by the effects of maternal care, early-life stress, and nutrition. Aberrant programming or inappropriate nutrition, as well as stress and diseases, can alter HPT activity and contribute to dysfunctional metabolic status in adults.

Policies and Protocols

The status of the HPT axis is primarily evaluated based on determination of the serum or plasma concentrations of TSH, total and free T4, and T3. Quantitative assays utilize specific antibodies that bind the hormone. In radioimmunoassay, hormone in sample competes in solution with a fixed quantity of radioactive hormone for antibody binding; the antibody-hormone complex is separated from the free hormone and signal quantified. In enzyme-linked immunosorbent assay, hormone in sample is immobilized onto a plate and detected by the specific antibody coupled to an enzyme that generates either a colored or fluorescent signal. The intermolecular interactions of antibody and ligand are susceptible to interferences from substances present in the sample; thus, it is extremely important to evaluate parallelism between standard curve and sample dilutions. It is also critical to choose an assay that is optimized for the species under study, since even if the chemical structure of TH is species independent, the concentration and type of serum-binding proteins differ between humans and rodents, making assay conditions optimized for human samples not applicable for rodent samples and vice versa. The knowledge of the factors that modulate the activity of the

HPT axis should also be considered when defining sampling time and not only fasting duration; for interpretation of clinical results, careful consideration of previous stress, body weight, sex, and age is necessary. Given the importance of accuracy, reliability, and reproducibility in measurements and evaluation of normal values, attempts have been made to set international standards (Vesper et al. 2016). Work with experimental animals allows measurements of TH-sensitive gene expression in multiple tissues, which complements information given by circulating hormone concentrations. A comprehensive manual for standardization of measurement of markers of HPT axis function has been recently published (Bianco et al. 2014).

Dictionary of Terms

- **Deiodinase** – An enzyme that removes an iodo group from one of the rings of thyroid hormone.
- **Energy balance** – Balance between energy intake and expenditure through basal metabolism, thermogenesis, and physical activity.
- **Hypophysiotropic thyrotropin-releasing hormone neurons** – Neurons of the hypothalamic-paraventricular nucleus, expressing thyrotropin-releasing hormone, that project to the median eminence and regulate thyrotropin secretion from the anterior pituitary.
- **Melanocortin system** – Arcuate nucleus neurons that synthesize α-melanocyte-stimulating hormone and Agouti-related peptide and target neurons expressing the melanocortin receptors 3 and 4, which are critically involved in energy homeostasis.
- **Programming** – Early-life conditions that set adult functions.
- **Tanycytes** – Modified ependymal cells localized at the base and ventral portion of the lateral wall of the third ventricle.
- **Thermogenesis** – Production of heat in response to changes in environmental temperature or diet.
- **Thyrotropin-releasing hormone-degrading ecto-enzyme** – A membrane-bound peptidase that inactivates thyrotropin-releasing hormone in the extracellular space.

Summary Points

- Animal research provides knowledge about energy balance and thyroid axis relationship.
- Thyroid axis is hierarchically organized; paraventricular hypophysiotropic thyrotropin-releasing hormone neurons integrate central and peripheral information to control thyrotropin secretion from pituitary; thyrotropin controls thyroid hormone production by the thyroid.

- Tissue concentrations of thyroid hormones depend on transporters and deiodinases, and their actions on thyroid hormone receptors.
- Thyroid hormones control basal metabolic rate, thermogenesis, lipolysis and glycolysis, and development and performance of immune and nervous systems; they exert feedback control on the hypothalamic-pituitary-thyroid axis at multiple levels.
- Thyrotropin-releasing hormone neurons in the paraventricular nucleus are target of proopiomelanocortin hormone/cocaine- and amphetamine-activated transcript, and neuropeptide Y/agouti-related peptide/γ-aminobutyric acid arcuate neurons, a major hub for sensing and relaying information related to energy balance.
- Acute stimuli, such as cold or exercise, transiently activate the hypothalamic-pituitary-thyroid axis.
- Chronic events as fasting, food restriction, malnutrition, stress, and disease downregulate the activity of the thyroid axis.
- Fasting or food restriction effects on the hypothalamic-pituitary-thyroid axis are mediated by a reduction in circulating leptin concentration.
- Interactions between stress and the thyroid axis activity occur through many mechanisms, including glucocorticoid receptor-protein kinase A-dependent interference with thyrotropin-releasing hormone transcription.
- Diet-induced obesity activates the thyroid axis, although deiodinases activities limit the capacity of this axis to compensate for energy excess.
- Inadequate activity of the thyroid axis leads to deleterious outcomes.
- Maternal under- or mal-nutrition, stress, infection, alcoholism, nicotine, and toxics including endocrine disruptors affect thyroid hormone signaling in the fetus, leading to defects in differentiation and maturation of many organs and systems, including the brain.
- Maternal nutritional status or stress during gestation, and/or lactation, programs the offspring's body weight, neuroendocrine axes, and energy metabolism in the adult.
- Mechanisms involved in the programming of adult energy balance include brain structural alterations, epigenetic regulation of key genes, and altered thyroid and adrenal axes.

Contents

Abstract

Caloric restriction has long been shown to improve insulin action and glucose control. In this chapter, we review the evidence behind different strategies to restrict calories, its impact on insulin sensitivity, putative mechanisms by which it improves insulin sensitivity, and the longevity of these methods in improving glucose metabolism where such evidence exists. Coverage includes sections on caloric restriction versus weight loss, techniques, macronutrients, the role of the liver and skeletal muscle after caloric restriction, and the gut microbiome.

Keywords
Caloric restriction · Insulin sensitivity · Glucose control · Weight loss

Introduction

The global incidence of obesity is rising bringing with it increased risk of weight-related medical complications including impairments in glucose metabolism. Weight loss can help slow down the progression of prediabetes to type 2 diabetes (Hamman et al. 2006), and caloric restriction is the cornerstone of any successful weight management program. In this chapter, we review the evidence behind different strategies to restrict calories, its impact on insulin sensitivity, putative mechanisms by which it improves insulin sensitivity, and the longevity of these methods in improving glucose metabolism where such evidence exists.

Caloric Restriction or Weight Loss?

Traditional caloric restriction is defined as a decrease in calorie consumption by 20–50% of needs (Omodei and Fontana 2011). In human intervention studies on people with or without type 2 diabetes (T2DM), reducing caloric intake has universally been shown to reduce insulin resistance and improve insulin action. Towards the end of the last century, the study of very low calorie diets (VLCD) was of great interest in the treatment of obese patients with type 2 diabetes. With this diet, patients were allowed to consume 400–800 kcals/ day of high-quality protein and carbohydrate, typically in liquid form, supported by an aggressive vitamin and mineral supplementation program. Hepatic glucose output decreased in conjunction with a decrease in fasting plasma glucose. Studies using the euglycemic-hyperinsulinemic clamp showed that VLCD enhanced the ability of insulin to suppress hepatic glucose production, and glucose disposal rates increased severalfold after weight loss with a VLCD. Therefore, it was concluded that VLCDs improved peripheral and hepatic insulin sensitivity in obese patients with T2DM, independent of weight loss (Henry et al. 1986). Although these diets resulted in improved metabolic parameters and an eventual reduction in body weight, there were several concerns regarding their generalizability and safety. Patients would often experience significant side effects including orthostatic hypotension, nausea, headache, and dehydration. There was a need for careful supervision of electrolytes due to early reports of death from cardiac arrhythmias and an increased risk of refeeding syndrome when calorie consumption was liberated (Frank et al. 1981). However, probably most relevant to the patient was the significant difficulty in adhering to the diet in the long term, which would often result in resumption of previous dietary habits and ultimately weight gain.

However, recent human data suggests that the initial improvements in glycemic control and insulin sensitivity that occur as a result of a VLCD may have sustained benefits in some people as long as the weight is not regained. Steven et al. studied

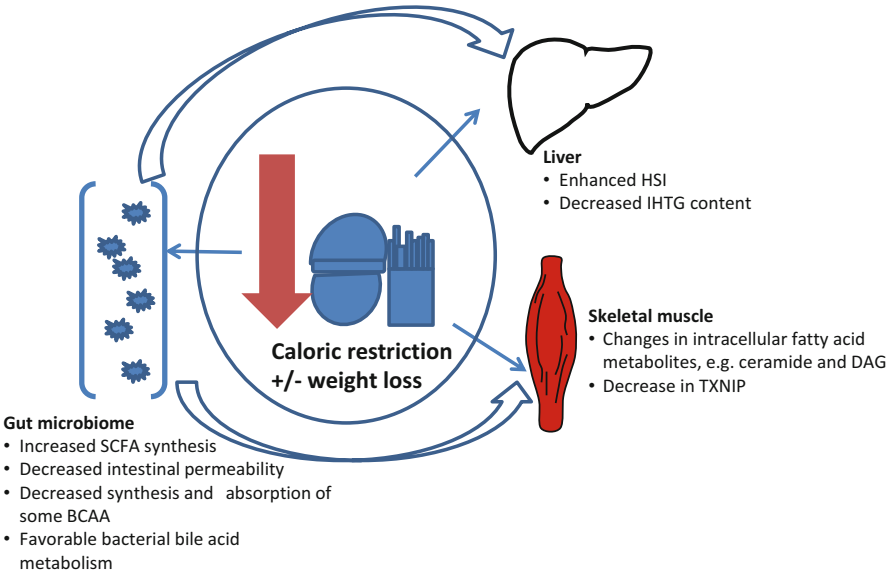

Fig. 1 The roles of the liver, skeletal muscle, and gut microbiome after caloric restriction in improving insulin sensitivity. Legend: *SCFA* short chain fatty acids, *BCAA* branched-chain amino acids, *HIS* hepatic insulin sensitivity, *IHTG* intrahepatic triglyceride content, *DAG* diacylglycerol, *TXNIP* thioredoxin-interacting protein

29 participants with type 2 diabetes who consumed 624–700 kcals/day for 8 weeks. Mean weight loss was 14% during this phase, after which there was gradual introduction of solid food to promote weight maintenance. Approximately 40% of participants ("responders") had normalization of fasting glucose which stayed normal off hypoglycemic agents at 6 months follow-up, suggesting that diabetes remission was achievable through an initial brief VLCD followed by a sustainable weight-management program. Hepatic insulin resistance improved in both responders and nonresponders based on results from euglycemic-hyperinsulinemic clamp studies. However, the primary driver of the robust improvement in glucose metabolism in responders was improved beta call responsivity, specifically first phase insulin response. Important to note that at baseline, responders were younger (52 years old vs. 60 years old), had lower HbA1c (7.1% vs. 8.4%) and shorter duration of diabetes (3.8 years vs. 9.8 years) versus nonresponders, emphasizing the importance of beta cell reserve in the improvements seen in glycemic control after VLCD and weight maintenance (Steven et al. 2016). Whether remission of type 2 diabetes through early VLCD has longevity beyond the study duration is not yet known, although data from bariatric surgery is certainly compelling in this regard (Schauer et al. 2014).

In recent years, bariatric surgery has offered an interesting in vivo model to address the question of which reigns supreme in improvements in glycemic control: caloric restriction or weight loss. Patients with type 2 diabetes who undergo Roux-en-Y gastric bypass (RYGB) surgery for weight loss often show impressive

improvements in glycemic control within the first few days of surgery, prior to any significant weight loss. Jackness et al. studied matched cohorts of obese patients with similar duration and control of diabetes to compare the effect of caloric restriction (CR) alone vs. caloric restriction in the setting of RYGB. Patients were subject to a 500 kcal/day diet for between 14 and 24 days and subsequently studied with an intravenous glucose tolerance test (IV GTT). The degree of weight loss after intervention (diet alone or diet plus surgery) was similar. The acute insulin response rate, sensitivity of glucose elimination to insulin and disposition index (measure of insulin secretion in relation to prevailing insulin sensitivity) as well as the homeostasis model assessment of insulin resistance (HOMA-IR) improved to a similar degree after equivalent caloric restriction in both groups (Jackness et al. 2013). However, the use of an intravenous GTT excluded the contribution of gut incretins, which are known to be elevated in the postprandial setting after RYGB and which influence glucose metabolism (Laferrere et al. 2008). Nevertheless, the conclusion of the authors regarding the fundamental role of caloric restriction in the metabolic changes observed after bariatric surgery is important and continues to be the subject of ongoing studies (Fig. 1).

Does Technique Matter?

The typical calorie restriction program advocates global calorie restriction of either a certain amount of calories (e.g., 500 kcals/day) or a certain percentage of calories (e.g., 25% of needs/day), and is usually based on the goals and abilities of the individual. However, this method works best when combined with rigorous self-monitoring (Das et al. 2007) which can be difficult to adhere to in the long term. Additionally, patients also report that restricting calories daily is frustrating and curtails their freedom to choose freely. Therefore an alternative method, intermittent fasting (IF), whereby calories are only restricted on a certain day or days of the week has been studied to assess its efficacy as a weight loss tool, and to determine the effects of this type of dietary intervention on markers of glucose metabolism including insulin sensitivity. A significant limitation of many CR and IF studies is the short duration of intervention and of subsequent follow-up. Nevertheless, certain themes have emerged as important in helping enhance our understanding of how calorie restriction improves insulin sensitivity.

Foremost, the degree of calorie restriction seems proportional to the improvements seen in insulin sensitivity. Varady et al. studied 16 patients with prediabetes and prescribed a supervised IF program consisting of 75% CR on 1 day a week followed by ad libitum intake for the remainder of the week. The average weight loss was 6%, with a corresponding decrease in HOMA-IR by 19% (Varady et al. 2009). When CR was 80% on 1 day followed by ad libitum feeding for the remainder of the week, an 8-week intervention in a population with prediabetes led to 8% weight loss, 6% improvement in fasting glucose, and 33% decrease in

HOMA-IR (Johnson et al. 2007). In both studies, participants were not provided advice on exercise and therefore the effects on body weight were assumed to be purely a result of caloric restriction. No relationship could be established between insulin sensitivity and visceral fat but this may be a limitation of the small number of participants in these studies. Similarly, studies using daily CR show a linear relationship between degree of caloric restriction and improvements in insulin sensitivity as measured by HOMA-IR. For example, a 6 week study using 50% CR resulted in a 70% decrease in HOMA-IR (Xydakis et al. 2004), while studies using 25% CR showed a decrease in HOMA-IR by 15–20% from baseline (Harvie et al. 2011; Trussardi et al. 2013). Also noteworthy is that improvements in insulin sensitivity were seen as early as 3 weeks (and 3% weight loss) after the intervention (Eshghinia and Mohammadzadeh 2013), providing further evidence that CR in any form, be it global reduction, intermittent fasting or alternate day fasting, may be utilized as a short-term strategy to improve insulin sensitivity.

Do Macronutrients Matter?

Several studies in humans have shown that improvements in insulin sensitivity are seen early during dietary restriction before any weight loss occurs (Kelley et al. 1993; Assali et al. 2001), highlighting the role of tissue sensitivity to nutritional cues; the natural follow-up question therefore is whether the type of macronutrient exposure determines tissue response. The macronutrient composition of CR diets has been studied to elicit if differences exist due to the relative amount of protein or fat in iso-caloric conditions. When weight loss was the primary goal of the study, the answer seems to be no as shown in the next few studies discussed. One group looked at two different alternate day fasting diets (25% CR) in obese individuals, consisting of 45% fat/40% carbohydrate and 25% fat/ 60% carbohydrate for 8 weeks (Klempel et al. 2013). At the end of the study period, both sets of participants lost an equivalent amount of weight and had preservation of fat free mass to a similar degree. There was a 7 cm decrease in waist circumference in both groups; waist circumference is an indirect marker for visceral fat mass. Also, participants who followed the high fat diet reported better adherence likely due to better palatability of the food.

Another group looked at how portion control, energy density, and glycemic index compared as weight loss methods. Participants were advised to restrict calories based on an individual weight loss goal of 0.5–1 kg/week and given individualized nutrition guidelines per their intervention group, i.e., information on low energy density or low glycemic index foods or portion control. After 12 weeks there was no significant difference in body weight and percentage body fat between groups. There was a significant improvement in HOMA-IR from baseline in all three groups, and no between-group difference was observed (Melanson et al. 2012).

Other groups however have shown that in the setting of weight neutrality, the quality of macronutrients may be important in determining effect on glucose metabolism. When overweight and obese volunteers were placed on an iso-caloric, weight-maintaining diet that differed only by the amount of whole grains (dietary fiber) consumed for 6 weeks, the group on the whole grain diet had a significant improvement in HOMA-IR and other insulin sensitivity indices as measured by the euglycemic-hyperinsulinemic clamp, compared to individuals on the refined grain diet (Pereira et al. 2002). The authors concluded that dietary fiber from whole grains modulated glucose metabolism and hypothesized that changes in gut microbial composition and the production of short chain fatty acids (SCFA) in particular explained some of the observed differences. The role of the gut microbiome in modulating glucose metabolism will be briefly discussed in this chapter.

The Role of the Liver After Caloric Restriction in Improving Insulin Sensitivity

The liver and skeletal muscles are the main organs where insulin action results in changes in glucose concentration. As mentioned previously, in the short term VLCDs have been shown to improve hepatic insulin sensitivity; however, there have also been reports of short-term fasting causing insulin resistance in humans (Duska et al. 2005; Bergman et al. 2007). The hypothesis put forward for this observation was that differences in carbohydrate consumption were responsible; such that acute insulin resistance was seen when total carbohydrate consumption was <50 g/day but not when it was >100 g/day, possibly due to increased lipolysis in the former with resultant higher free fatty acid concentrations (Jensen et al. 1987; Kelley et al. 1993). To address the short- and long-term effects of equivalent caloric restriction with a high carbohydrate (>180 g/day, "HC") and low carbohydrate (<50 g/day, "LC") diet in obese insulin-resistant subjects, 22 subjects were studied after 48 h of the intervention and again after a 7% weight loss was achieved (Kirk et al. 2009). Both groups achieved equivalent weight loss at the end of the intervention and there were no between group differences seen in body-fat and fat-free mass. In general and in both groups, short-term caloric restriction led to a decrease in intrahepatic triglyceride (IHTG) content, increase in hepatic insulin sensitivity, and decrease in endogenous glucose production rate, whereas 7% weight loss improved skeletal muscle insulin sensitivity and improved in cellular insulin signaling. However, acutely, the LC diet led to a greater reduction in the rate of appearance of glucose (Ra) and greater improvement in the hepatic insulin sensitivity index compared to the HC diet. The authors hypothesized that the decline in circulating insulin levels with the LC diet led to enhanced lipolysis of IHTG and hepatic fatty acid oxidation and a decline in endogenous glucose production, similar to the physiologic adaptations that occur during the early response to starvation (Klein and Wolfe 1992). They also propose this to be one mechanism by which improvements in glucose metabolism seen early after RYGB occur.

The Role of Skeletal Muscle After Caloric Restriction in Improving Insulin Sensitivity

The cellular mechanisms that modulate insulin sensitivity have been studied extensively and are well understood. In this context, there are several pathways that are able to self-regulate in a nutrient-rich environment, i.e., excess caloric consumption. For example, the p85 regulatory subunit in skeletal muscle can be induced after as little as 3 days of positive energy balance (Cornier et al. 2006), while caloric restriction in rodents improves glucose transport within the skeletal muscle in conjunction with decreasing the abundance of p50 and p55 (McCurdy et al. 2005). Human studies have shown an increase in the expression of another regulatory protein, the deacetylase sirtuin 1 (SIRT1) during caloric restriction, which leads to improvements in insulin sensitivity (Civitarese et al. 2007). Furthermore, weight loss does decrease fatty acid flux, but to what extent this contributes to the improvements seen in insulin sensitivity is unknown (Kelley et al. 1993; Assali et al. 2001).

Several groups have studied overweight or obese subjects to further elicit underlying mechanisms in humans, with inconsistent results. In overweight subjects, induction of acute muscle insulin resistance was associated with a transient increase in total and cytosolic diacylglycerol (DAG) content (an intermediate product of fatty acid metabolism) (Szendroedi et al. 2014), but there was no association observed between insulin resistance and alterations in muscle ceramide, another intermediate product of fatty acid metabolism. Conversely, another group showed that muscle ceramide accumulation in in vitro culture inhibited muscle insulin sensitivity (Chavez et al. 2005). Yet another group showed that a 16 week CR program resulting in 9% weight loss decreased the concentrations of bioactive lipids including ceramide and DAG and improved insulin sensitivity (Dube et al. 2011). In contrast, the reductions in these intramyocellular lipids were not observed by a group that studied obese participants under similar conditions. The average weight loss achieved was 10% body weight. The group did, however, uncover the potential role of lower thioredoxin-interacting protein (TXNIP) levels in enhancing nonoxidative glucose disposal, thus supporting the role of TXNIP in mediating the improvement in peripheral insulin sensitivity after CR (Johnson et al. 2016). TXNIP impairs insulin signaling, and skeletal muscle TXNIP deletion has been shown to be protective against high-fat diet–induced insulin resistance in rodents (Hui et al. 2008). The differences observed in these studies may be due to the type of participants studied and the methodology used, but does in sum support the role of caloric restriction in modulating intracellular insulin signaling, and thus insulin action at the tissue level.

The Role of the Gut Microbiome After Caloric Restriction in Improving Insulin Sensitivity

The human host has ~10^{14} microbes in the colon which contain approximately 10-fold more genes than the human genome. These genes have diverse functions including energy harvest, neurohormonal function, gut barrier function, and bile

acid modification. The genetic material that encodes enzymes (e.g., to break down dietary polysaccharides or utilize glycans) can affect fatty acid concentrations including SCFA, an example of which is butyrate. The biggest influence of the composition of the gut microbiome is diet, and therefore a compelling relationship between caloric restriction, diet, and the gut microbiome composition may exist to explain improvements seen in insulin sensitivity with dietary change.

Even when subjects are exposed to the same sort of diet, there is a range of clinical effects observed and one explanation for the heterogeneity of response to caloric restriction may be differences in microbial gene richness, defined as the number of bacterial genes in an individual's stool. Cottilard and colleagues (Cotillard et al. 2013) studied a matched European cohort of overweight and obese individuals stratified by gene richness. Interestingly, subjects with lower gene richness had greater prevalence of metabolic dysregulation at baseline. With 6 weeks of caloric restriction, this group showed an increase in gene number but had less of a robust response in terms of improvement in HOMA-IR and hsCRP when compared to the group with higher gene richness. Conversely, higher gene richness at baseline was associated with a more marked improvement of adipose tissue and systemic inflammation following equivalent caloric restriction. The authors concluded that gene richness may help predict the efficacy of dietary intervention on inflammatory variables in overweight or obese individuals. It is estimated that up to 40% of the European population may have low gene richness, and therefore the clinical implication of this finding is considerable (Cotillard et al. 2013).

The gut microbiome also has an important role in maintaining gut barrier function and intestinal permeability, and there may be a correlation between systemic inflammation and insulin resistance. Studies in mice have shown that fluorescently labeled *E. Coli* mixed in chow were able to be detected in the circulation particularly after a high-fat diet, providing evidence for intestinal translocation. These mice exhibited higher levels of lipopolysaccharide (LPS), new insulin resistance, and changes in the composition of gut microbiota. When the cell surface receptor for LPS, CD 14, was knocked out, the mice had less weight gain, were more insulin sensitive, and had less systemic and tissue inflammation. Mice that were given probiotic supplementation for 1 month showed decreased bacterial translocation and improved insulin sensitivity suggesting that an intervention designed to manipulate gut microbial composition could reverse the adverse metabolic phenotype induced by high-fat diet (Amar et al. 2011a). Taken together, this outlines the interplay between endotoxins, intestinal permeability, and insulin sensitivity, at least in rodents. In humans, there is indirect evidence that bacterial translocation may contribute to insulin resistance and dysregulation of glucose homeostasis. In a small study, a group of patients were followed for 9 years and then stratified according to the presence or absence of type 2 diabetes (T2DM). The level of circulating bacterial genetic material (16SrDNA) in the blood at baseline moderately predicted the onset of T2DM (OR = 1.29 after adjustment for age, sex, and fasting blood glucose) (Amar et al. 2011b). Although preliminary, this observation potentially provides an alternative mechanistic explanation for how dietary change improves parameters of glucose metabolism.

In one of only a handful of human intervention studies looking at changes in the gut microbiome and associations with insulin sensitivity, investigators were able to show improvements in insulin sensitivity by infusing intestinal microbiota from lean healthy donors to male recipients with metabolic syndrome. This improvement was associated with increased levels of butyrate-producing intestinal microbiota (Vrieze et al. 2012). Interestingly, the authors also found increased gut microbiota diversity was associated with improved insulin sensitivity.

Other putative mechanisms by which the gut microbiome may improve glucose metabolism include decreased synthesis and absorption of branched-chain amino acids that lead to insulin resistance (Derrien et al. 2004) and bacterial metabolism of bile acids, e.g., stimulation of FGF-19 which has metabolic effects on the farsenoid X receptor (FXR) in the β cell and liver (Gerhard et al. 2013). Whether dietary manipulation can recreate the microbial profile associated with improved insulin sensitivity is still unknown but may offer a novel mechanistic insight and potential therapeutic approach to address the problem in humans.

Conclusion

Obesity and insulin resistance share the common risk factor of excess calorie consumption, and calorie restriction in various forms has been shown to ameliorate this process. The effect of caloric restriction on cellular signaling, fatty acid metabolism, and potentially favorable changes in the composition of the gut microbiome are mechanisms by which these improvements occur, and offer novel insights into potential therapeutic strategies for the treatment of insulin resistance in humans.

Dictionary of Terms

- **Calorie** – A unit used to measure the energy value of food.
- **Insulin sensitivity** – The ability of insulin to change glucose concentrations. When insulin sensitivity is low, this is often termed insulin resistance.
- **Prediabetes** – The state of either having impaired glucose tolerance or impaired fasting glucose.
- **Very low calorie diet (VLCD)** – Traditionally, this describes an intake of less than 800 kcals/day.
- **Refeeding syndrome** – A physiologic response to the reintroduction of calories after a prolonged period of calorie deprivation, characterized by significant intracellular electrolyte shifts and manifests as low phosphorus, potassium, and magnesium concentrations in the blood.
- **Euglycemic-hyperinsulinemic clamp** – A research method used to quantify insulin secretion and action, i.e., insulin sensitivity.
- **Homeostasis model assessment of insulin resistance (HOMA-IR)** – A mathematical formula for assessing β-cell function and insulin resistance from basal (fasting) glucose and insulin or C-peptide concentrations. Another method used to measure insulin sensitivity.

Summary Points

- Caloric restriction in any form improves insulin sensitivity, although the durability of effect is yet unknown.
- Calorie restriction improves insulin sensitivity before weight loss occurs.
- Caloric restriction improves insulin sensitivity by enhancing skeletal muscle insulin signaling and hepatic insulin action.
- Macronutrient composition during caloric restriction may have an impact on the degree of improvement of insulin sensitivity.
- The gut microbiome is a novel player in the improvements seen in insulin sensitivity during caloric restriction.

The Ketone Body Beta-Hydroxybutyrate in Starvation

58

P. Rojas-Morales and J. Pedraza-Chaverri

Contents

Abstract

The ketone body β-hydroxybutyrate (BHB) is a central molecule that plays pivotal roles in whole-body energy metabolism by fueling most tissues in conditions of nutrient deprivation, but its function is not limited to a metabolic intermediate during nutritional challenge. Emerging studies have positioned BHB as a signaling metabolite regulating a broad range of processes – from

inflammation to longevity – through cellular receptors, epigenetic modifications, and by yet unknown mechanisms. In addition, several pieces of evidence point out that BHB might function as a signal controlling energy metabolism in the particular scenario of negative energy balance. This chapter provides an overview of how BHB, apart from helping to solve energy crisis by directly fueling oxidative metabolism, has the potential ability to reduce energy expenditure and promote autophagy, thus contributing to fine-tune systemic energy balance in the face of food limitation.

Keywords

Starvation · Beta-hydroxybutyrate · Ketone bodies · Signaling · Autophagy · Energy expenditure · Fuel metabolism · Gene expression · Inflammation · Insulin resistance

List of Abbreviations

AcAc	Acetoacetate
AcAc-CoA	Acetoacetyl-coenzyme A
acetyl-CoA	Acetyl-coenzyme A
AKT	Protein kinase B
AMPK	AMP-activated protein kinase
BDH1	BHB dehydrogenase
BHB	β-Hydroxybutyrate
CoA	Coenzyme A
$FADH_2$	Flavin adenin mononucleotide
FFA	Free fatty acids
FFAR3	Free fatty acid receptors 3
FOXO3	Forkhead box O3
GPCRs	G Protein-coupled receptors
HCAR2	Hydroxycarboxylic acid receptor 2
HDACs	Histone deacetylases
HMGCL	3-Hydroxy-3-methylglutaryl-CoA lyase
HMG-CoA	3-Hydroxy-3-methylglutaryl-CoA
HMGCS2	3-Hydroxy-3-methylglutaryl-CoA synthase 2
mTOR	Mechanistic target of rapamycin
NAD^+	Oxidized nicotinamide adenine dinucleotide
NADH	Reduced nicotinamide adenine dinucleotide
NF-kB	Nuclear factor kappa B
NLRP3	Nucleotide-binding domain, leucine-rich-containing family, pyrin domain-containing-3
PI3K	Phosphatidylinositol 3-kinase
SCOT	Succinyl-CoA:3-oxoacid CoA transferase
Suc-CoA	Succinyl-CoA
TCA	Tricarboxylic acid cycle
TG	Triglycerides

Introduction

Prolonged starvation is a common occurrence in the wild and has profound metabolic consequences that may result in tissue dysfunction and ultimately death. Thus, the ability to cope with fluctuating nutritional resources is paramount for life. One decisive strategy to survive starvation is the mobilization and utilization of fat depots. The ketone body β-hydroxybutyrate (BHB) is a fat-derived molecule that contribute to maintain basal energy metabolism by fueling most tissues during food limitation (Robinson and Williamson 1980). In this regard, BHB functions as a "superfuel" by yielding more ATP molecules per oxygen consumed than the oxidation of other fuels such as glucose and pyruvate (Cahill and Veech 2003). However, because it has become evident that BHB has the ability to regulate energy metabolism by acting at the central nervous system and peripheral tissues through elaborated signaling pathways, it is tempting to say the term "superfuel" would fall short of what BHB can actually do. This chapter is aimed to describe ketone body metabolism and the signaling functions of BHB along with its several distinct metabolic consequences that might be important in determining the successful adaptation to starvation.

Metabolic Adaptation to Starvation

Food deprivation imposes a tremendous metabolic challenge to eukaryotic organisms. In order to face nutritional stress and survive, organisms reduce energy expenditure by eliminating unnecessary activities and temporally avoiding growth and reproduction to allocate nutritional resources only for tissue maintenance and function (Wang et al. 2006). In this sense, at both cellular and systemic levels, several metabolic processes and biochemical pathways are activated (or enhanced) while other are suppressed. For example, in mammals, when nutrient supply is limited, the highly conserved "self-eating" process autophagy is enhanced in most, if not all, tissues to degrade cytoplasmic components and to provide nutrients (lipids, amino acids, and carbohydrates) to cells for recycling and energy production. Importantly, metabolic pathways such as glycogen breakdown, gluconeogenesis, lipolysis, fatty acid oxidation, and ketogenesis parallel autophagy to coordinately satisfy systemic energy requirements and to provide glucose mainly for neurons, the highest energy-demanding cells in the brain. Thus, as a result of reduced glucose levels, occurring at the onset of fasting, blood concentrations of both fatty acids and ketone bodies rise (Fig. 1a).

Virtually, all organs in the body exhibit particular metabolic profile and require specific metabolic fuels to meet their energy needs. The brain is one of the most energy-demanding tissues that, in optimum nutritional conditions, continuously consumes large amounts of glucose to support synaptic activity and related processes (Mergenthaler et al. 2013); however, during food shortage, in order to maintain cognitive function essentially constant over time, the brain relies on ketone bodies as major metabolic fuels. In this regard, ketone bodies provide more than half of the

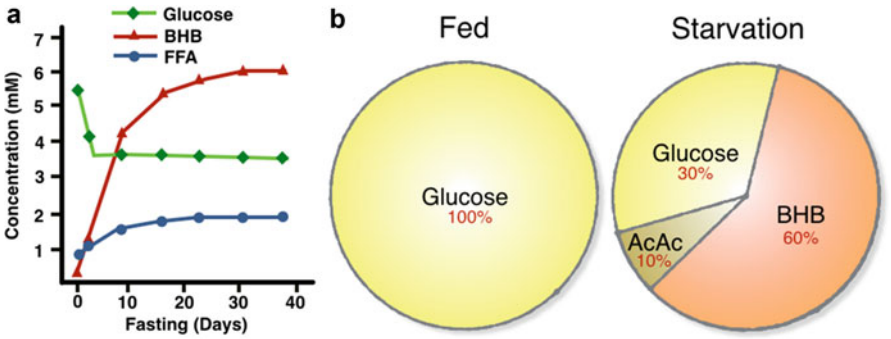

Fig. 1 Metabolic changes and fuel partitioning in the brain during starvation. (**a**) Blood concentrations of glucose, free fatty acids (*FFA*), and β-hydroxybutyrate (*BHB*) during fasting in humans. (**b**) The ketone bodies BHB and acetoacetate (*AcAc*) displace the limiting glucose in supplying the energy that brain requires to function correctly during periods of food limitation

energy that brain requires during starvation (Fig. 1b). Since a continuous glucose supply to the brain is a major goal of the metabolic rearrangements occurring during starvation, glycogen breakdown and gluconeogenesis in the liver directly contribute to maintain blood glucose at a suboptimal level. On the other hand, the adipose tissue and the liver significantly contribute to spare glucose by providing fatty acids, through lipolysis, and ketone bodies, through fatty acid oxidation and ketogenesis, respectively, as alternative fuels for most tissues (Fig. 2).

Because proteins have a broad range of important cellular functions (in the form of structural proteins, enzymes, and signaling hubs) and they constitute neither a real energy storage nor an efficient metabolic fuel and because the waste product ammonia that result from oxidative deamination of protein-derived amino acids might lead to toxicity, during fasting protein catabolism becomes a tightly regulated process: in the first hours of fasting, muscle protein breakdown increases to support gluconeogenesis, but then decline allowing the fat-derived carbon backbones to supply almost all the energy that tissues (including the brain) need to maintain essential functions for extended periods of time (days, weeks, or months depending on the species). However, in extreme cases of prolonged nutrient scarcity, when fat depots are exhausted and no food is ingested, muscle proteins are used as the ultimate resource until death.

Because of the ability of fat to spare glucose along with vital proteins during both acute (fasting) and long-term (starvation) food shortage, it comes to no surprise that the survival of an organism to famine will depend on how much fat can store during periods of plenty. For example, laboratory rats having more fat due to high-fat diet feeding survive food deprivation twice as long as the lean, chow-diet fed, age-matched controls (Goodman et al. 1984). In the same sense, while a lean human being can barely survive a few months with only water (with mineral and vitamin supplements), obese humans can survive for up to 1 year without any bite of food (Stewart and Fleming 1973). In other cases, it is known that both naturally

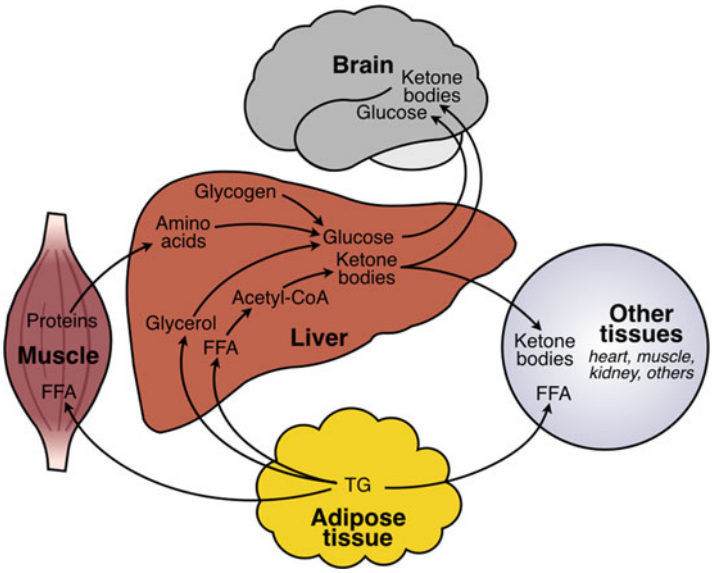

Fig. 2 Fuel metabolism in starvation. During starvation, the energy stored in the form of triglycerides (*TG*) in the adipose tissue is used to sustain whole-body energy requirements. This energy travels through the bloodstream to distant tissues in the form of free fatty acids (*FFA*) or ketone bodies (produced mainly in the liver). Also, in this situation, muscle proteins are coordinately degraded to synthesize glucose for the brain

occurring king (*Aptenodytes patagonicus*) and emperor (*Aptenodytes forsteri*) penguins repeatedly survive long-lasting breeding cycles without feeding at the expense of fat depots, resulting in reproductive success but also in severe weight loss (Groscolas and Robin 2001). Similarly, in insects such as flies and ants, starvation resistance is positively correlated with adiposity (Ballard et al. 2008; Dussutour et al. 2016). Thus, relying on endogenous, large energy stores, particularly as fats, is remarkable advantageous during starvation.

Ketone Body Metabolism

In order to utilize the energy stored in the form of fats, activation of tissue-specific metabolic programs occurs to break down triglycerides, to oxidize the resulting fatty acids, and to produce ketone bodies, mainly BHB. In the fed state, insulin stands out as the principal hormone inhibiting lipolysis, but during fasting, along with reduced insulin signaling, glucagon becomes a major hormone triggering the activation of adipocyte lipases, thus promoting the mobilization of free fatty acids (FFA). Circulating FFA are avidly taken up by peripheral tissues, such as the heart and skeletal muscles, and then oxidized in a multistep pathway (β-oxidation) to produce acetyl-coenzyme A (acetyl-CoA), which can be further oxidized in the tricarboxylic

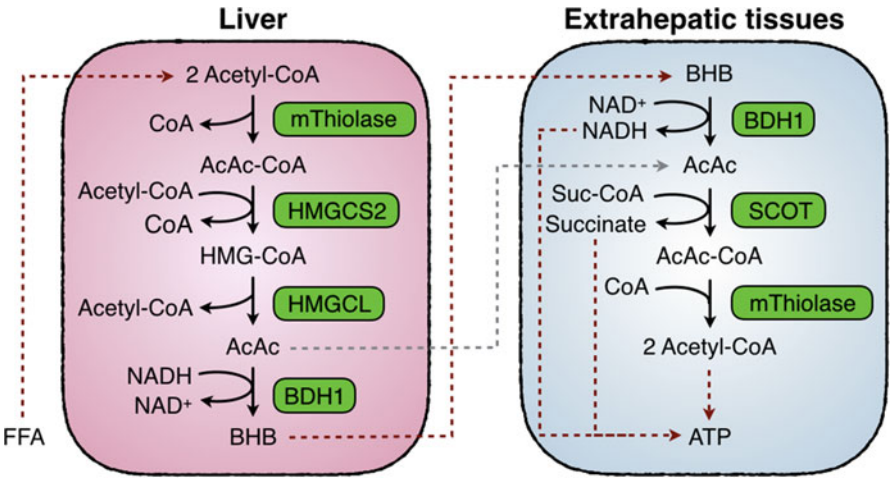

Fig. 3 Ketone body metabolism. Oxidation of free fatty acids (*FFA*) in liver mitocondria produces acetyl-coenzyme A (*acetyl-CoA*). Accumulating acetyl-CoA is preferentially directed to enzymatically produce first acetoacetate (*AcAc*) and then β-hydroxybutyrate (*BHB*). Both ketone bodies are exported out of the liver to produce acetyl-CoA back again and then ATP in distant tissues. Key: *CoA*, coenzyme A; *AcAc-CoA*, acetoacetyl-CoA; *HMG-CoA*, 3-hydroxy-3-methylglutaryl-CoA; *HMGCS2*, 3-hydroxy-3-methylglutaryl-CoA synthase 2; *HMGCL*, 3-hydroxy-3-methylglutaryl-CoA lyase; *BDH1*, BHB dehydrogenase; *SCOT*, succinyl-CoA:3-oxoacid CoA transferase; *Suc-CoA*, succinyl-CoA

acid cycle to produce reducing equivalents (NADH and $FADH_2$) for ATP synthesis. However, in the liver, FFA-derived acetyl-CoA is diverted to produce ketone bodies, first acetoacetate (AcAc) and then BHB, through a series of sequential enzymatic reactions within the process called ketogenesis, the synthesis of ketone bodies (Fig. 3). The rate-limiting enzyme in this process is 3-hydroxy-3-methylglutaryl-CoA synthase 2 (HMGCS2) which condenses acetoacetyl-CoA (AcAc-CoA) and acetyl-CoA into 3-hidroxy-3-methylglutaryl-CoA (HMG-CoA). This tightly regulated (transcriptionally and posttranslationally) enzyme, almost exclusively expressed in the liver, is decisive in channeling increasing amounts of acetyl-CoA into the ketogenic pathway. As such, HMGCS2 is particularly important in preventing liver injury during fatty acid overload (Cotter et al. 2014). Once synthesized, HMG-CoA is cleaved into one molecule of AcAc and one of acetyl-CoA by the action of the enzyme HMG-CoA lyase. To finally terminate ketogenic reactions, the inner mitochondrial membrane-bound enzyme BHB deshidrogenase 1 (BDH1) produces BHB from AcAc. By using the $NADH/NAD^+$ redox potential, BDH1 facilitates the interconversion between AcAc and BHB, allowing the liver to synthesize and peripheral tissues to oxidize BHB.

Once synthesized, BHB is exported out of the liver to be oxidized into AcAc within extrahepatic mitochondria. Because most tissues except the liver exhibit high protein levels of the enzyme succinyl-CoA:3-oxoacid-CoA transferase (SCOT), AcAc is rapidly activated into AcAc-CoA. Then, mitochondrial thiolases

can oxidize AcAc-CoA to produce two acetyl-CoA molecules. Additionally, the oxidation of AcAc also results in succinate production that together with acetyl-CoA and NADH (initially produced by BDH1) contribute to ATP synthesis through oxidative phosphorylation.

The ketone body AcAc is also exported out of the liver, but the actual BHB blood concentrations are typically threefold higher than those of AcAc. Because AcAc is efficiently oxidized within extrahepatic mitochondria, it is unknown why BHB is produced as a metabolic intermediate that connects fat stores in adipocytes to ATP production in most tissues. Nonetheless, two major potential explanations exist. The first one is related to the high stability of BHB: as AcAc is spontaneously decarboxylated into acetone, which does not contribute to ATP production, and lead only to energy wasting in times of energy crisis, synthesizing BHB may be key to bypass this futile route. Second, as the coenzyme NADH is required for AcAc reduction into BHB, it is likely that the BHB synthesis is a strategy to regenerate the NAD^+ pool that sustains the β-oxidation flux, since every round of the oxidation cycle of the acyl chain of FFA requires NAD^+. Nonetheless, since BHB is an ancient energy source (from bacteria to humans) (Cahill 2006) plus the fact that it is now part of a growing list of metabolites having signaling functions (as discussed later) (Newman and Verdin 2014), it would be simplistic to say that BHB is synthesized just to fulfill these two metabolic requirements.

The balance between ketone body synthesis and degradation is of special importance, so that, in extreme cases, high blood ketone body concentrations might result in the death of the organisms. Many conditions that favor reduced blood glucose levels also promote the activation of hepatic ketogenesis. Prolonged fasting and endurance exercise are the main physiological situations that drastically reduce blood glucose levels and also promote an elevated glucagon-to-insulin ratio, thus rapidly increasing ketone body levels (from micromolar to millimolar concentrations). However, in pathological situations such as diabetes, not only enhanced ketogenesis but also reduced ketolysis is observed (the utilization of ketone bodies), thus promoting an accumulation of these molecules, which is associated with oxidative stress and aberrant activation of signaling pathways that together might contribute to tissue dysfunction and diabetes complications (Kanikarla-Marie and Jain 2016).

There is no doubt that the liver is the principal contributor of blood ketone bodies when nutritional stress occurs, but some studies point out that other tissues and cell types have the ability to provide ketone bodies at least locally. Some of them are the kidney, skeletal muscle, astrocytes, and the gut and retinal epithelial cells (Puchalska and Crawford 2017). However, more studies are needed in order to reveal the physiological consequences of ketogenesis in extrahepatic tissues.

Requirement of β-Hydroxybutyrate During Starvation

It is a general thought that ketone bodies are essential molecules in the metabolic adaptation to starvation. However, despite this longstanding dogma that has remained for almost a century, it is still unknown whether ketone bodies are really

necessary to survive starvation. Contrary to what intuition would indicate, it turns out that disruption of ketone body oxidation in specific ketolytic tissues does not compromise survival in mice during moderate starvation (Cotter et al. 2013). This finding suggests, at a first glance, that ketone bodies are dispensable under nutritional challenge. Intriguingly, previous experiments have shown that newborn mice having higher levels of ketone bodies due to impaired ketolysis die perinatally as a result of energy imbalance but also by ketoacidosis (Cotter et al. 2011), suggesting a prominent role of ketone body metabolism in neonatal metabolic homeostasis. However, experimental approaches designed to finally delineate the role of ketone bodies in starvation physiology in the adulthood – as such with whole-body conditional disruption of ketone body oxidation – are still lacking. Moreover, the fact that many tissues such as the kidney and especially the heart and skeletal muscle can utilize both FFA and ketone bodies during fasting complicates even harder the scenario for researchers in elucidating the net contribution of ketone body in fueling starved organisms. Thus, the real biological significance of ketone bodies, and of BHB, in metabolic homeostasis during negative energy balance, until now, is far from clear.

Signaling Functions of β-Hydroxybutyrate

Many metabolites have the ability to regulate signaling transduction pathway, and BHB is one of them. Although the signaling functions of ketone bodies were recognized more than three decades ago (Robinson and Williamson 1980), it was only recently that the in vitro and animal experiments showing that (a) BHB regulates lipolysis and sympathetic activity through G protein-coupled receptors (GPCRs), the hydroxycarboxylic acid receptor 2 (HCAR2), and the free fatty acid receptor 3 (FFAR3), respectively (Taggart et al. 2005; Kimura et al. 2011) and that (b) physiological concentrations of BHB inhibit class I and class II histone deacetylases (HDACs) – as similar as its structurally related molecule butyrate (which only differs in the hydroxyl group that is present in the BHB molecule) – to affect the expression of a discrete set of genes (Shimazu et al. 2013) represented a breakthrough in the field of metabolic control and gene expression regulation by metabolites and paved the way for more studies positioning BHB as a signaling molecule that links nutritional status to stress response pathways.

For example, it is known up to date that BHB possesses anti-inflammatory activity in part by inhibiting the nucleotide-binding domain, leucine-rich-containing family, pyrin domain-containing-3 (NLRP3) inflammasome and the nuclear factor kappa B (NF-kB) signaling (Youm et al. 2015). Also, BHB induces the AMP-activated protein kinase (AMPK) signaling to reduces endoplasmic reticulum stress (Bae et al. 2016) and reduces the mechanistic target of rapamycin (mTOR) pathway to promote cellular differentiation (Wang et al. 2017). In addition, BHB extents lifespan in the nematode *Caenorhabditis elegans* though several putative signaling pathways (Edwards et al. 2014). Furthermore, recent studies have found β-hydroxybutyrilation – a form of posttranslational modification – as

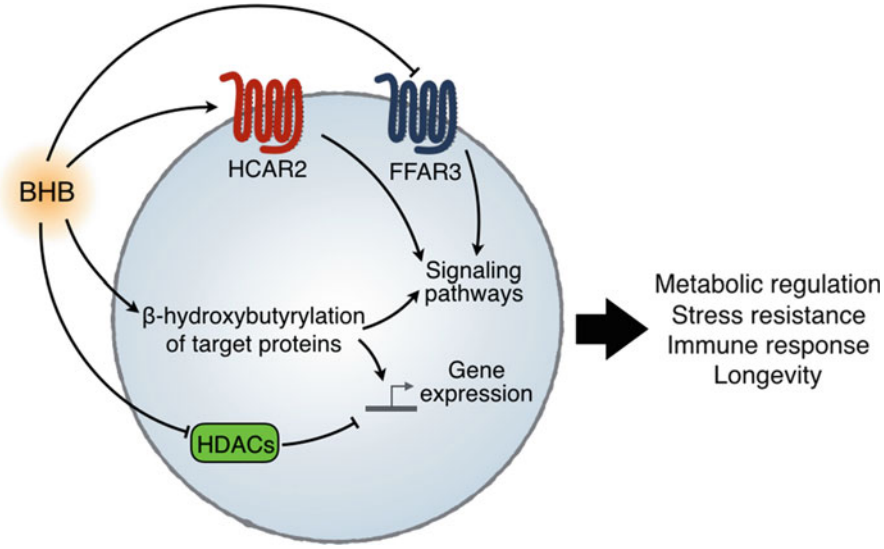

Fig. 4 Regulatory functions of β-hydroxybutyrate (*BHB*). BHB regulates several processes through G protein-coupled receptors, posttranslational modification of proteins, or by controlling gene expression by epigenetic mechanisms. Key: *HCAR2*, hydroxycarboxylic acid receptor 2; *FFAR3*; free fatty acid receptor 3; *HDACs*, histone deacetylases

another level of regulation by BHB (Xie et al. 2016). Taken together, these findings suggest that BHB has profound effects in a broad range of processes by acting as a signaling molecule (Fig. 4).

β-Hydroxybutyrate as a Starvation Signal

As explained above, BHB regulates several processes through receptors, posttranslational and epigenetic modifications, and by yet unknown mechanisms. Additionally, cumulating evidence reveals that BHB overlaps starvation in different ways (Fig. 5). Furthermore, BHB might function even as a signal fine-tuning metabolic pathways and processes to successfully cope with nutritional stress imposed by starvation (Rojas-Morales et al. 2016).

For example, it is believed that, by activating HCAR2, BHB inhibits adipocyte lipolysis to reduce FFA overload and possible premature death during starvation (Taggart et al. 2005). In addition, by acting through the same receptor, it is likely that BHB promotes adiponectin release to control feeding behavior at the central nervous system (Plaisance et al. 2009). On the other hand, by inhibiting FFAR3, BHB lowers sympathetic activity and overall metabolic rate (Kimura et al. 2011). Also, through partially unknown mechanisms, BHB reduces norepinephrine signaling, thus contributing to reduce catecholamine-induced thermogenesis (Cañas et al. 1998) and possibly energy expenditure as seen during starvation.

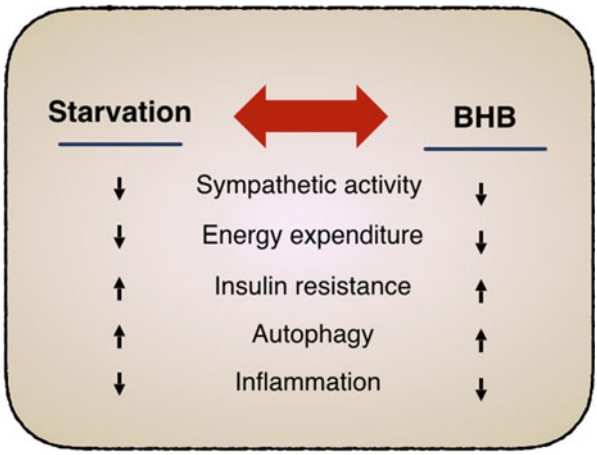

Fig. 5 Similar effects of starvation and β-hydroxybutyrate (*BHB*). BHB replicates the effect of starvation on several processes

During nutrient deprivation, tissues become insulin resistant in order to spare glucose for the brain, a process called starvation-induced insulin resistance. It has been shown that BHB reduces insulin-mediated glucose uptake in both skeletal muscle and cardiomyocytes through a mechanism likely dependent on PI3K/AKT signaling down-regulation (Yamada et al. 2010; Pelletier et al. 2007), suggesting that during starvation, by targeting insulin signaling in peripheral tissues, BHB contributes to fuel brain energy metabolism partly by its own oxidation in neuronal cells and also by providing glucose.

By inhibiting HDACs, BHB epigenetically controls gene expression. Among the most strongly unregulated stress response genes in the kidney of mice exposed to BHB was the transcription factor FOXO3, which orchestrates an antioxidant program to counteract oxidative stress (Shimazu et al. 2013). Notwithstanding, the function of FOXO3 is not limited to keeping redox balance, but this protein is also a transcriptional activator that upregulates many genes participating in autophagy (Mammucari et al. 2007). In this sense, owing to the fact that autophagy serves as one of the most ubiquitous survival mechanisms to nutrient deprivation, it is likely that BHB also regulates autophagy during starvation. Recently, this has been shown to be true in neurons deprived of glucose, where BHB promoted autophagy flux and survival (Camberos-Luna et al. 2016). Currently, in addition to FOXO3, it has been enumerated several potential, yet untested signaling routes regulated by BHB that might promote autophagy during nutrient deprivation (Rojas-Morales et al. 2016).

Finally, BHB might also be engaged in reducing inflammation during starvation. Since organisms require large amounts of both energy and building blocks to mount an appropriate inflammatory response, reducing inflammation is the most plausible thing to do when nutrient resources are scarce. By inhibiting inflammatory intermediates participating in the onset of inflammation (as noted previously), BHB might tip the balance toward saving energy in response to energy crisis (Rojas-Morales et al. 2016). Taken together, although incomplete information still exists, all these findings indicate BHB serves important regulatory role during starvation.

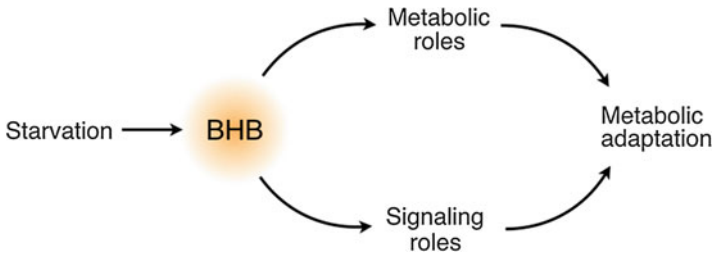

Fig. 6 The dual nature of β-hydroxybutyrate (*BHB*) during starvation. BHB can function as a substrate and a signal during nutritional challenge. By doing this, BHB might contribute to fine-tune metabolic adaptation to starvation

Concluding Remarks

Today, it is well recognized that BHB is not simply a metabolic intermediate because of its ability to engage both cell-surface and intracellular receptors and to coordinately regulate major cellular function and metabolism through its action on gene expression and signaling transduction pathways. Processes spanning from immunity to longevity are regulated by BHB. In this chapter, we have reviewed both the metabolic and signaling properties of BHB in the particular scenario of nutrient deprivation. We believe that BHB mediates metabolic response to nutrient availability through a complex set of mechanisms that still await further elucidation. Essentially, this response involves the dual nature of BHB: as a substrate and a signal (Fig. 6). Although it can take quite a long time to reveal the molecular underpinnings defining the net contribution of BHB to the biology of starvation, the functions of BHB in many aspects of biomedical research are increasingly rising.

Policies and Protocols

In this chapter, we have described that blood β-hydroxybutyrate (BHB) level rises during starvation. In the following, we describe how to measure plasma BHB in a 96-Well microtiter plate.

Principle

The assay is based on the oxidation of BHB into acetoacetate by β-hydroxybutyrate dehydrogenase that uses NAD^+ as a cofactor. Thus, as a result of BHB oxidation, NADH levels increase. In experimental settings, NADH can be easily detected spectrophotometrically at 340 nm. The addition of hydrazine to the reaction ensures complete conversion of BHB into acetoacetate.

Reagents

1. Tris-HCl buffer 100 mM, pH 8.5
2. D-β-hydroxybutyrate stock solution (Cayman Chemical, 700,192) 1 mM, suspended in Tris-HCl buffer.
3. BHB standards (0 to 0.5 mM) prepared from BHB stock solution.
4. β-Nicotinamide adenine dinucleotide (NAD^+) 4 mM, suspended in Tris-HCl buffer.
5. β-hydroxybutyrate dehydrogenase (Sigma, H9408) 4 U/ml, suspended in Tris-HCl buffer.
6. Hydrazyne hydrate (Sigma, 225,819) 4 mM, suspended in Tris-HCl buffer.

Procedure

7. Add 50 μl of each standard or plasma sample to wells.
8. Add 50 μl of hydrazyne hydrate.
9. Add 50 μl of NAD^+.
10. Add 50 μl of D-β-hydroxybutyrate dehydrogenase.
11. Incubate the plate at 25 °C for 10 min.
12. Read the absorbance at 340 nm using a plate reader.

Calculation

To calculate the amount of BHB in samples, plot the absorbance values of each standard as a function of BHB concentration, and then calculate the BHB concentration in samples from the standard curve.

Dictionary of Terms

- **Autophagy** – Autophagy is a process enhanced during stressful situations such as starvation that degrade cytoplasmic components within membranous structures called autolysosomes. This process is activated with the purpose of delivering essential molecules (lipids, amino acids, and carbohydrates) for recycling and energy production in most cells.
- **Histone deacetylases (HDACs)** – A family of proteins that remove the acetyl moiety of acetylated proteins (mainly histones). These enzymes are associated with transcriptional repression.
- **Ketoacidosis** – Pathological situation that results from both elevated production and reduced oxidation of ketone body characterized by a drop in blood pH. This pathological state is commonly observed in diabetic patients.

- **Ketogenesis** – Set of enzymatic reactions acting in concert to convert acetyl-CoA – produced during the oxidation of lipids and some amino acids – to the ketone bodies acetoacetate and β-hydroxybutyrate, occurring mainly in the liver.
- **Ketolysis** – The process of utilization/oxidation of ketone bodies to produce acetyl-CoA and then ATP, occurring in most tissues but not in the liver.
- **β-hydroxybutyrylation** – A newly identified type of posttranslational modification of lysine residues of proteins with β-hydroxybutyrate.

Summary Points

- This chapter describes the functions of ketone bodies, specially β-hydroxybutyrate (BHB), in starvation.
- BHB is a metabolic intermediate that connects fat stores in adipose tissue to ATP synthesis in most tissues in the body.
- By functioning as a metabolic intermediate, BHB sustains energetic requirements and spares both glucose and proteins during starvation.
- Recent studies have shown that BHB stands out as a signaling metabolite controlling signaling transduction pathways and gene expression.
- BHB functions as a substrate and a signal.
- BHB contributes to starvation-induced insulin resistance.
- BHB contributes to reduce energy expenditure and inflammation during starvation.
- BHB regulates autophagy through several putative signaling pathways.
- We propose that β-hydroxybutyrate regulates metabolic pathways contributing to fine-tune metabolic adaptation to starvation.

Health Impacts of Omega-3 Fatty Acid Deficiency

59

F. D. Russell and L. T. Meital

Contents

Abstract

Humans lack the capacity to synthesize omega-3 polyunsaturated fatty acids (n-3 PUFAs); thus, these essential nutrients must be obtained from the diet. Pelagic fish are a rich source of the long chain n-3 PUFAs, docosahexaenoic acid (DHA), and eicosapentaenoic acid (EPA), while oil derived from plants such as flaxseed and soybean are excellent sources of the shorter chain n-3 PUFA, α-linolenic acid (ALA). Although national and international health and government organizations provide recommendations for dietary intake of n-3 PUFAs, targets are rarely met by most populations. Furthermore, segments

V. R. Preedy, V. B. Patel (eds.), *Handbook of Famine, Starvation, and Nutrient Deprivation*, https://doi.org/10.1007/978-3-319-55387-0_110

within these populations may have particularly low intake and/or bioavailability of n-3 PUFAs that correlate with actual or increased risk of disease. Specific examples include babies that are fed nonfortified infant milk formula, individuals with polymorphic genes encoding enzymes with low efficacy for transport of fatty acids across membranes, and vegan populations with negligible EPA and DHA intake. The relationship between n-3 PUFA intake and n-3 PUFA bioavailability is complex and influenced by many factors, including genetics, smoking status, age, gender, and ratio of n-6 to n-3 PUFAs in the diet of the individual. The omega-3 index is a measure of the combined EPA plus DHA content of red blood cell membranes, expressed as a percentage of total membrane fatty acids, and serves as a better indicator of an individual's n-3 PUFA status than measurements of dietary intake. This chapter examines evidence highlighting associations between n-3 PUFA deficiency and adverse impacts on human mental and physical health. While the focus is on human n-3 PUFA deficiency, findings from cell and animal-based research have been included where this contributes toward improved understanding of human deficiency. The chapter also explores new and developing methods for production of n-3 PUFAs that promise clean and sustainable alternatives to fish, to address n-3 PUFA deficiency in human populations.

Keywords

Omega-3 polyunsaturated fatty acids · Omega-3 index · Docosahexaenoic acid · Eicosapentaenoic acid · Alpha-linolenic acid · Deficiency · Vegan · Vegetarian · Visual acuity · Fish intake

List of Abbreviations

ALA	Alpha-linolenic acid
DHA	Docosahexaenoic acid
DPA	Docosapentaenoic
EPA	Eicosapentaenoic acid
GC-MS	Gas chromatography-mass spectrometry
LPC	Lysophosphatidylcholine
Mfsd2a	Major facilitator superfamily domain 2a
mRNA	Messenger ribonucleic acid
n-3 index	Omega-3 index
n-3 PUFA	Omega-3 polyunsaturated fatty acid

Introduction

The beneficial, pleiotropic effects of omega-3 polyunsaturated fatty acids (n-3 PUFAs), whether acquired through the diet or consumed as a nutrient supplement, have been widely reported by an extensive research literature. Consequent to this,

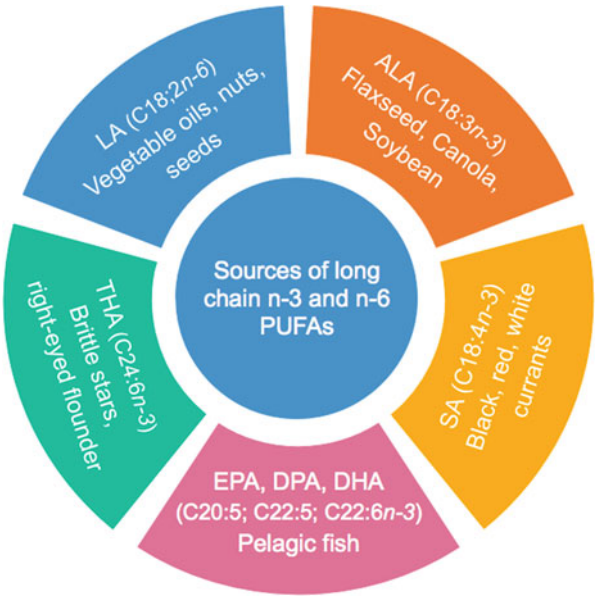

Fig. 1 Primary dietary sources of n-3 and n-6 polyunsaturated fatty acids. Linoleic acid (LA); α-linolenic acid (ALA); stearidonic acid (SA); eicosapentaenoic acid (EPA); docosapentaenoic (DPA); docosahexaenoic acid (DHA); tetracosahexaenoic acid (THA)

national and international health and government organizations have provided recommendations regarding dietary intake of n-3 PUFAs, primarily α-linolenic acid (ALA), docosahexaenoic acid (DHA), and eicosapentaenoic acid (EPA), as a means of maintaining good health or providing protection against disease (Russell and Bürgin-Maunder 2012). However, for many individuals basal intake of DHA and EPA falls well below recommended levels (Meyer 2016). Notable exceptions are Japanese and Inuit populations, the diets of which include high intakes of oily, pelagic fish, seafood or marine mammal fat, all rich sources of DHA and EPA (Fig. 1). The Codex Alimentarius Commission develops international food standards as part of the Food and Agriculture Organization of the United Nations and the World Health Organisation. An electronic Working Group of the Commission is currently exploring whether a nutrient reference value of 250 mg/day for EPA + DHA can be recommended for risk reduction of fatal coronary heart disease events (Codex Alimentarius Commission CX/NFSDU 17/39/6). Opinion within the electronic Working Group is divided, and deliberations on this matter are ongoing. A related consideration to identifying if, and how much EPA and DHA is needed to provide health benefit, is whether dietary deficiency of these fatty acids may lead to adverse health outcomes. In this chapter, n-3 PUFA deficiency is defined as suboptimal levels of n-3 PUFA that correlate with actual or increased risk of disease that can be corrected with dietary or nutraceutical supplementation. The aim of this chapter is to examine evidence highlighting associations between n-3 PUFA deficiency and adverse impacts on human mental and physical health. Findings from studies that have used cell or animal models of n-3 PUFA deficiency have been included where this provides insight into n-3 PUFA deficiency in humans.

Impact of Diet on Erythrocyte Membrane Phospholipid n-3 PUFA Content

The omega-3 index (n-3 index) provides a quantitative measure of EPA + DHA, expressed as a proportion of total fatty acids incorporated into erythrocyte membrane phospholipids. Table 1 compares the n-3 index for groups of people consuming vegan, vegetarian, omnivore, or high-fish diets. The table includes several studies that have used nonstandardized protocols to calculate the n-3 index as evidenced by some differences in fatty acid selection for determination of total fatty acids. With this limitation in mind, the n-3 index was typically high for individuals with greater intakes of fish or marine mammal fat. A study by Kawabata et al. (2011) found that the mean daily intake of fish in a cohort of Japanese men aged 67.1 ± 4.3 years was 111.2 g (905 mg/day EPA + DHA), providing an n-3 index of 9.0%. In the same study, the mean daily intake of fish in a cohort of Japanese women aged 63.5 ± 4.3 years was 77.9 g (751 mg/day EPA + DHA), providing an n-3 index of 8.3% (Table 1). While populations with a high-fish diet had a correspondingly high n-3 index (>8%), those who adhered to a long-term vegan diet had a correspondingly low n-3 index (<4%), with omnivores somewhere in between these two extremes. These findings are not surprising and are consistent with the n-3 PUFA content of foods included in the respective diets. The EPA intake of vegan men and women has been reported to be ~14.4-fold and ~50-fold lower than a population who consumed fish and meat (Welch et al. 2010). In the same populations, vegan men and women were shown to consume no DHA in their diet whilst the cohort that consumed fish and meat had a daily intake of 0.18 g/day (men) and 0.15 g/day (women).

Daily dietary intake of ALA has been reported to be between 8.8- to 37.5-fold higher than EPA and 6.6- to 18.7-fold higher than DHA in surveys of fatty acid intake in Western populations (Welch et al. 2010; Tressou et al. 2016; Raatz et al. 2017). Despite this, the level of ALA in plasma and membrane phospholipids of most cell types is lower than that of EPA and DHA, suggesting a metabolic precursor role of ALA (Baker et al. 2016). When supplemented with an ALA-enriched diet, subjects were observed to have a significantly increased plasma EPA concentration with little or no change in DHA concentration (Brenna et al. 2009). Although soybean, chia seed, flaxseed, and canola oil are abundant sources of ALA, efficiency of conversion of ALA to EPA and DHA is estimated to be only ~5% and < 0.5%, respectively (Welch et al. 2010) (Fig. 2), raising the possibility that adherence to a nonfatty acid supplemented vegan diet may lead to n-3 PUFA deficiency. However, this conclusion requires some qualification. (i) Higher conversion rates are reported for women than for men (Proust et al. 2014) and for smokers compared to nonsmokers (Pawlosky et al. 2007). (ii) Genetic variability in genes encoding Δ^6 and Δ^5 desaturases, two rate-limiting enzymes involved in the biosynthesis of n-3 and n-6 PUFAs, may affect rate of fatty acid conversion. Two haplotypes have been identified, one having significantly greater efficiency for conversion of ALA to DHA than the other (Ameur et al. 2012). (iii) In rats, liver Δ^6 desaturase mRNA expression is increased when animals are fed an ALA-depleted diet (Hofacer et al. 2011). However, conversion efficiency is also influenced by the ratio of n-6 to n-3 PUFAs. In a

Table 1 n-3 Index in selected populations adhering to vegan, vegetarian, omnivore, or high fish/marine fat diets. The types of fatty acids used in the determination of the n-3 index are shown

Diet	Population	n-3 Index	Fatty acids	Reference
Vegan (duration ≥1 year and no fatty acid supplements)	22–85 years; $n = 166$; men/women (1:1.09 ratio)	3.73%	14:0, 16:0, 18:0, 18:1 t, 18:1n-9, 18:2 t, 18:2n-6, 18:3n-3, 20:3n-6, 20:4n-6, 20:5n-3, 22:4n-6, 22:5n-3, 22:6n-3	(Sarter et al. 2015)
Vegan (duration ≥1 year and no fatty acid supplements)	20–54 years; $n = 40$; men	3.48%	14:0, 16:0, 18:0, 18:1 t, 18:1n-9, 18:2 t, 18:2n-6, 18:3n-3, 20:3n-6, 20:4n-6, 20:5n-3, 22:4n-6, 22:5n-3, 22:6n-3	(Sarter et al. 2015)
Vegan (duration ≥2 years)	Mean 49 years (40–70 yr); $n = 23$; men/women (1:1.88 ratio)	2.71 wt%	16:0, 16:1n-7, 18:0, 18:1n-9, 18:2n-6, 18:3n-3, 20:3n-6, 20:4n-6, 20:5n-3, 22:4n-6, 22:5n-6, 22:5n-3, 22:6n-3	(Pinto et al. 2017)
Vegan (duration ≥1 year)	21–66 years; $n = 22$; men/women (1:0.833 ratio)	2.1 wt%	16:0,18:0, 22:0, 24:0, 18:1, 24:1, 18:2n-6, 20:2n-6, 20:3n-6, 20:4n-6, 22:4n-6, 22:5n-6, 20:5n-3, 22:5n-3, 22:6n-3	(Sanders et al. 1978)
Vegetarian (≤1 fish meal/month for ≥1 year)	18–43 years; $n = 103$; men/women (1:3.22 ratio)	4.6–4.8 wt%	16:0, 18:0, 16:1n-7, 18:1n-9, 20:3n-9, 18:2n-6, 18:3n-6, 20:3n-6, 20:4n-6, 22:4n-6, 22:5n-6, 18:3n-3, 20:5n-3, 22:5n-3, 22:6n-3	(Geppert et al. 2005)
Omnivore	21–66 years; $n = 22$; men/women (1:0.833 ratio)	7.0 wt%	16:0,18:0, 22:0, 24:0, 18:1, 24:1, 18:2n-6, 20:2n-6, 20:3n-6, 20:4n-6, 22:4n-6, 22:5n-6, 20:5n-3, 22:5n-3, 22:6n-3	(Sanders et al. 1978)
Omnivore	Mean 54 years, $n = 24$; men/women (1:1 ratio)	5.42 wt%	16:0, 16:1n-7, 18:0, 18:1n-9, 18:2n-6, 18:3n-3, 20:3n-6, 20:4n-6, 20:5n-3, 22:4n-6, 22:5n-6, 22:5n-3, 22:6n-3	(Pinto et al. 2017)
High fish diet in a Japanese population (mean daily intake, 77.9–111.2 g)	Men, 60–75 years, $n = 22$; women, 56–73 years, $n = 32$	9.0% (men); 8.3% (women)	Full list of fatty acids not provided, but included: 18:3n-3, 20:5n-3; 22:5n-3, 22:6n-3; 18:n-6; 20:3n-6; 20:4n-6	(Kawabata et al. 2011)

(*continued*)

Table 1 (continued)

Diet	Population	n-3 Index	Fatty acids	Reference
High marine mammal fat diet in an Inuit population (≥5 g/day)	45–74 years, $n = 232$; men/women (1:1.34 ratio)	9.35%	C18:3n-3, C20:5n-3, C22:5n-3, C22:6n-3, C20:4n-3, C22:3n-3, C182n-6, C20:4n-6, C20:3n-6, C22:4,n-6, C18:1n-7, C18:1n-9, C22:1n-9, C24:1n-9, C16:0, C18:0, C22:0, C24:0	(Proust et al. 2014)

The n-3 index is the EPA + DHA peak areas as a percentage, or mole percentage of total peak areas of all identified fatty acids within erythrocyte membranes. Vegan; no meat, fish, eggs, or dairy products. Vegetarian; typically no meat products. Omnivore; mixed diet, including meat, fish, eggs, and dairy products. High fish diet, as indicated

cell-based assay tracking [^{13}C]-labeled fatty acids, conversion of ALA to EPA and DHA was much higher when cells were exposed to medium containing a low (e.g., 0:1, 1:1) compared to a high (e.g., 4:1, 9:1) n-6 to n-3 PUFA ratio (Harnack et al. 2009). This is of interest because the ratio of n-6 to n-3 PUFAs in the diet of vegan and vegetarian populations is greater than omnivorous populations (Davis and Kris-Etherton 2003) and may therefore contribute to a low conversion of ALA to EPA and DHA in these cohorts.

Animal Models of n-3 PUFA Deficiency

The impact of n-3 PUFA deficiency has been investigated in animal models through mechanisms involving gene deletion and through dietary modification.

Δ^6 Desaturase catalyzes the metabolism of linoleic acid (LA) to fatty acid precursors of arachidonic acid and the metabolism of ALA to fatty acid precursors of EPA and DHA (Leonard et al. 2002) (Fig. 2). The deletion of the gene encoding for Δ^6 desaturase leads to deficiency of EPA and DHA if the diet is not supplemented with these fatty acids. The effect of n-3 PUFA deficiency on motor coordination was investigated in Δ^6 *desaturase* knockout and wild-type mice that were bottle-fed a diet comprising LA + ALA with or without DHA supplementation (Harauma et al. 2017). Cerebellar DHA composition in Δ^6 *desaturase* knockout mice was only 39.6% of that in wild-type mice, consistent with substantial DHA deficiency within the brain. Evaluation of cerebellar function was measured indirectly using a motor coordination ability test. Motor function was significantly impaired in Δ^6 *desaturase* knockout mice compared to wild-type mice, suggesting a causal effect of DHA deprivation. Consistent with this hypothesis, motor function was rescued by addition of DHA to the diet of the Δ^6 *desaturase* knockout animals (Harauma et al. 2017).

An unexpected and unique opportunity to examine the effect of n-3 PUFA deficiency within the brain was presented following the discovery that lysophosphatidylcholine-esterified DHA (LPC-DHA) is transported across the blood-

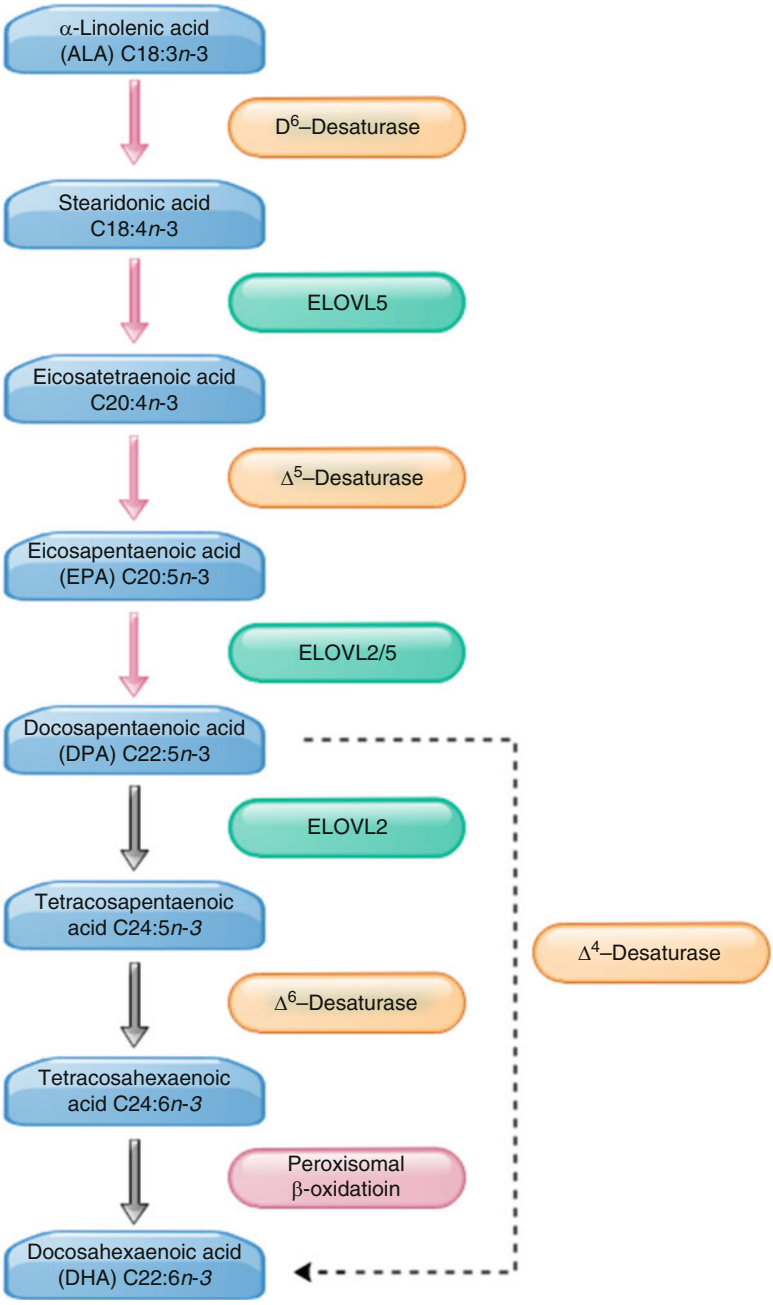

Fig. 2 Biosynthesis pathway for production of n-3 PUFAs from plant-derived ALA. Fatty acids are metabolized by activity of desaturase and elongase enzymes. DPA may be processed via a coupled microsomal-peroxisomal pathway (grey arrows), or activity of Δ^4 desaturase (dashed arrow), which was recently reported in human cells (Park et al. 2015)

brain barrier by the sodium-dependent symporter, major facilitator superfamily domain 2a (Mfsd2a) (Nguyen et al. 2014; Wong et al. 2016). Mfsd2a, which is expressed in cerebral microvessel endothelial cells, is needed to maintain a high DHA composition within brain phospholipids. Deletion of the *Mfsd2a* gene in mice leads to a 60–77% lower level of DHA in brain phospholipids compared to wild-type mice (Nguyen et al. 2014; Wong et al. 2016), and this was associated with loss of Purkinje cells in the cerebellum and mature neurons in the hippocampus, microcephaly, motor dysfunction, anxiety, and deficits in learning and memory (Nguyen et al. 2014). While *Mfsd2a* knockout mice were reported to have reduced blood-brain barrier function (Ben-Zvi et al. 2014), blood-brain barrier integrity was found to be preserved in a later study (Wong et al. 2016). Although deficiency of other fatty acids in *Mfsd2a* knockout mice may contribute to structural and functional abnormalities, it is noteworthy that arachidonic acid levels were *higher* in *Mfsd2a* knockout mice compared to wild-type mice (Nguyen et al. 2014; Wong et al. 2016) and that Mfsd2a has greater capacity to transport LPC-DHA than other LPC-conjugated fatty acids such as oleate and palmitate (Nguyen et al. 2014).

DHA is incorporated into glycerophospholipids of the retina of the eye and is the most abundant n-3 PUFA within photoreceptor outer segment membrane discs (Wong et al. 2016). In addition to its expression within the blood-brain barrier, Mfsd2a is also expressed in retinal capillary endothelium that forms the blood-retinal barrier and in retinal pigment epithelium. Deletion of the *Mfsd2a* gene in mice leads to a 50% reduction in DHA uptake in the eyes, with levels of DHA-containing phospholipids in the eyes declining by 40% compared to wild-type mice (Wong et al. 2016). The deficiency of DHA in the eyes was associated with disorganization and atrophy of the outer segment, formation of gaps between the outer segment and retinal pigment epithelium, and edema within the basal membrane of the retinal pigment epithelium (Wong et al. 2016). Selective knockout of *Mfsd2a* gene in the capillary endothelium (but not retinal pigment epithelium) leads to preserved structural integrity of the eye, suggesting that transport of DHA within the retinal pigment epithelium is critical to structural integrity and development within the eye (Wong et al. 2016).

Health Effects of n-3 PUFA Deficiency in Humans

Investigations into the effect of DHA deficiency on visual acuity in humans have primarily used newborn term or preterm babies as subjects, with the babies receiving infant formula as the sole source of nutrition. Advantages of this approach are firstly that the fatty acid composition of the infant formula can be easily manipulated and secondly that the baby does not receive additional fatty acids, including DHA that is present in human breast milk. In humans, the photoreceptor outer segment begins to form at about 25 weeks of gestation (Martinez et al. 1988). Martinez and colleagues examined postmortem tissue of a baby born prematurely at 25 weeks gestation and who died at 4 months from viral pneumonia. The baby, who had been fed milk formula that was deficient in ALA and DHA, had a retinal DHA level that was only

50% of that expected for a baby receiving these fatty acids in the diet. While the study supports the importance of diet on DHA incorporation in retinal membranes in the early stages of life, the impact of this on eye function was not investigated. This has since been examined in several studies. The effect of DHA deficiency on visual evoked potential visual acuity in humans was examined in 244 term babies that were randomized to receive infant milk formula (infant formula) containing an absence of DHA, or 0.32%, 0.64%, or 0.96% DHA (Birch et al. 2010). Each formula was matched for levels of arachidonic acid, LA and ALA. Visual acuity was significantly poorer in babies that were deprived of DHA compared to those receiving DHA-fortified formula, at ages 1.5, 4, 6, 9, and 12 months. Interestingly, the magnitude of response was the same for the five DHA doses, consistent with a maximal effect with 0.32% DHA.

In addition to visual acuity deficits, a substantial research literature suggests lower levels of n-3 PUFAs correlate with a heightened predisposition toward developmental and mental disorders, cancer and cardiovascular, inflammatory, and neurodegenerative diseases (Table 2).

Factors Leading to n-3 PUFA Deficiency in Humans

Deficiencies of n-3 PUAFs in human populations can be traced to restricted dietary intake of EPA and DHA in foods or nutritional supplements. Indeed, many countries have population data indicating low erythrocyte membrane fatty acid composition that can be ascribed to low consumption of foods that are enriched in EPA and DHA (Stark et al. 2016). Other factors leading to n-3 PUFA deficiency include genetic abnormalities that reduce the efficiency of movement of n-3 PUFAs across non-aqueous barriers, and genetic variation that affects the efficiency of n-3 PUFA metabolism.

Dietary Restriction in Infants

Young children represent a segment of the population at particular risk of n-3 PUFA deficiency, with vulnerability spanning the developmental stages from conception through infancy. During prenatal growth and development, n-3 PUFAs are delivered to the fetus via placental transfer. The *in utero* accretion of DHA in the last trimester of pregnancy is estimated to be 43 mg/kg/day (Lapillonne and Jensen 2009). Taking into account the amount of DHA that is obtained through enteral and parenteral routes and through synthesis, the amount of DHA available to preterm infants (gestational age of $\leq$28 weeks) for accretion after the first week of life is only 16% of that normally accumulated *in utero* (Lapillonne et al. 2010). Although the amount of DHA available for accretion in the preterm infant increases over the first 4 weeks of life, the cumulative amount of DHA at gestational age of 32 weeks is estimated to be only 43–73% of that which is accumulated *in utero* (Lapillonne et al. 2010). Notwithstanding several limitations reported by the authors in the

Table 2 Meta-analyses examining low fish intake and/or low n-3 PUFA levels and association with developmental disorders, mental disorders, inflammatory disease, cardiovascular disease, neurodegenerative disease, or cancer

Disorder		Population characteristics	Summary of inclusion criteria	Main finding	Effect size or relative risk (95% CI)	Heterogeneity	Source
Developmental disorders	Autism spectrum disorder (ASD)	Children (≤12 years; $n = 825$)	Case ($n = 423$); control group with typical development ($n = 402$) Measurement of erythrocyte, serum, plasma, plasma phospholipid or whole blood n-3 PUFAs	Lower n-3 PUFAs in case compared to control group	DHA SMD -2.14^{***} (-3.22 to -1.07) EPA SMD -0.72^{**} (-1.25 to -0.18)	DHA; $I^2 = 97\%$ EPA; $I^2 = 88\%$	(Mazahery et al. 2017)
	Attention deficit hyperactivity disorder (ADHD)	Children and adults (8–35 years; $n = 587$)	Case ($n = 311$); control group with typical development Measurement of erythrocyte and/or plasma n-3 PUFAs	Lower n-3 PUFAs in case compared to control group	EPA, DHA, ALA, and DPA; $g = 0.42^{***}$ (0.26 to 0.59)	EPA, DHA, ALA, and DPA; $I^2 = 0\%$	(Hawkey and Nigg 2014)
		Children and adolescents (4–17 years; $n = 396$)	Case ($n = 200$); control group with typical development ($n = 196$) Measurement of erythrocyte, blood phospholipid, cholesteryl ester, or buccal cell n-3 PUFAs	Lower n-3 PUFAs in case compared to control group	Total n-3 PUFAs $g = -0.58^{***}$ (-0.87 to -0.29)	Total n-3 PUFAs $I^2 = 46\%$	(Chang et al. 2018)

Mental disorders	Depression	General population and community dwellers ($n = 107{,}098$)	Fish consumption assessed by validated food frequency questionnaires	Populations with the highest fish consumption had a 22% lower risk of depression when compared with the lowest fish consumption	RR = 0.78 (0.69 to 0.89)	$I^2 = 61\%$	(Grosso et al. 2016)
		Adolescents and adults from the general population (150,278)	Studies in which fish consumption was assessed Depression, excluding postpartum depression and depression in pregnancy	Populations with the highest fish consumption had a 17% lower risk of depression when compared with the lowest fish consumption. Subgroup analysis revealed reduced risk for studies conducted in Europe only	RR = 0.83^{***} (0.74 to 0.93)	$I^2 = 64.5\%$	(Li et al. 2016)
	Bipolar disorder	Adolescents and adults ($n = 265$)	Case ($n = 118$); control group with typical development ($n = 147$) Erythrocyte n-3 PUFAs	Lower DHA levels in case compared to control group	$d = -0.98^{***}$ (-1.33 to -0.63)	$I^2 = 0.0\%$	(Mcnamara and Welge 2016)
	Schizophrenia	Adults ($n = 1222$)	DPA: (i) medication naïve ($n = 104$), (ii) nonmedicated, previous neuroleptic use ($n = 61$); (iii) neuroleptics ($n = 286$) DHA: (i) medication naïve ($n = 104$); (ii) nonmedicated, previous neuroleptic use ($n = 74$); (iii) neuroleptics ($n = 389$) Erythrocyte n-3 PUFAs	Antipsychotic-naïve and treated patients with schizophrenia were found to have decreased erythrocyte levels of both DPA and DHA when compared to a healthy control cohort	DPA $d = 1.14^{***}$ (0.72 to 1.57) DHA $d = 0.67^{***}$ (0.26 to 1.07)	Overall DPA $I^2 = 87.4\%$ Overall DHA $I^2 = 90.5\%$	(Hoen et al. 2013)

determination of the above estimates, the conclusion of the studies is that infants born prematurely are particularly susceptible to DHA-deficiency and may benefit from additional dietary DHA supplementation.

In breastfed infants, n-3 PUFAs are delivered across the blood-milk barrier from mother to infant. Whilst breastfeeding is endorsed as the preferred method for provision of n-3 PUFAs to infants (Koletzko et al. 2008), this is not always adopted for a variety of reasons (Zhang et al. 2015). In these circumstances, infant formula is often the only source of nutrition to be received by the infant. The Food and Agriculture Organization and the World Health Organisation (FAO/WHO) and Food Standards Australia New Zealand set no mandatory minimum requirement for DHA or EPA in infant formula (FSANZ, Consultation Paper, 2016; FSANZ SD1 Attachment A1.1 – Nutrition Assessment: Proposal P1028; CODEX STAN 72-1981). Inclusion of DHA in infant formula is optional for manufacturers, and if it is present, its level must be no greater than the amount of added arachidonic acid and no less than the amount of added EPA to reflect fatty acid ratios naturally present in breast milk (CODEX STAN 72-1981). Some manufacturers add DHA to infant formula, providing consumers with choice of product. Not surprisingly, the lipid composition of formula has a marked influence on plasma lipid composition. Infants who were fed formula that contained no added arachidonic acid or DHA for 4 months had a very low total plasma concentration of DHA-containing lipids (Uhl et al. 2016). In contrast, infants who were fed formula containing added arachidonic acid and DHA (each at 72 mg/mL) for 4 months had a total plasma concentration of DHA that was not different to breast-fed infants (Uhl et al. 2016). An assessment by FSANZ was that "the addition of LCPUFAs to infant formula does appear to have some positive, albeit minor influence on the development of visual acuity in infants compared to standard formulations" (FSANZ Final Assessment Report, 2007). There is now a growing body of evidence showing that severe deprivation of DHA during development has considerable negative impact on brain function. With concerns for detriment to brain and eye function, a consensus recommendation was issued by a group of pediatric medicine researchers for the addition of DHA to infant formula at levels between 0.2% and 0.5% of total fatty acids, arachidonic acid at levels at least that of DHA, and EPA at levels that do not exceed that of DHA (Koletzko et al. 2008).

Restricted Consumption of n-3 PUFAs in Vegan and Vegetarian Populations

Oily fish are a particularly rich source of n-3 PUFAs with key health organizations recommending consumption of 2 to 3 fish meals per week, providing 250–500 mg of EPA + DHA per day (NHF Position Statement, 2015; European Food Safety Authority). Although meat and poultry have a more moderate n-3 PUFA composition than fish, high-level consumption of these foods can contribute substantially to total dietary intake (Howe et al. 2006). While plant-derived foods provide large amounts of ALA, they tend to be relatively deficient in DHA and EPA and, as mentioned above, are converted to DHA and EPA with poor efficiency. Thus,

individuals favoring vegan and vegetarian (lacto-, ovo-, or lacto-ovo) eating styles may become deficient in DHA and EPA if their diets do not include n-3 PUFA supplementation (refer to section "Impact of Diet on Erythrocyte Membrane Phospholipid n-3 PUFA Content" and Table 1).

Genetic Abnormalities Leading to n-3 PUFA Deficiency

When HEK293 cells were made to express Mfsd2a with p.Thr159Met and p.Ser166Leu substitutions, esterification of exogenous LPC containing DHA into phosphatidylcholine was significantly lower than in cells expressing wild type Mfsd2a (Guemez-Gamboa et al. 2015). The findings raise the question as to whether individuals who express a gene encoding an aberrant Mfsd2a protein might also exhibit cerebral DHA deficiency. A recent study identified two families with genetic abnormalities in the *Mfsd2a* gene: one presenting with a p.Thr159Met amino acid substitution and another with a p.Ser166Leu amino acid substitution (Guemez-Gamboa et al. 2015). Individuals with the aberrant genes exhibited microcephaly and intellectual disability, suggesting that loss of fatty acid transport function across the blood-brain barrier contributes to cerebral DHA deficiency and that this is associated with severe structural and functional abnormalities. It is important to note that LPC-DHA is not the only plasma source of DHA for the brain. The rate of uptake of nonesterified DHA from the plasma to the brain is ten-fold higher than the rate of LPC-DHA uptake (Chen et al. 2015a). This level of redundancy in DHA supply would be expected to temper any diminution in supply of LPC-DHA by aberrant Mfsd2a protein expression.

Processes That Affect Omega-3 Fatty Acid Content and Quality

Food production (e.g., aquaculture) and food processing procedures (e.g., cooking methods) can impact on the quantity and quality of n-3 PUFAs that are consumed in the diet.

Aquaculture contributes 26.5% of production and comprises 38.4% of the monetary value of the New South Wales seafood industry (Hussain et al. 2017). Fish are unable to synthesize n-3 PUFAs and so must obtain these from ingestion of supplied feed. Studies investigating fatty acid profiles of wild and farmed fish report higher levels of n-3 PUFAs in wild compared to farmed fish (Strobel et al. 2012). A fall in n-3 PUFA content of farmed fish was attributed to changes to aquaculture practice in which feed of marine origin was replaced with plant protein sources (Strobel et al. 2012). Strategies to provide new sources of EPA and DHA in aqua-feed have been reviewed recently (Sprague et al. 2017).

The quality of fatty acids in dietary products such as fish and infant formula may be affected by thermal treatment. For example, pan frying of freshwater fish caused a significant decrease in n-3 PUFA content, while the n-3 PUFA content of baked fish was similar to that of the raw fish (Schneedorferová et al. 2015). A

decrease in n-3 PUFA content was observed in Pacific saury, a pelagic fish, following pan frying, grilling, and deep frying, with the greatest loss observed after deep frying (42% loss) (Cheung et al. 2016). The reduction in n-3 PUFA content was attributed to spillage of liquefied subdermal fat during grilling or leaching of fatty acids into the frying oil during deep-frying (Cheung et al. 2016). Lipid oxidation was also reported in grilled and pan-fried saury, and this may have contributed to the observed loss of fatty acid content.

Where infant formula is given to babies, this product is usually prewarmed prior to feeding. In a study examining the amount of fatty acids in ready-to-feed infant formula, the DHA content was reported to be unaffected by warming milk in preboiled water or warming using a microwave (Loughrill and Zand 2016). In contrast, a 22.2% decrease in ALA content was observed in milk formula that was microwave-treated compared to nonheated milk formula. In view of these findings, consideration may need to be given to the type of thermal treatment of dietary products when striving to meet recommended intake levels of n-3 PUFAs.

Strategies to Increase Plasma, Cell, and Tissue n-3 PUFA Levels

Dietary modification is a commonly employed method of increasing n-3 PUFA intake. The Heart Foundation of Australia recommends consumption of food that can deliver levels of EPA + DHA between 250 to 500 mg/day and ALA at 1 g/day (Heart Foundation Position Statement). Oily fish and seeds and nuts are foods with particularly high levels of these fatty acids (Fig. 1). However, despite reports identifying associations between good health and dietary intake of n-3 PUFAs, daily intake of n-3 PUFAs is below recommended levels in most Western populations (Meyer 2016). Potential reasons for this are many and include high cost of fish, undesirable taste or smell of fish, concerns for sustainability in fishing practices, and perceived risk of heavy metal toxicity (Grieger et al. 2012). The consumption of capsules containing fish, krill or flaxseed oil, consumption of red meat, or fortified foods such as eggs, yoghurt, and milk, and for babies, n-3 PUFA-fortified infant formula, may provide satisfactory alternative methods for increasing plasma and cell membrane levels of n-3 PUFAs.

As described above, vegan and vegetarian populations may be deficient in n-3 PUFAs; thus, interest exists in strategies that increase n-3 PUFA levels while avoiding consumption of fish or other animal products. Although ALA is a plant source of n-3 PUFAs, efficiency in conversion of ALA to EPA and DHA is low in humans, particularly when the n-6 to n-3 PUFA ratio is high (see above) (Harnack et al. 2009). A working group of the Italian Society of Human Nutrition recommended that vegetarians should regularly consume foods that are enriched in ALA while limiting intake of foods that have a high LA content (Agnoli et al. 2017). The advice is underpinned by evidence that ALA and LA are competitive substrates for Δ^6 desaturase and that an increase in dietary intake of ALA and concomitant decrease in LA will favor ALA as a Δ^6 desaturase substrate. Consistent with this, erythrocyte EPA composition increased by 51.3% and erythrocyte

DHA composition increased by 18.8% in subjects who reduced their consumption of LA from 7.4% to 2.4% of energy, for 12 weeks, without altering their intake of n-3 PUFAs (Macintosh et al. 2013). The working group also recommended that vegan and vegetarian populations who have an increased requirement for n-3 PUFAs (e.g., pregnant and breastfeeding women) should include an algal-derived supplement that contains EPA + DHA.

Algal sources of n-3 PUFAs, such as marine phytoplankton, contain preformed EPA and DHA. In the food-web, certain species of marine phytoplankton are consumed by filter-feeding zooplankton, which are in turn consumed by zooplanktonivorous fish (Sargent 1997). While these fish are a primary dietary source of n-3 PUFA for humans, the fatty acids can also be obtained from the algal source. Marine phytoplankton-derived oil contains high levels of DHA and EPA, and this was used as a source of n-3 PUFAs to investigate its effect on the n-3 index in a cohort of 48 vegans. Participants consumed algal-derived oil (172 mg DHA, 82 mg EPA per day) for 4 months, during which time the mean n-3 index rose from 3.1% to 4.8% (Sarter et al. 2015).

Transgenic plants are also being developed that can improve the efficiency of long chain n-3 PUFA production. For example, transgenic *Camelina sativa* has been engineered with improved desaturase and elongase enzyme activities. The plants were found to accumulate 12.4% DHA and 3.3% EPA within the seed oil, rivaling levels that are accumulated in pelagic fish (Petrie et al. 2014). Importantly, the increased n-3 PUFA content of the seed oil was not accompanied by new production of n-6 PUFAs, leading to the expectation that consumption of the seed oil would maintain a low n-6 to n-3 PUFA ratio.

Policies and Protocols

Determination of the n-3 index involves extraction of phospholipids from erythrocytes using chloroform and KCl solutions. Extracted lipids are hydrolyzed using a HCl/H_20/acetonitrile solution and exposed to a derivatizing agent (e.g., 1-tert-butyldimethylsilylimidazole), prior to GC-MS analysis. The n-3 index is the combined EPA and DHA peak areas, calculated as a proportion of total area of fatty acids, within the sample. The HS-Omega-3 Index® is a proprietary technology that was developed to standardize the n-3 status of clinical subjects using erythrocytes or whole blood, dried blood spot samples (Köhler et al. 2010). The premise of the application is that the n-3 index is most meaningful when the same group of fatty acids are used to assess "total" erythrocyte membrane fatty acid composition. This is important because the relative abundance of EPA + DHA in membranes is affected by selection of fatty acids included in the assay. The HS-Omega-3 Index® method evaluates the fatty acids esterified in membrane glycerophospholipids, not sphingolipids, and uses a mathematical correction factor to convert dried blood spot data to an equivalent erythrocyte n-3 index. A series of 24 fatty acids used to determine the HS-Omega-3 Index® has been reported previously (Köhler et al. 2010).

Dictionary of Terms

- **Omnivore** – A person with a mixed diet, consuming both meat, and plant products.
- **Pelagic fish** – Oily fish that inhabit deep water, not in contact with either shore or ocean-floor.
- **Phytoplankton** – Unicellular algae belonging to the taxonomic kingdom Protista.
- **Polyunsaturated Fatty Acids** – Fatty acids that include two or more double bonds in their chemical structure.
- **Vegan** – A person who adheres to a plant-based dietary style involving complete avoidance of animal-derived food, including meat, fish, eggs, honey, and dairy products.
- **Vegetarian** – A person who adheres to a plant-based dietary style that typically excludes meat, fish and other marine animals but may include animal by-products in the form of eggs (ovo-vegetarian), milk (lacto-vegetarian), or both (ovo-lacto-vegetarian).
- **Zooplankton** – Aquatic organisms that feed on phytoplankton.

Summary Points

- With the exception of island nations such as Iceland and Japan, basal intake levels of DHA and EPA fall well below recommended guidelines.
- The relationship between the amount of n-3 PUFAs consumed in the diet and n-3 PUFA bioavailability is influenced by a range of factors including genetic make-up, smoking status, age, gender, and ratio of n-6 to n-3 PUFA consumption.
- Transgenic and animal models of restricted n-3 PUFA supply have revealed an important role for DHA in normal brain growth and cognition and have highlighted associations between DHA deprivation and motor dysfunction, visual impairment, and cognitive deficits.
- Although ALA features prominently in modern human diets, conversion of this plant-based n-3 fatty acid to EPA and DHA is reported to be highly inefficient (~5% and $< 0.5\%$, respectively). Individuals favoring plant-based eating styles are thus vulnerable to n-3 PUFA deficiency with adherence to a long-term vegan diet being reported to correlate with an n-3 index $<4\%$. The corresponding value in populations consuming high fish diets is typically $>8\%$.
- Young infants represent an additional at-risk segment of the population with n-3 PUFA deficiency presaging adverse impacts on brain and eye function.
- Meta-analytical studies involving large cohorts of adolescents and/or adults have reported a correlation between low n-3 PUFA levels and a heightened risk of developmental impairments, mental, inflammatory and neurodegenerative disorders, cardiovascular diseases, and neoplasms.
- Strategies to address low n-3 PUFA levels in vulnerable segments of the population include dietary or nutraceutical intervention and provision of alternative n-3 PUFA-rich products in the form of marine phytoplankton or transgenic plants.

Abstract

The heart consumes the highest energy substrates per weight in the entire body. The heart preferentially uses fatty acids (FAs) as energy-providing substrates; 60–90% of cardiac adenosine triphosphate (ATP) is derived from FA oxidation (FAO), with the remaining derived from glucose, lactate, ketone bodies, and amino acids. During fasting, FAO is increased, whereas glucose utilization is reduced. Sources of FAs in circulation are free FA (FFA) bound to albumin and two forms of triglyceride-rich lipoproteins (TGRLP), chylomicrons (CM), and very-low-density lipoproteins (VLDL). Following lipolysis of TG (triglyceride) of TGRLP on the cell surface of endothelial cells, FAs traverse the muscle-type continuous capillary layer via protein-mediated and/or nonprotein-mediated pathways. In turn, FAs bound to albumin in the interstitial space are taken up by the heart via the flip-flop mechanism, which is likely facilitated by several plasma-membrane proteins, including FAT (FA translocase)/CD36. Most FAs are utilized in the heart to generate ATP and the remaining FAs are used as TG storage, membrane phospholipid components, and lipid mediators. During fasting, FA uptake and oxidation are enhanced via transcriptional activation by peroxisome proliferator-activated receptor γ (PPARγ) in capillary endothelial cells and by PPARα and PPARγ coactivator-1α (PGC-1α) in cardiomyocytes. Inherited disorders that affect FAO compromise the function of the heart in catabolic states, such as fasting, which causes sudden infant death syndrome. This section describes the mechanisms that regulate FA uptake by the heart in the fed or fasted state as well as the effects of fasting on cardiac function.

FFA · TGRLP · CM · VLDL · Lipolysis · LPL · GPIHBP1 · FAT/CD36 · Flip-flop · Trans-endothelial fatty acid transport · FABP3/4/5 · FAO · PPARα · PPARγ · PGC-1α · Inherited disorders

List of Abbreviations

ATP	Adenosine triphosphate
CM	Chylomicrons
ECs	Endothelial cells
ETC	Electron transport chain
FABP	Fatty acid binding protein
FAD	Flavin adenine dinucleotide

FAO	Fatty acid oxidation
FAT	Fatty acid translocase
FATP	Fatty acid transport protein
FFA	Free fatty acid
GPIHBP1	Glycosylphosphatidylinositol-anchored protein 1
LPL	Lipolysis, lipoprotein lipase
Meox2	Mesodermal homeobox-2
NAD	Nicotinamide adenine dinucleotide
PDH	Pyruvate dehydrogenase
PDK4	Pyruvate dehydrogenase kinase 4
PGC-1α	PPARγ coactivator-1α
PPAR	Peroxisome proliferator-activated receptor
PPRE	PPAR response elements
REE	Resting energy expenditure
RXR	Retinoid X receptor
TCA cycle	Tricarboxylic acid cycle
Tcf15	Transcription factors 15
TG	Triglyceride
TGRLP	TG-rich lipoproteins
VEGF-B	Vascular endothelial growth factor-B
VLDL	Very-low-density lipoproteins
VLDLR	VLDL receptor

Introduction

Energy Expenditure of the Entire Body and Heart

The heart weight is less than 0.5% of the total body weight, but its resting energy expenditure (REE) is the highest among all organs (440 kcal/kg/day, Table 1). As a result, the heart accounts for approximately 9% of the total REE despite its small size (Gallagher et al. 1998). Although muscle preferentially takes up and metabolizes FAs in the fasting state, all of the muscle energy requirements cannot be met by β-oxidation. By contrast, the liver has a greater capacity for β-oxidation than it requires and produces a large amount of acetyl-CoA as the length of fasting increases (Marray 2009). This acetyl-CoA in the liver is used to synthesize ketone bodies, which are major metabolic fuel for skeletal and cardiac muscle as well as the brain. During prolonged starvation, glucose represents less than 10% of the total body energy consumption.

Energy Substrates and ATP Production in the Heart

The normal adult heart uses two main energy substrates, FA and glucose, to generate adenosine triphosphate (ATP), the high-energy phosphate, for cardiac work (Doenst et al. 2013; Huss and Kelly 2004; Kolwicz et al. 2013). The amount of ATP

Table 1 Mass-specific organ metabolic rate at rest in humans (kcal/kg/day). Heart weight is less than 0.5% of the total body weight, but its resting energy expenditure is the highest among all organs (Data are cited from the study by Gallagher et al. (1998) with permission from the American Physiological Society)

combusted by the heart during a 1-day period is 15–20 times its own weight. The major functions of cardiomyocytes in cardiac work are contraction (pump function), Ca^{2+} uptake into the sarcoplasmic reticulum, and maintenance of the sarcolemmal ion gradients. Under normal conditions, nearly all ATP is generated from mitochondrial oxidation of FA and glucose; 2% or less is derived from anaerobic glycolysis. FA oxidation (FAO) supplies 60–90% of myocardial ATP in the healthy adult heart, whereas the remaining (10–40%) comes from glucose, lactate, ketone bodies, and certain amino acids (Fig. 1). FAs are catabolized in the mitochondrial matrix during β-oxidation, which generates NADH, FADH2 (supply of H^+; proton), and acetyl-CoA. Pyruvate is derived from glucose, and lactate is oxidized by the pyruvate dehydrogenase (PDH) complex to generate acetyl-CoA. Acetyl-CoA derived from both pathways is oxidized by the tricarboxylic acid (TCA) cycle to generate NADH.

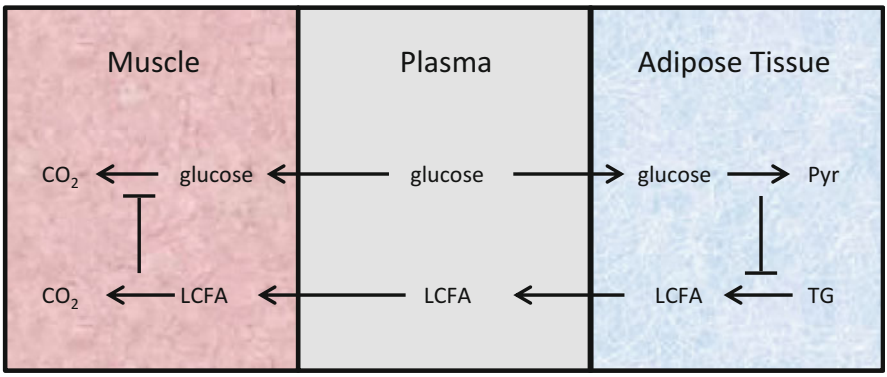

Fig. 2 The "glucose-fatty acid cycle," a homeostatic mechanism to control circulating concentrations of glucose and FAs. The effect of glucose is mediated by insulin. Hormones that control adipose tissue lipolysis affect circulating concentrations of FAs, and FAs, in turn, control fuel selection in muscle. *LCFA* long chain FA, *TG* triacylglycerol, *Pyr* pyruvate (This figure is from the review by Hue and Taegtmeyer (2009) with permission from the American Physiological Society)

A proton gradient established by the electron transport chain (ETC) drives ATP formation when coupled to oxidative phosphorylation (Fig. 1). During fasting, FAO serves as the primary myocardial ATP generating pathway, whereas glucose utilization is minimized. Prolonged fasting results in an (paradoxical) increase in cardiac glycogen and lipid stores (Goldberg et al. 2012; Suzuki et al. 2002; Taegtmeyer et al. 2016), but their storage capacity is very limited for cardiac work. Therefore, the pathways of cellular FA uptake are a major source of energy supply during fasting and FA uptake and oxidation must be tightly coupled to generate ATP.

Competition Between FA and Glucose (Randle Cycle)

The effects of hormones on fuel metabolism are well known. The high insulin/glucagon ratio of the postprandial state promotes lipid and carbohydrate storage. A high glucagon/insulin ratio, characteristic of the fasted state, stimulates adipose tissue lipolysis, and hepatic glucose production to preserve the glucose supply to tissues that exclusively rely on glucose. The glucose-fatty acid cycle, generally referred to as the Randle cycle (Hue and Taegtmeyer 2009), represents nutrient-mediated fine-tuning that works on top of the more coarse hormonal control (Figs. 2 and 3). This dynamic adaptation to nutrient availability applies to the interaction between adipose tissue and muscle (Fig. 2). Hormones that control adipose tissue lipolysis affect the circulating concentrations of FAs, and FAs, in turn, control fuel selection in muscle. Although the biochemical mechanism by which FAO inhibits glucose utilization in muscle seems to be clear, the reciprocal aspect, namely, inhibition of FAO by glucose, only has a limited plausible mechanistic explanation (Fig. 3). Impairment of glucose metabolism by FA (or ketone body) oxidation is mediated by short-term inhibition of several glycolytic steps, namely,

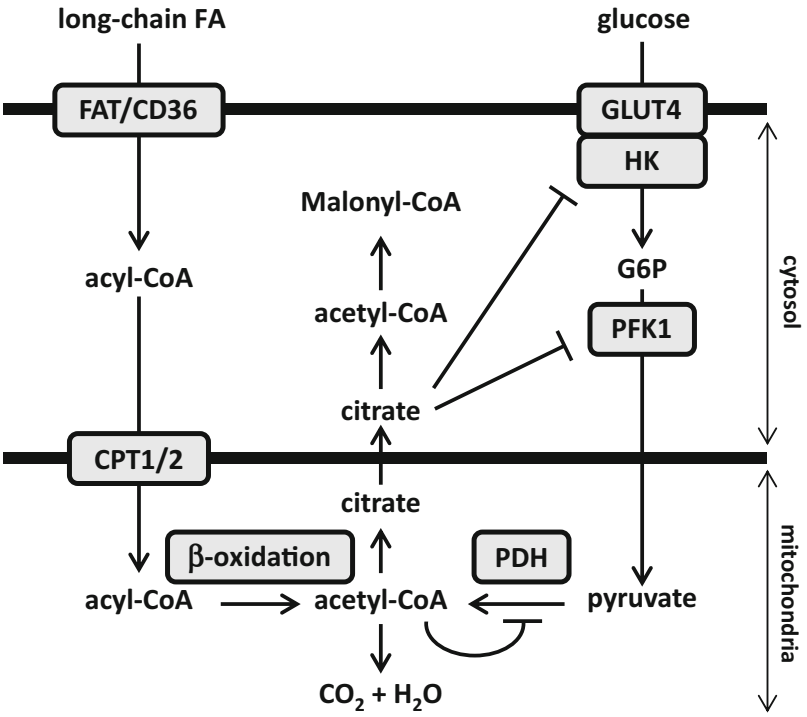

Fig. 3 Mechanism of inhibition of glucose utilization by FA oxidation in cells. PDH inhibition is caused by acetyl-CoA and NADH accumulation resulting from FA oxidation, whereas PFK inhibition results from citrate accumulation in the cytosol. The mechanism of inhibition of glucose uptake is not clear. *CPT* carnitine palmitoyltransferase, *FAT* fatty acid translocase, *GLUT* glucose transporter, *G6P* glucose-6-phosphate, *HK* hexokinase, *PFK* phosphofructo-1-kinase, *F6P* fructose-6-phosphate, *PDH* pyruvate dehydrogenase (Original figure)

glucose transport (Glut4 and hexokinase: HK) as well as phosphorylation of phosphofructo-1-kinase (PFK-1) and pyruvate dehydrogenase (PDH). The extent of inhibition is most severe at the level of PDH and less severe at the level of PFK and glucose uptake. Allosteric inhibition of PDH is caused by acetyl-CoA and NADH accumulation resulting from FAO, whereas PFK inhibition results from citrate accumulation in the cytosol. PDH is also inactivated by phosphorylation via pyruvate dehydrogenase kinase 4 (PDK4), which is induced by the nuclear receptor PPARα during fasting. The mechanism of inhibition of glucose uptake is not clear.

Competition Between FA and Ketone Bodies

The heart also readily oxidizes ketone bodies (β-hydroxybutyrate and acetoacetate) in a concentration-dependent manner (Cotter et al. 2013; Stanley et al. 2003). Whereas plasma ketone body concentrations are normally very low, the concentrations become

elevated during fasting (Marray 2009). A moderate elevation of the plasma ketone body concentration inhibits FAO in the normal heart in vivo. Suppression of FAO by ketone bodies might be mediated through inhibition of FA uptake by the myocardium, independent of changes in myocardial malonyl-CoA concentrations, and not through effects on mitochondrial oxidation. The mechanism underlying inhibition of the cellular FA transport system by ketone bodies remains unclear.

Fatty Acid Uptake by the Heart

Complexity of the Machinery Used in FA Metabolism in the Heart

During the past two decades, there have been many major advances toward understanding FA metabolism in the heart. For example, recent findings have demonstrated that capillary vessels in the heart are not only conduits for plasma and blood cells but also have a significant role in FA metabolism, which dramatically affects FA uptake. Lipoprotein lipase (LPL) produced by cardiomyocytes is transported and anchored by a newly found protein produced by endothelial cells, in which the complex works. Interestingly, it is likely that FAs released from CM and VLDL are taken up via different routes. Several key molecules in the endothelium have been found to function in unique fashions. This main text describes several topics, including the source of FAs, mechanism of capillary endothelial FA uptake, mechanism of myocardial FA uptake, transcriptional regulation of key molecules for FA metabolism, and human genetic disorders associated with cardiac FA metabolism.

Source of FAs

FAs are supplied to the heart as either free FA (FFA) bound to albumin or as FAs released from TG contained in TGRLP: CM, synthesized in the intestine from exogenous dietary fat and VLDL, or synthesized by the liver from endogenous lipid (Evans and Hauton 2016; Lopaschuk et al. 2010). FFAs bound to albumin originate from adipose tissue lipolysis, with some derived from "spillover" through the action of LPL. Both circulating FFA and TGRLP significantly contribute to the overall FA supply to cardiac myocytes. Normal circulating FFA concentrations range between 0.2 and 0.6 mM. These levels can vary dramatically from very low concentrations in fetal circulation to over 2 mM during severe stress, such as myocardial ischemia and uncontrolled diabetes. Prolonged fasting also increases the release of FFA from adipose tissue. Chronic or acute increases in circulating FFA have a major impact on the rates of cardiac FA uptake and β-oxidation, as the arterial FA concentration is the primary determinant of the rate of myocardial FA uptake and oxidation. The plasma TG concentration is also highly variable: fasting plasma TG is typically 0.6–0.7 mM, increasing to 1.5–3.0 mM following a mixed meal. Because TG yields 3×FA

upon complete hydrolysis, availability of plasma TG-FA greatly (90%) exceeds the availability of circulating FFA. However, defining the myocardial preference for lipids has proved difficult.

Mechanism of Capillary Endothelial FA Uptake

Among the complicated machinery that regulates cardiac energy metabolism, FA uptake from circulation and its further transfer to cardiac myocytes through capillary endothelial cells (ECs) are the first critical components (van der Vusse et al. 2000). FAs are supplied to tissues as FFA bound to albumin or TGRLP. In contrast to sinusoidal ECs, which have a large fenestrate (100–200 nm) that allows for the passage of small particles, including albumin (5–10 nm) and chylomicron remnants (30–80 nm), capillary ECs in the heart and skeletal muscle (i.e., muscle-type continuous capillary) do not allow these processes. Instead, theoretically, trans-endothelial FA transport is the most likely mechanism that supplies FA to cardiac myocytes (Wagenmakers et al. 2016). In terms of trans-endothelial FA transport, there are several critical steps: (1) lipolysis on the cell surface, (2) FA uptake by capillary ECs, and (3) FA transport across endothelial cells, each of which has complex mechanisms.

Lipolysis of TGRLP by LPL on the Surface of Capillary ECs

LPL is an essential enzyme that hydrolyses TG contained in TGRLP (Evans and Hauton 2016). Despite contributing less than 0.5% of the total body mass, the myocardium possesses 5% of the total heparin-releasable LPL. Given that more than 90% of plasma FA is contained within TGRLP and that the heart has the highest amount of expressed LPL, lipolysis of TGRLP mediated by LPL is likely to be a principal source of FA for cardiomyocyte metabolism (Chiu et al. 2016). Indeed, cardiac-specific LPL knockout mice exhibited postprandial triglyceridemia (Augustus et al. 2004), whereas cardiac-specific LPL expression in systemic LPL knockout mice improved triglyceridemia (Levak-Frank et al. 1999). These findings support the notions that lipolytic activity by LPL in the heart is a major determinant in the regulation of the plasma TG level, and therefore, FAs derived from TGRLP are a major energy substrate for the heart. Importantly, in the heart, LPL is produced in cardiomyocytes and is transferred to the luminal side of the ECs, where the enzyme functions (Fig. 4). For a long time, it was assumed that LPL was bound to heparin sulfate proteoglycans on the surface of capillary ECs (Adeyo et al. 2012). Recently, it was reported that GPIHBP1, a glycosylphosphatidylinositol-anchored protein of capillary ECs, is the principal binding site for LPL on endothelial cells and that it is responsible for transporting LPL to the capillary lumen (Fig. 4). GPIHBP1 binds to LPL from interstitial spaces and shuttles it across endothelial cells to the capillary lumen. At the luminal side, its ability to bind to both TGRLP and LPL allows it to serve as a platform for TG lipolysis along the luminal surface of capillaries (Adeyo et al. 2012). Mice lacking LPL as well as GPIHBP1 develop severe chylomicronemia, even when fed a low-fat diet. Likewise, patients with genetic mutations of LPL as well as GPIHBP1 have severe chylomicronemia (Adeyo et al. 2012; Merkel et al. 2002).

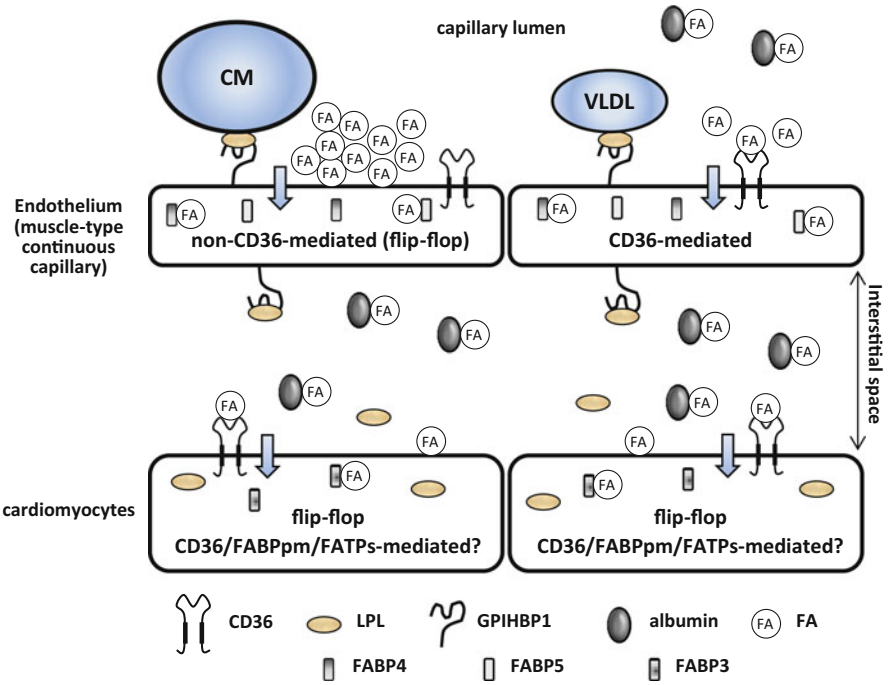

Fig. 4 Lipolysis of TG contained in TGRLP on the luminal side of the capillary endothelium, trans-endothelial FA transport, and FA uptake by cardiomyocytes. This figure has a long and essential story in this section. See the text for details (Original figure)

FA Uptake by Capillary ECs

Studies in many mammalian cell types using FA bound to albumin at increasing molecular ratios yielded evidence of two distinct pathways of FA uptake (Abumrad and Goldberg 2016), a low-capacity saturable pathway and a high-capacity non-saturable pathway (Fig. 4). The saturable pathway has kinetics that are consistent with protein facilitation, with a high affinity for long-chain FAs (Km approximately 10 nM). The nonsaturable pathway operates at high ratios of FA, presumably via the flip-flop mechanism. Indeed, CD36, also known as fatty acid translocase (FAT), is a high-affinity receptor for long-chain FAs (Km of 5–10 nM) and is suitable for the low levels of FFAs in circulation. In the heart, CD36 is more abundant on capillary ECs compared to cardiomyocytes. Bharadwaj et al. demonstrated by using heart-specific LPL-KO and CD36-KO mice that VLDL-derived TG-FA (low local release of FAs) entered the cell through a CD36-mediated channel (high affinity, low capacity, saturable), whereas CM-derived TG-FA (high local release of FAs) entered through a non-CD36-mediated route (low affinity, high capacity, nonsaturable, presumably by the flip-flop mechanism) (Bharadwaj et al. 2010). Unlike deficiencies for LPL as well as GPIHBP1, CD36 deficiency in humans and mice does not cause hyperchylomicronemia, supporting the notion that FAs released from CM are taken up by free diffusion in the absence of CD36. However, the details of TG-FA channeling are still uncertain.

Fatty acid transport proteins 3 and 4 (FATP3/4), which are induced in capillary ECs in response to an increase in vascular endothelial growth factor-B (VEGF-B) secreted from cardiomyocytes, are also required for FA transport of capillary ECs (Hagberg et al. 2010). However, the contribution of these molecules, including CD36 and FATP3/4, to FA uptake is still uncertain because endothelial-specific knockout models for them have not yet been established.

FA Transport Across Capillary ECs

Following FA uptake on the luminal side of ECs through several possible routes, intracellular FAs need to be delivered to the abluminal side of capillary ECs (van der Vusse et al. 2000). Although there are several options for this process, trans-endothelial FA transport mediated by fatty acid binding proteins 4 and 5 (FABP4/5) is a possible pathway that allows FAs to be shuttled in the cytoplasm (Fig. 4). Cytoplasmic FABPs are a family of 14–15 kDa proteins that bind to long-chain FA with high affinity. As lipid chaperones, FABPs may actively facilitate the transport of lipids to specific compartments in cells. FABP4/5 are exclusively expressed in capillary ECs in the heart (Iso et al. 2013). In double knockout mice for FABP4/5, cardiac uptake of FA was substantially reduced, whereas the uptake of glucose was remarkably increased. Importantly, FA uptake was not altered in isolated cardiomyocytes ex vivo, suggesting that capillary ECs can transport FAs via cytoplasmic FABP4/5 to cardiomyocytes (Fig. 4). The hypothesis of trans-endothelial FA transport by FABP4/5 needs to be addressed using endothelial-specific knockout mice.

Mechanism of Myocardial FA Uptake

Following FA transport through the muscle-type capillary endothelial layer, FAs are bound by albumin (300 μM) in the interstitial space of the heart (Fig. 4). After being taken up by cardiomyocytes, FAs are bound by cytoplasmic FABP3 (also designated as H-FABP; 150–300 μM), which acts as the intracellular counterpart of albumin (Glatz et al. 2016). The total FA concentration is 100–400 μM in the interstitial space, whereas it is 50 μM in the cytoplasm. Albumin and FABP3 each provides a buffer for FAs, whereby each FA molecule is immediately replenished by the release of another FA molecule from the protein binding site. The direction and overall rate of FA uptake are determined by the transsarcolemmal gradient of FAs. Trans-sarcolemmal uptake of FA by cardiomyocytes comprises three separate steps: adsorption, flip-flop and desorption.

1. **Adsorption**: Entry of FAs into the outer leaflet of the lipid bilayer, which is facilitated by membrane-associated proteins.

Similar to capillary ECs, the main membrane-associated protein facilitating FA uptake is CD36 in cardiomyocytes (Figs. 1 and 4). Recently, the crystal structure of LIMP2 (Lysosomal Integral Membrane Protein 2), a member of the CD36

superfamily of scavenger receptors, was determined (Neculai et al. 2013). The putative structure of CD36 according to homology modelling suggests that it has a large cavity that serves as a tunnel through which lipids are delivered to the outer leaflet of the plasma membrane. Another protein, plasma membrane FABP (FABPpm; also known as GOT2), is expressed on the extracellular side of cardiomyocytes, myocytes, and ECs. FABPpm associates with CD36 at the plasma membrane, where its primary role seems to be to assist CD36 in the binding and transport of FAs. All FATPs (FATP1–6) have been shown to enhance cellular FA uptake. However, there has been much debate regarding the localization of FATPs and whether they are true FA transporters or whether they simply drive cellular FA influx by intracellular acylation of FAs. The contributions of FABPpm and FATPs to FA uptake are unlikely to be as much as that of CD36.

2. **Flip-flop**: Flip-flop is a transbilayer lipid motion that occurs in the phospholipid bilayer membrane and is independent of receptor-mediated fatty acid uptake.

Biophysical studies have shown that the "flip-flop" of FA in the phospholipid bilayer is very fast for virtually all FA types. Therefore, the possible role for membrane-associated proteins in the adsorption step is most likely restricted to determining the membrane domain where "flip-flop" takes place, rather than the rate of FA translocation from the outer to the inner leaflet.

3. **Desorption**: Movement of FA into the intracellular aqueous phase and hydration of FAs.

This step appears to be rate-limiting for all transmembrane transport and is strongly dependent on the chain length and degree of unsaturation of the FA. There is some evidence that transmembrane proteins, particularly CD36, provide a docking site for cytoplasmic FABP3 (Figs. 1 and 4) or for enzymes that act on FAs, such as acyl-CoA synthetase (Fig. 1). These protein-protein interactions may facilitate the desorption step.

Lipoprotein Receptor-Mediated TGRLP Uptake by the Heart

Direct uptake of CM and VLDL particles or remnant particles via lipoprotein receptors has also been proposed, although their contributions to TG uptake remain disputed (Evans and Hauton 2016). Receptor-mediated assimilation of TGRLP has been reported for many tissues, including the heart; the principal cardiac lipoprotein receptor is believed to be the VLDL receptor (VLDLR). VLDLR binds and internalizes VLDL as well as other apo-E containing lipoproteins, in concert with LPL and apo-E, suggesting that VLDLR has a LPL-facilitating function. VLDLR knockout mice fed high fat diets show decreased cardiac uptake of [^{3}H]TG without altered plasma lipoprotein levels, despite decreased LPL expression. The mechanism of transport of TGRLP across capillary ECs also remains elusive.

The PPAR Family Transcriptionally Regulates Myocardial Energy Metabolism

Acute changes in flux through metabolic pathways are mediated by changes in substrate concentrations and allosteric modification of enzymes catalyzing these reactions (e.g., Randle cycle). Chronic changes in mitochondrial oxidative capacity and substrate selection are also mediated at the gene transcriptional level. Cardiac metabolism is transcriptionally regulated by the three members of the PPAR family (PPARα, β/δ, and γ) of ligand-activated transcription factors (Finck 2007; Huss and Kelly 2004; Rowe et al. 2010). PPARs do not act on a single target, but rather orchestrate several pathways whereby nutrients regulate their own metabolism. The expression of PPARα is high in tissues with an elevated capacity for FAO, such as the liver, heart, brown fat, and kidneys. PPARα regulates FA homeostasis via transcriptional activation of genes encoding key enzymes in FA catabolism, such as FA uptake and FAO. PPARβ/δ is almost ubiquitously expressed and transcriptionally regulates FAO, but these metabolic effects are probably not as essential as those of PPARα. PPARγ is adipose tissue-enriched and thought to play a vital role in regulating fat storage.

Transcriptional Regulation by PPARs and Cofactors

PPAR family members regulate the expression of target genes by binding to direct repeat response elements (PPAR response elements; PPRE) in the promoter region of target genes with their obligate heterodimeric partner, retinoid X receptor (RXR) (Fig. 5). The activity of the PPAR/RXR complex is modulated by the availability of ligands for PPAR and RXR (Finck 2007; Huss and Kelly 2004; Rowe et al. 2010). Potentially, the most relevant endogenous ligands for PPARs are long-chain FAs and their metabolites. However, the specific species of FA metabolites that serve as endogenous natural ligands for PPARs have yet to be fully established. High-affinity pharmacological agents that can modulate the activity of PPARs exist, including fibrates for PPARα and thiazolidinediones for PPARγ. When engaged by a ligand, PPARs recruit transcriptional coactivators that are necessary to initiate target gene transcription. Several coactivators interact with PPARα, including steroid receptor coactivators (SRC) and p300. The best-characterized coactivator of PPARs in the heart is cardiac-enriched PPARγ coactivator-1α (PGC-1α) (Fig. 5). In cardiac myocytes, the activation of PGC-1α drives a strong induction of PPARα target genes encoding FAO enzymes. PGC-1α also coactivates other transcription factors, including estrogen-related receptors (ERRα and γ) and the nuclear respiratory factor 1 (NRF-1), to stimulate mitochondrial biogenesis and enhance expression of components of the electron transport chain. These findings suggest that PGC-1α acts to augment the capacity for ATP production in a global manner by inducing expression of enzymes that are involved in multiple components of these catabolic pathways.

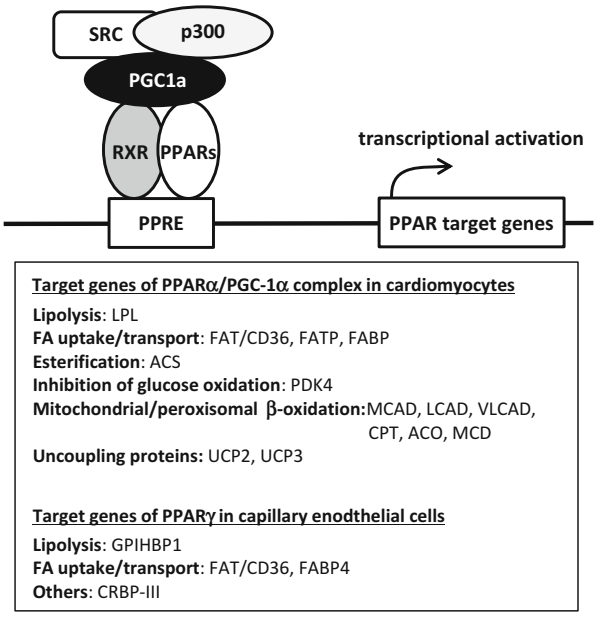

Fig. 5 Transcriptional regulatory complex by PPARs and their cofactors and PPAR-regulated genes involved in cardiac energy metabolism. Many key players for cardiac metabolism are transcriptionally regulated by PPARγ in capillary endothelial cells and by PPARα in cardiomyocytes. *PPRE* PPAR response elements, *RXR* retinoid X receptor, *SRC* steroid receptor coactivator (Original figure)

Gene Expression Regulated by PPARα and PGC-1α in the Heart During Fasting

PGC-1α activity and expression levels are induced by cold exposure, fasting, and exercise, stimuli that are known to promote oxidative metabolism (Rowe et al. 2010). PGC-1α binds to and co-activates PPARα in cardiomyocytes, thereby inducing numerous genes that are critical for FA handling (Fig. 5), including CD36 (import into cell), CPT1b (import into mitochondria), PDK4 (reciprocal inhibition of pyruvate entry into mitochondria), and MCAD (rate-limiting step in medium chain FA β-oxidation). The expression of several PPARα target genes and the rates of FAO are diminished in the hearts of PPARα null mice as well as PGC-1α at baseline and fail to be induced in response to fasting. Thus, PPARα and PGC-1α are essential transcription factors for controlling FA oxidation in the heart during fasting.

Gene Expression Regulated by PPARγ in Capillary ECs During Fasting

Unlike cardiomyocytes, critical genes for FA handling in capillary ECs are regulated by PPARγ (Fig. 5). Expression of PPARγ is induced in capillary ECs by fasting, leading to induction of its target genes, such as GPIHBP1, CD36, and FABP4 (Goto et al. 2013; Kanda et al. 2009). Importantly, endothelial-specific PPARγ knockout mice exhibited hyperchylomicronemia after olive oil gavage as well as higher levels of circulating FFA during fasting, which are consistent with defective function of GPIHBP1 (via LPL) and defective function of FABP4/CD36, respectively. Thus,

endothelial PPARγ in the heart facilitates FA uptake via both a LPL-mediated low affinity/high capacity/nonsaturable pathway and a CD36-midiated high affinity/low capacity/saturable pathway, both of which are enhanced during fasting.

Gene Expression Regulated by Other Factors

Meox2/Tcf15 Heterodimer

Mesodermal homeobox-2 (Meox2) is a homeobox gene that is expressed in EC. Meox2 forms a heterodimer with a basic helix-loop-helix transcription factors 15 (Tcf15), which is highly expressed in capillary ECs. The Meox2/Tcf15 heterodimer drives endothelial expression of genes associated with FA metabolism, including PPARγ, FABP4/5, CD36 and GPIHBP1, to facilitate FA uptake and transport across the capillary endothelium (Chiu et al. 2016; Coppiello et al. 2015). Given that the haplodeficiency of Meox2/Tcf15 in mice impairs cardiomyocyte contractility, this heterodimer not only plays a role in endothelial regulation of FA but may also be involved in altering cardiac energy substrates. The involvement of Meox2/Tcf15 in fasting-induced gene expression remains to be addressed.

VEGF-B/FATPs Axis

Paracrine signaling by VEGF-B from tissues also regulates trans-endothelial FA transport (Hagberg et al. 2010). VEGF-B is expressed in most adult tissues, with the highest expression found in the myocardium, skeletal muscle, and BAT. VEGF-B secreted from myocardium specifically binds to VEGF receptor-1 and to the common co-receptor neuropilin-1 expressed in capillary ECs, which in turn induces the expression of two FA transport proteins, FATP3 and FATP4. Endothelial FATP3/4 are required for FA transport across the vascular endothelial layer. In sharp contrast to the induction of PPARα target genes during fasting, the expression level of VEGF-B is suppressed by fasting and is enhanced by a high fat diet. These findings suggest that the VEGF-B/FATPs axis and cardiac PPARα plus endothelial PPARγ axis function in different nutritional states.

Cardiac Function During Starvation

The effect of starvation on the heart may not be well recognized because it rarely results in heart failure (Taegtmeyer et al. 2016; Webb et al. 1986). Starvation causes a decreased rate of protein synthesis without a change in the rate of protein degradation, leading to a reduction in contractile protein subunits, resulting in cardiac atrophy (Samarel et al. 1987). As the myocardial mass decreases during starvation, the stroke volume and cardiac output decrease proportionately. However, the stroke-volume index and cardiac index remain normal or rise slightly because of the decrease in body size. Additionally, starvation is also associated with a fall in heart rate, blood pressure, and blood volume. Cardiac function in patients with

anorexia nervosa is also known to be maintained. Thus, cardiac atrophy during starvation is unlikely to cause heart failure because the demand of cardiac work is simultaneously reduced.

Refeeding Syndrome

Although cardiac failure is rare in malnutrition, it is common that fatal responses occur by the refeeding of starved people, which is known as refeeding syndrome (Webb et al. 1986). Potential complications of refeeding syndrome include heart failure, fatal arrhythmia, respiratory insufficiency, and hematological derangements. Refeeding is associated with a sudden reversal of compensatory factors, including catecholamines, renin-angiotensin-aldosterone system, salt intake, and sodium retention. These changes increase blood volume and pressure. Furthermore, catecholamines augment the shift of potassium, magnesium, and phosphate into cells, with potentially deleterious effects on cardiac function and rhythm.

Association Between Defective FA Utilization and Cardiac Dysfunction in Humans

Inherited disorders that affect FA oxidation (FAO) seriously compromise the function of the heart and other highly energy-dependent tissues, such as the brain, skeletal muscle, kidney, and liver (Houten and Wanders 2010; Spiekerkoetter and Wood 2010). For almost every enzyme involved in FAO, including CACT (carnitine-acylcarnitine translocase), CPT1a, CPT2, MCAD (medium-chain acyl-CoA dehydrogenase), MTP (mitochondrial trifunctional protein), and VLCAD (very long-chain acyl-CoA dehydrogenase), inherited defects have been reported. Such defects encompass a wide spectrum of clinical disease, presenting in the neonatal period or infancy with recurrent hypoketotic hypoglycaemia, liver dysfunction, myopathy/rhabdomyolysis, and cardiac diseases, such as dilated or hypertrophic cardiomyopathy and/or arrhythmias. These functional disturbances can cause sudden infant death syndrome. This disease is triggered by a catabolic state, such as during fasting, sustained aerobic exercise, surgery, and infections. Thus, a decrease in metabolic flexibility (FAO defects + hypoketotic hypoglycaemia) may lead to acute cardiac dysfunction in a catabolic state. Alternatively, accumulating metabolites, such as acylcarnitines and FAs, due to defective FAO might be toxic to the heart, which may contribute to arrhythmias.

Other gene mutations with defective FA utilization in human are CD36, LPL, and GPIHBP1. CD36 deficiency results in a reduction of myocardial FA uptake and a marked increase in glucose uptake (Abumrad and Goldberg 2016; Glatz et al. 2016). Although CD36 mutations are known to be associated with an increase in the left ventricular mass and cardiovascular events, there are no obvious symptoms and physical findings due to these mutations throughout their life (Love-Gregory and Abumrad 2011). Genetic mutations for LPL and GPIHBP1 cause type I

hyperlipoproteinemia, or familial chylomicronemia (Patni et al. 2000). Often, patients with deficiencies in LPL and GPIHBP1 are not diagnosed until they develop pancreatitis, at which time the serum levels of TG are severely elevated. In contrast to FAO deficiency, genetic mutations of CD36, LPL, and GPIHBP1 do not result in cardiomyopathy, even in a catabolic state. In these genetic disorders, the partial FA uptake pathway should function, as suggested by animal models. Additionally, gluconeogenesis and ketogenesis by the liver are maintained. These findings suggest that energy supply by partial uptake of FAs and by other compensatory energy substrates is sufficient for cardiac work, even under a situation in which the cardiac energy demand is increased.

Protocol

Methods to Estimate Fatty Acid Uptake by the Heart

The traditional methods of organ balance measurements of fuel metabolism require measurements of the rates and amounts of fuel delivery and uptake by using invasive tools to collect blood samples. Imaging studies using radiolabelled tracers can provide accessible, accurate, and quantitative measurements of fatty acid uptake safely and non-invasively. ^{123}I-BMIPP (15-(p-iodophenyl)-3-(R,S)-methyl pentadecanoic acid) has been most extensively used in humans. The 3-methyl group in the side chain of BMIPP inhibits β-oxidation, resulting in prolonged retention in the myocardium. Gamma rays from ^{123}I are imaged by SPECT (single photon emission CT). The uptake of ^{123}I-BMIPP appears to reflect the uptake of circulating free fatty acid, but not fatty acid derived from TGRLP through lipolysis. Instead of ^{123}I-BMIPP, ^{125}I-BMIPP is frequently used for animal studies because of its longer half-life. Fatty acid oxidation is not estivated by radiolabelled BMIPP. To estimate fatty acid uptake from TGRLP, radiolabelled chylomicron and VLDL are necessary. These studies have been performed using animal models, but not in humans. The preparation of radiolabelled chylomicron and VLDL requires a complicated special process, which limits extended studies regarding the uptake of fatty acid derived from TGRLP.

Dictionary of Terms

- **Triglyceride-rich lipoprotein (TGRLP)** – A collective term for chylomicron and VLDL. TGRLP is a major source of fatty acid supply to the heart.
- **Free fatty acid (FFA)** – Most FFA is produced by lipolysis of triglyceride in adipocytes and bound to albumin in plasma. Some are derived from the spillover of those of TGRLP through the action of lipoprotein lipase.
- **Chylomicron** – Chylomicron is the largest TGRLP and is synthesized in the intestine from exogenous dietary fat.

- **Very low density lipoprotein (VLDL)** – VLDL is the second largest TGRLP and is synthesized by the liver from endogenous lipid.
- **Lipolysis** – Triglycerides in TGRLP or adipocytes are hydrolyzed by several types of lipases, resulting in the generation of glycerol and FFA. This process is termed lipolysis.
- **Flip-flop** – Flip-flop is a transbilayer lipid motion that occurs in the phospholipid bilayer of membranes and is independent of receptor-mediated fatty acid uptake.
- **Trans-endothelial fatty acid transport** – Muscle-type nonfenestrated capillary functions as a barrier between circulation and the interstitial space for the movement of FFA. FFA is transported across the endothelial layer by several steps of protein-mediated mechanisms, not by passive diffusion.
- **Peroxisome proliferator-activated receptor (PPAR)** – Three members of the PPAR family (PPARα, β/δ, and γ) are ligand-activated transcription factors that regulate metabolism in many organs, including cardiomyocytes and capillary endothelial cells.

Summary Points

- FA is a central energy substrate for the heart, both in the fed and fasted state. FA oxidation supplies 60–90% of myocardial ATP, whereas the remaining ATP (10–40%) comes from glucose, lactate, ketone bodies, and certain amino acids.
- FA uptake through capillary endothelial cells in the heart comprises three separate steps: lipolysis on the cell surface, FA uptake by the plasma membrane, and FA transport in the cytoplasm.
  1. Lipolysis: Circulating TG contained in TG-rich lipoproteins (CM and VLDL) is hydrolyzed by LPL located on the luminal surface of the capillary endothelial cell. In the heart, LPL is produced by cardiomyocytes. GPIHBP1, expressed in capillary endothelial cells, is indispensable as a binding site for LPL on endothelial cells and for transporting LPL to the capillary lumen.
  2. FA uptake: Low levels of FAs derived from VLDL are taken up by a CD36-mediated channel (high affinity, low capacity, saturable), whereas high levels of FAs from CM are taken up by free diffusion through the plasma membrane via the flip-flop mechanism (low affinity, high capacity, nonsaturable).
  3. FA transport: Capillary endothelial cells can transport FAs via cytoplasmic FABP4/5 to the interstitial space of cardiomyocytes.
- FA uptake by cardiomyocytes comprises three separate steps: adsorption, flip-flop, and desorption.
  1. Adsorption of FAs bound to albumin in the interstitial space is facilitated by plasma-membrane proteins, such as CD36 and others, which enhances the next step, flip-flop.
  2. Flip-flop of FA in a phospholipid bilayer of the plasma membrane is through free diffusion and is very fast for virtually all FA types.
  3. The desorption step is rate-limiting and is facilitated by cytoplasmic FABP3 as well as some enzymes that have binding sites for CD36.

- Direct uptake of CM and VLDL particles or remnant particles via lipoprotein receptors has also been proposed, although their contributions to TG uptake remain disputed.
- The expression of genes associated with FA catabolism in cardiomyocytes is enhanced by PPARα and its coactivator, PGC-1α, during fasting, which facilitates FA uptake and oxidation.
- Expression of FA handling genes in capillary endothelial cells is mainly enhanced by PPARγ, which facilitates lipolysis and trans-endothelial FA transport.
- Cardiac atrophy during starvation does not cause heart failure because the demand of cardiac work is simultaneously reduced.
- Uncontrolled refeeding often causes potential complications, including heart failure and fatal arrhythmia, in the starved people, which is known as refeeding syndrome.
- Inherited disorders that affect mitochondrial FA oxidation cause acute cardiac dysfunction in a catabolic state, such as fasting, which is observed in patients with sudden infant death syndrome.
- Cardiac dysfunction does not occur in patients with genetic mutations of genes associated with FA uptake (CD36) and lipolysis of TG contained in TG-rich lipoproteins (LPL and GPIHBP1), even in a catabolic state.

Abstract

Infants with marasmus have lower mortality rates than infants with kwashiorkor during the acute phase of severe acute malnutrition. The intermediary metabolism of marasmic infants during this acute phase is more "thrifty" than kwashiorkor infants, and thus they appear better adapted to survive starvation/famine. The lower birth weight of marasmus infants also suggests that they previously experienced intrauterine growth restriction, which may account for their altered metabolism. While this provides a survival effect during severe acute malnutrition, it becomes maladaptive if they are in more obesogenic environments. Adult marasmus survivors are smaller, more stunted, more likely to have beta-cell dysfunction and glucose intolerance, and more liver fat than kwashiorkor survivors. Both adult survivors of marasmus and kwashiorkor are at increased risk of hypertension and other cardiac outcomes. Preliminary epigenetic studies have highlighted differentially methylated genes that can explain the observed phenotypes in the marasmus survivors. These data indicate that survivors of severe acute malnutrition, especially marasmus survivors, are at high cardiometabolic risk in later life. There is a lack of data on effective interventions in these individuals.

Introduction: Defining Marasmus and Kwashiorkor, and Their Clinical Differences

Since 1999, the World Health Organization identifies severe acute malnutrition (SAM) in children ages 6–60 months by severe wasting and/or the presence of bilateral nutritional edema. In 2006, the criteria were modified and wasting was defined as the weight-for-height (WFH) being less than −3 SD (or z-scores) of the WHO growth standards, or alternatively, if the mid-upper arm circumference is less than 115 mm. The rationale for the WFH cutoff was that infant mortality was increased below −3 z-scores. Also, at that cutoff, there is little harm using therapeutic feeding in the currently recommended protocols and therapeutic feeds. The presence of bilateral nutritional edema is a clinical indicator that facility-based, rather than community-based, care is urgently needed.

Historically though, many countries used a more qualitative classification of SAM where they described the syndromes of marasmus and kwashiorkor. The clinical features and outcomes of these syndromes were very distinctive. Children with nonedematous severe wasting (marasmus) had a better prognosis than edematous children wasted (kwashiorkor), even though kwashiorkor children often had less severe wasting. These clinical syndromes were reinforced by the 1970 Wellcome classification system, which classified marasmus as wasting using a weight-for-age criterion <60% in comparison to the National Center for Health Statistics (NCHS) standard growth curves. Kwashiorkor was defined as wasting of 60–80% weight-for-age and the presence of edema (Wellcome Trust Working Party 1970). Kwashiorkor also had other clinical signs such as skin and hair changes (dermatoses), hypopigmentation, fatty liver (hepatic steatosis) and hypoalbuminemia. An intermediate syndrome called marasmic-kwashiorkor was defined as weight-for-age <60% and the presence of nutritional edema. At present, less clinicians use the Wellcome classification and instead use the WHO criteria. However, the older classification may have utility if the clinical syndromes have different short-term prognoses, pathophysiologic origins, or long-term outcomes. As such, kwashiorkor was associated with much higher mortality rates than marasmus. In more recent times, marasmus mortality rates have increased mostly due to concomitant infections with HIV and respiratory pathogens (Trehan et al. 2013; Munthali et al. 2015).

Differences in Intermediary Metabolism

The origins of the distinct differences in the two clinical syndromes have not been clearly elucidated and remain mysterious. To date, no reliable differences have been shown in premorbid diets, exposure to environmental toxins, pattern of infections, or genetic polymorphisms. Notably though, there are differences in their intermediary metabolism. During the acute phases of SAM, both syndromes show the appropriate changes in fat, protein, and carbohydrate metabolism as seen in fasting states. That

Table 1 Intermediary metabolism of children with severe acute malnutrition

Metabolism during acute phase	Marasmus	Kwashiorkor
Protein turnover	↑↑	↑
Lipid turnover	↑↑	↑
Gluconeogenesis	↑↑	↑
Glycogenolysis	↑↑	↑
Glutathione levels	↓	↓↓
Salvage of urea-N	↑↑	↑

The relative differences in the intermediary metabolism of children during the acute phase of severe acute malnutrition are shown and these may give a survival advantage of marasmus children compared to kwashiorkor children. The table summarizes some of the data from (Reid et al. 2000, 2002; Badaloo et al. 2002; Jahoor et al. 2005, 2008; Badaloo et al. 2006a, b)

is, protein and lipid turnover are increased to provide sufficient amino acids, glycerol, and nonesterified fatty acids to support energy metabolism and to maintain plasma glucose concentrations close to 5 mmol/L for proper brain function. However, marasmus infants have higher rates (Table 1) of lipolysis, whole body protein turnover, gluconeogenesis, glycogenolysis, salvage of urinary urea nitrogen, and better concentrations of the intercellular antioxidant glutathione (Reid et al. 2000, 2002; Badaloo et al. 2002, Badaloo et al. 2006a, b; Jahoor et al. 2005, 2008). This differential response would improve the ability of marasmic children to sustain amino acid and lipid supply for intermediary metabolism during the period of starvation. Infants with kwashiorkor are less likely to compensate metabolically even though they have greater tissue stores than marasmus infants. Following recovery, protein turnover is approximately 30% faster and lipid oxidation is approximately 35% higher in kwashiorkor survivors than in marasmus. Metabolomic studies confirm that their metabolic signatures are different (albeit with some degree of overlap) as there are significant differences in certain amino acids, biogenic amines, sphingomyelins, phosphatidylcholines, and acylcarnitines even after clinical recovery (Di Giovanni et al. 2016).

This metabolic pattern suggests that marasmus infants are better adapted to fasting and famine compared to kwashiorkor infants. As such, during starvation, infants with kwashiorkor decompensate clinically as they are unable to provide metabolic fuel fluxes and thus have higher mortality rates.

Does Developmental Biology Explain Their Metabolic Differences?

If this teleological concept is correct, the metabolic adaptations would have occurred in earlier life, that is, before birth. In support, individuals who develop marasmus in infancy have lower birth weights than their kwashiorkor counterparts (Coulter et al. 1988; Forrester et al. 2012). In Jamaica, marasmus infants were 333 g (95% CI: 217–449 g) lighter at birth than kwashiorkor infants (Forrester et al. 2012). The survival of the marasmus infants was also better, as the mortality rate for

kwashiorkor infants was higher (odds ratio for death 3.7 [95% CI 1.5–9.2]). This demonstrates a fitness-advantage for marasmus infants in a nutritionally constrained, postnatal environment.

One possible explanation is a *predictive adaptive response* is operating (Gluckman et al. 2008). In other words, fetuses may experience intrauterine growth retardation if the prepregnancy nutritional state of the mother is poor, or if maternal nutrition during pregnancy is inadequate. These offspring undergo metabolic adaptions during this plastic period similar to that seen in marasmus so as to enable survival in utero (Barker 1995). These changes would increase their fitness and odds of survival if the postnatal environment is also a situation of famine (see chapter ▶ "The Effects of Prenatal Exposure to the Dutch Famine 1944–1945 on Health Across the Lifecourse").

If individuals who survive marasmus are demonstrating a predictive adaptive response and their nutritional plane subsequently improves, they will become "mismatched" for their environment, that is, adapted for famine, but now live in a calorie-surfeit environment. Such individuals would be predisposed to cardiometabolic risk in later life, such as increased ectopic and intra-abdominal adiposity, less lean mass with a tendency toward sarcopenia and osteopenia, abnormal appetite, obesity, glucose intolerance, insulin resistance, beta-cell dysfunction, elevated blood pressure, low-HDL-cholesterol, increased serum triacylglycerols, accelerated atherosclerosis, nonalcoholic fatty liver disease, and polycystic ovary disease. There are several studies that have examined the effect of starvation and famine per se on the development of cardiometabolic changes in various retrospectively assembled cohorts. However, there are sparse data specifically examining the differences in survivors of marasmus and kwashiorkor. If both syndromes also have different long-term clinical outcomes (e.g., mortality, chronic noncommunicable diseases, neurocognitive outcomes), this would support identifying the different clinical phenotypes and after recovery, individuals should be marked as high-risk and deserving of more aggressive interventions. Also, it is unclear if malnutrition in infancy per se increases their cardiometabolic risk. Infancy (birth to age 2 years) is a plastic period and thus postnatal malnutrition such as in SAM (where there is macronutrient deficiency, as well as micronutrient deficiencies) may induce a predictive adaptive response.

Cardiometabolic Risk in Later Life

Body Composition in Later Childhood and Adulthood

In many lower and middle income countries, there is the coexistence of malnutrition and obesity – the so-called double nutritional burden. Children with SAM are more prone than children who never experienced malnutrition to develop obesity in later life if they live in an obesogenic environment (Tzioumis and Adair 2014). One hypothesis that can connect both planes of nutrition is that malnutrition induces persistently lower growth levels, lower levels of serum growth factors (e.g., IGF-I), and possibly higher cortisol levels and lower insulin levels. This endocrine milieu is

conducive to stunting, less muscle mass as well as a greater propensity to adiposity during calorie-surfeit periods (Sawaya et al. 2004).

In the ChroSAM study, Malawian children who were admitted for SAM before age 2 years, and were reviewed at age 9 years, had less lean mass, more stunting, smaller mid-upper arm circumference and less handgrip strength than their sibling or community controls despite evidence of catch-up growth (Lelijveld et al. 2016). Survival bias and probable persistence of a lower socioeconomic status may have impacted their findings, but other studies show that survivors of SAM in general may have persistent growth deficits and increased risk of obesity and the metabolic syndrome in later life (Hult et al. 2010; Vaiserman 2017). However, in many of these studies, the data were not analyzed by SAM syndrome. One study in South African adolescents found that survivors of kwashiorkor had longer growth spurts and were heavier and possibly taller than their community controls (Cameron et al. 1986). However, they were not different to their siblings (Sauniere et al. 1986). There is little information on marasmus survivors and even less that compare marasmus and kwashiorkor survivors.

In Jamaica, the mortality rate of SAM during infancy is low (4.1%) (Forrester et al. 2012), so survival bias is less of a confounder. In a retrospectively assembled cohort study of Jamaican survivors of SAM (86 had marasmus, 77 had kwashiorkor, and 78 had marasmic-kwashiorkor) who were treated in hospital as infants within the previous 50 years (Soares-Wynter et al. 2011), there were differences in anthropometry and body composition by DEXA imaging. After adjusting for age and sex, adult kwashiorkor survivors were 2.6 cm taller, 8.9 kg heavier, and had greater BMI (~ 2.6 kg/m^2) than marasmus survivors (Fig. 1).

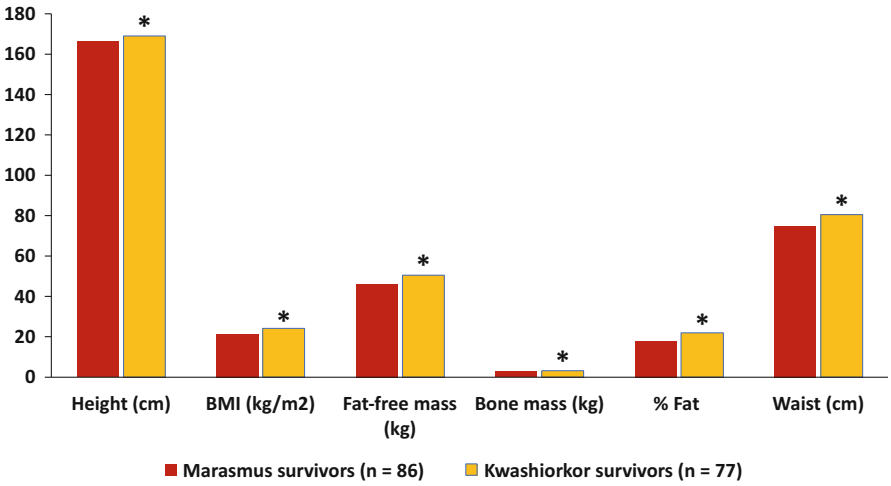

Fig. 1 Anthropometry and body composition in adult survivors of severe acute malnutrition. This graph shows the anthropometry and body composition measured by dual x-ray absorptiometry in adult marasmus and kwashiorkor survivors in Jamaica. In general, marasmus survivors were significantly shorter, smaller and had less fat-free, bone and fat mass. *$P < 0.01$ (Data adapted from Soares-Wynter et al. 2011)

They had significantly more fat-free mass (50.5 vs. 46.2 kg), bone mass (3.15 vs. 2.79 kg), fat mass (15.2 vs. 10.7 kg), % fat (21.9 vs. 17.8%), and waist circumference (80.5 vs. 74.8 cm) compared to marasmus survivors. Even after adjusting for adult height, these differences remained. When matched for BMI, the differences for fat-free mass and bone mass remained significant. Survivors of marasmus-kwashiorkor had intermediate values.

The kwashiorkor survivors weighed more at birth than the marasmus survivors (3.06 vs. 2.60 kg; $P < 0.001$), and marasmus-kwashiorkor were intermediate (2.85 kg). Multiple regression analyses adjusting for stunting (i.e., height-for-age), wasting (i.e., weight-for-height), and birth weight showed that the presence of nutritional edema was associated with adult fat-free mass and fat mass. Birth weight was positively associated with fat-free mass but not with fat mass. So, these data indicate that adult survivors of marasmus are smaller, more stunted, have less lean mass, and that birth weight is a predictor of their fat-free mass. The adult kwashiorkor survivors were similar in size to community controls who never experienced SAM (unpublished data). The implications are that marasmus survivors are more prone to sarcopenia in later life. If they are later exposed to an obesogenic environment, they are also at risk of sarcopenic obesity, since they have limited capacity to store fat in subcutaneous depots and a greater tendency to accumulate in visceral compartments.

Glucose Metabolism in Later Childhood and Adulthood

During the acute phase of SAM, there is increased secretion of counter-regulatory hormones, increased lipolysis and higher concentrations of nonesterified fatty acids leading to increased peripheral insulin resistance in many (Cook 1967; Becker 1983), although not all studies (Spoelstra et al. 2012). Infants with kwashiorkor and marasmus are glucose intolerant to a similar degree, but some studies suggest that this is due mostly to impaired insulin secretion (Robinson and Picou 1977; Spoelstra et al. 2012) rather than insulin resistance. Intestinal absorption of glucose is more impaired in kwashiorkor children, although it is also seen in marasmus children with hypoalbuminemia (Bandsma et al. 2011; Kvissberg et al. 2016).

In general, these changes in glucose metabolism resolve after nutritional rehabilitation (i.e., restoring WFH to >85%), especially in kwashiorkor patients (Robinson and Picou 1977), (Soliman et al. 1986). Marasmic children have delayed recovery of glucose-stimulated insulin responses up to 3 months after recovery despite normalization of glucose utilization and lipolysis (James and Coore 1970), (Graham et al. 1976). However, there is very little data on metabolic studies of marasmus survivors in later childhood. Survivors of kwashiorkor during childhood probably have normal glucose metabolism. In support of this, Ugandan children had normal insulin responses and glucose tolerance at ages 11–19 years (Kajubi 1972), while South African adolescents had normal insulin responses during intravenous glucose tolerance testing 10 years after experiencing SAM (Becker et al. 1971). There is one report of survivors having

more impaired glucose tolerance 6–12 years after their in-patient admission for kwashiorkor (Cook 1967). It is possible that these survivors experienced further postnatal undernutrition after their hospital discharge (James and Coore 1970), which could explain this observation. In the ChroSAM study (Lelijveld et al. 2016), glucose tolerance was normal in the entire Malawian cohort, but the data were not segregated by SAM syndrome.

Data on adults are few, but in general, the experience of famine in infancy and childhood can increase the risk of diabetes in later life. Epidemiological studies show adult survivors of famine have more glucose intolerance than those not exposed (Vaiserman 2017). Dutch and Chinese women who underwent famine/starvation during childhood (i.e., during ages 0–17 years) (Li et al. 2010; van Abeelen et al. 2012a) had an increased risk of type 2 diabetes as adults after adjusting for potential confounders (such as smoking and socioeconomic status). The risk was more in persons who self-reported exposure to severe famine compared to those with moderate exposure. Famine during young adulthood (i.e., age $\geq$18 years) was not associated with increased risk. This age-specific effect of famine is supported by animal models. In undernourished rats, reduced dietary protein in early life (i.e., gestation, during lactation and as a weanling) had persistent effects into older life, but not if the insults occurred in adult life (Minana-Solis Mdel and Escobar 2008). The effect of famine was increased in Chinese women who adopted a Western diet or became overweight (Li et al. 2010). In a meta-analysis of 11 published articles, early-life famine exposure was associated with an increased relative risk of 1.36 (95% CI 1.12–1.65) for those exposed during fetal-infant life, and there was a trend for childhood exposure (RR 1.40 [95% CI 0.98–1.99]) (Liu et al. 2016) (Fig. 2). However, these famine studies did not differentiate by malnutrition phenotype. Also, the mechanism of glucose intolerance was not clear, that is, if it was due to more insulin resistance or beta-cell dysfunction. Young Mexican men who had SAM in infancy were more glucose intolerant and hyperinsulinemic compared to controls (Gonzalez-Barranco et al. 2003), but they were not less insulin sensitive (as measured by euglycemic hyperinsulinemic clamp) than controls except when they were matched for high levels

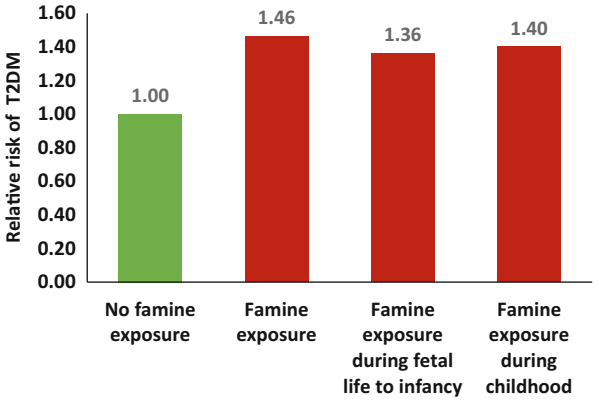

Fig. 2 Meta-analysis of the studies examining the exposure to famine in early life and the risk of type 2 diabetes in adulthood. In this 2016 meta-analysis of 11 cohort studies, famine exposure during early life, especially fetal-infant exposure, was associated with increased risk of type 2 diabetes (*T2DM*) in adulthood (Data are from Liu et al. 2016)

of intra-abdominal fat (Boule et al. 2003). Notably, in that study they did not report any measure of beta-cell function, neither did they differentiate the participants by nutritional edema.

In a cohort of adult Jamaican survivors (age 17–50 years), glucose metabolism was studied in 43 marasmus survivors, 38 kwashiorkor survivors, 70 age, sex, and BMI-matched community controls; and 40 age- and birth weight matched controls using a five-point oral glucose tolerance test (Francis-Emmanuel et al. 2014). Marasmus survivors had a 10.9-fold increased prevalence of glucose intolerance (95% CI: 2.1–55) and more fasting hyperinsulinemia compared to kwashiorkor survivors after adjusting for age, sex, and BMI. The degree of fasting during infancy also correlated with the 2-h postchallenge glucose levels as adults. Birth weight was correlated with the fasting glucose levels. The insulin sensitivity (calculated by the Matsuda index) in marasmus survivors tended to be less but insulin secretion (as estimated by the insulinogenic index and oral disposition index) was significantly reduced (Fig. 3a). In a subset (20 marasmus survivors, 20 kwashiorkor survivors) who also had euglycemic hyperinsulinemic clamps performed, there was no significant difference in insulin sensitivity, insulin clearance, adiponectin, or lipids (Fig. 3b) (Thompson et al. 2011). Also, their insulin sensitivity was not significantly different from community controls who never experienced SAM.

These results suggest that the endocrine pancreas is plastic in early life. Marasmus survivors have significantly lower birth weight probably due to intrauterine growth restriction which caused beta-cell dysfunction and then glucose intolerance in later life. Thus, persons with marasmus may have two nutritional insults - the first during intrauterine life making the beta-cells more sensitive to a second postnatal insult during an episode of SAM in infancy. A single nutritional insult in infancy, as seen in kwashiorkor, may not be sufficient to permanently alter glucose metabolism. It is not clear if the defect in glucose-stimulated insulin secretion is due to altered beta-cell function and/or mass. Possible mechanisms include decreased beta-cell neogenesis, differentiation, apoptosis, necrosis, or even increased alpha-cell function/mass. Subsequent sedentary lifestyle and increased food consumption in later life can then increase the prevalence of diabetes by inducing insulin resistance or glucolipotoxicity. It is likely that this phenotype increases the risk of developing the variant of diabetes associated with malnutrition (also called atypical diabetes, ketosis-prone diabetes, J-type diabetes, malnutrition-related diabetes) (Morrison et al. 1995; Rao and Yajnik 1996).

Cardiovascular System in Adulthood

During the acute phase of SAM in infants and children, the mean arterial pressure is about 8.6 mm Hg lower than those without severe malnutrition (Silverman et al. 2016). The systemic vascular resistance index is also lower, but there are no

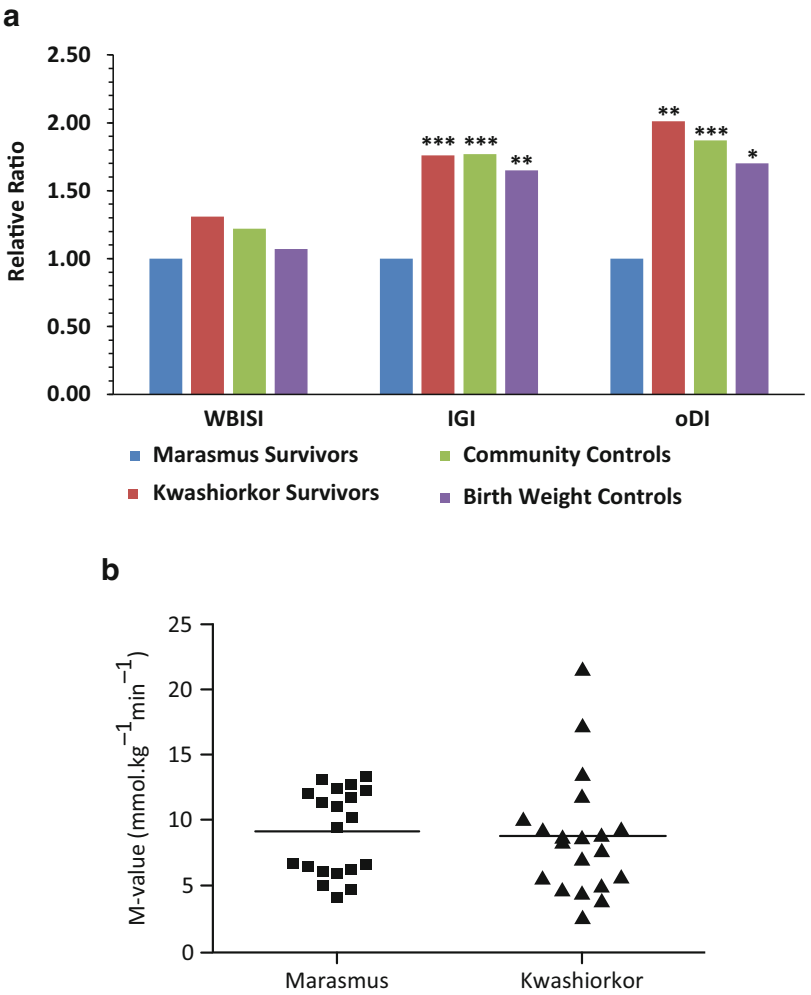

Fig. 3 (**a**) and (**b**) Glucose metabolism in adult survivors of severe acute malnutrition. The relative ratios after adjustment for age, sex, and BMI for measures of glucose metabolism were calculated during a five-point oral glucose tolerance test in adult survivors of marasmus (43) and kwashiorkor (38), as well as 70 community controls and 40 birth weight controls. Insulin sensitivity was calculated by the whole body insulin sensitivity index (*WBISI*) and was not significantly different among the groups using marasmus survivors as the comparator group. Marasmus survivors had significantly lower insulin secretion as measured by the insulinogenic index (*IGI*) and the oral disposition index (*oDI*). Notes: $*P < 0.05$, $**P < 0.01$, $***P \leq 0.001$ (Data are from Francis-Emmanuel et al. 2014). Insulin sensitivity measured during a euglycemic hyperinsulinemic clamp in adult marasmus and kwashiorkor survivors. There was no difference in their insulin sensitivity expressed as M-value (the glucose disposal rate during the last 30 min of the clamp). These data on insulin sensitivity are consistent with insulin sensitivity as measured by WBISI in 3A (Data are from Thompson et al. 2011)

differences in the cardiac index, heart rate, or stroke volume index. This is despite the wasting effects of SAM on the heart muscle (Alleyne 1966) and the cardiovascular changes were thought to fully recover after nutritional rehabilitation.

Irrespectively, adult survivors of SAM do have pervasive alterations in their cardiovascular system. Exposure to famine is associated with increased risk of hypertension in Chinese adults after adjustment for age and other potential confounders. There was at least a 24% increased risk in people if the exposure to the famine was in fetal life, 83% in infancy, 44% in early childhood, 67% in mid-childhood, and more than twofold in late childhood (Wang et al. 2012; Chen et al. 2014; Yu et al. 2017). The risk of hypertension was higher for persons who were overweight and who were at the upper and lower economic strata after experiencing severe famine in infancy (Wang et al. 2016b) giving a "U"-shaped association. This indicates that the risk is further exacerbated by the postfamine nutritional environment. The Biafran famine during the Nigerian Civil War also emphasized this fact, as exposure during the fetal-infant period was associated with 2.49 increased odds of having systolic blood pressures $\geq$140 mm Hg in lean adults, but there was an almost sevenfold increased odds in overweight/obese adults (Hult et al. 2010). Arterial calcification is seen in hypertensive adults who may be at risk of coronary artery disease and this may be affected by exposure to famine. Hence, postmenopausal Dutch women, who were exposed to famine as adolescents (ages 10–17 years) in the Second World War, had more coronary artery calcification (OR 3.5–4.6), but there was no apparent increase in those exposed at younger ages (Idris et al. 2013).

There is one study that evaluated whether the risk of hypertension is different by clinical phenotype of SAM during infancy. So, 62 adults who survived kwashiorkor, 54 marasmus survivors, and 45 age, sex, and BMI-matched community controls (mean age 28.8 $\pm$ 7.8 years) were evaluated using echocardiography and tonometry (Tennant et al. 2014). After adjusting for age, sex, weight, and height, major differences were found between former SAM cases and controls but not between marasmus and kwashiorkor survivors. Systolic blood pressure and heart rate were normal and not significantly different between the groups. However, diastolic blood pressure was significantly increased in all SAM survivors compared to controls (4.3 mm Hg; 95% CI: 1.2–7.3 mmHg). SAM survivors had smaller left ventricular outflow tract diameters and hence decreased stroke volume, cardiac output and higher systemic vascular resistance than controls (Table 2). The difference in systemic vascular resistance between SAM survivors and controls was large – about 5.5 (95% CI: 2.8–8.4) mmHg*min/L (approximately half a standard deviation).

Since there was a marked inverse correlation between left ventricular outflow tract diameter and systemic vascular resistance, SAM survivors are potentially at higher risk of developing hypertension than controls. Their reduced cardiac output may also put them at risk of heart failure. It is not clear what the pathophysiological mechanisms of these observed changes are, but theoretically they include:

Table 2 Differences in cardiovascular measures (SD scores and confidence intervals) between controls and all severe acute malnutrition (*SAM*) survivors

Measurement	Difference in SD scores of controls minus all SAM survivors*	*P*
Cardiac output	0.53 (0.21–0.85)	0.001
Stroke volume	0.44 (0.11–0.77)	0.009
Systemic vascular resistance	−0.67 (−1.01 to −0.33)	<0.001
Left ventricular outflow tract diameter	0.67 (0.36–0.99)	<0.001
Ejection fraction	−0.42 (−0.77 to −0.07)	0.02
Carotid intimal media thickness	0.25 (−0.08–0.58)	0.1
Visceral fat mass	−0.07 (−0.38–0.24)	0.6

Measurements of cardiac anatomy and function are shown as the differences in SD scores between participants with SAM and community controls.
*The SD scores are controlled for age, sex, height, and weight (Data are from Tennant et al. 2014)

- Higher sympathetic drive leading to arteriolar constriction, secondary to enhanced adrenergic and hypothalamic-pituitary-adrenal axes (as seen in adults who had a lower birth weight).
- Underdevelopment of the arterial tree which could lead to the abnormal systemic vascular resistance.
- The increased systemic vascular resistance may be a compensatory mechanism to preserve perfusion of some organs in the face of reduced cardiac output.

Nonalcoholic Fatty Liver Disease (NAFLD) in Childhood and Adulthood

Infants with SAM have hepatic steatosis, or fatty liver, by ultrasonography or necropsy, although kwashiorkor infants have more than marasmus infants (Doherty et al. 1992). While the pathogenesis is not clear, it is unlikely to be related to the export of triacylglycerols from the liver in very low density lipoproteins (VLDL). Both marasmus and kwashiorkor infants synthesize VLDL-apo B-100 at a faster rate as the degree of hepatic steatosis increases (Badaloo et al. 2005). Since the rates of lipolysis in kwashiorkor are lower than in marasmus, persons with kwashiorkor may have less beta-oxidation of fatty acids leading to the accumulation of intrahepatic triacylglycerols. The degree of this hepatic steatosis slowly reduces with successful nutritional rehabilitation. Resolution occurs by later childhood as was shown in Ugandan children (mean age 8.8 years) who had liver biopsies 7 years after having kwashiorkor, although a few had stellate fibrosis radiating from the portal area (Cook and Hutt 1967).

Despite this resolution by childhood, early life exposure to food restriction is associated with fatty liver disease later in life. Children with NAFLD were four times more likely to have experienced intrauterine growth restriction (Nobili et al. 2007).

Persons exposed to the Chinese Famine (1959–1961) during fetal life and infancy had more NAFLD as adults (Chen et al. 2016). However, these associations were sex specific. That is, women, but not men, who were exposed during fetal life and childhood had a significantly higher prevalence of moderate-severe steatosis (OR 1.8 after adjusting for age, rural/urban residence, economic status, BMI, diabetes, dyslipidemia, and hypertension) as diagnosed by ultrasonography compared to those who were not exposed (Wang et al. 2016a). Women who were exposed during adolescence did not have a change in their risk. However, this sex dimorphism was not seen in another group of individuals who were also exposed to the Chinese famine in the Chongqing district. Both men and women born during the famine had increased risk (OR 1.38–1.55) and this risk was still elevated in those born after the famine (OR 1.14 vs. 1.24 for men and women after adjustment of age). The men also had increased risk of obesity and hyperglycemia (Chen et al. 2016).

There is a dearth of data of NAFLD in survivors of marasmus and kwashiorkor, but based on the predictive adaptive response hypothesis, one would expect that marasmus survivors to have more liver fat, despite kwashiorkor survivors having more fatty liver as infants. In a Jamaican study of 45 marasmus survivors, 43 kwashiorkor survivors, and 84 community controls (age 29.0 ± 8.4 years; BMI 23.5 ± 5.0 kg/m^2) liver attenuation and liver: spleen ratio was measured using single slice computerized tomography at T12/L1 intervertebral disc space (Thompson et al. 2015). Both measurements are indices of hepatic steatosis and lower values indicate more fat. Malnutrition survivors had less liver fat than controls (1.3 ± 0.2 vs. 1.2 ± 0.9, $P = 0.03$). Marasmus survivors had lower birth weight than kwashiorkor survivors (−0.51 kg; $P = 0.02$), had smaller waists, and were significantly thinner with less body fat. After adjusting for age, sex, and birth weight, marasmus survivors had a lower mean liver attenuation than kwashiorkor survivors indicating they had more hepatic steatosis (Fig. 4). Interestingly, they did not did not have changes in alanine transaminase, adiponectin, fetuin A or insulin resistance (measured by HOMA-IR) as would be expected in steato-hepatitis. Neither were there any significant changes in serum triglycerides, HDL-cholesterol or LDL-cholesterol.

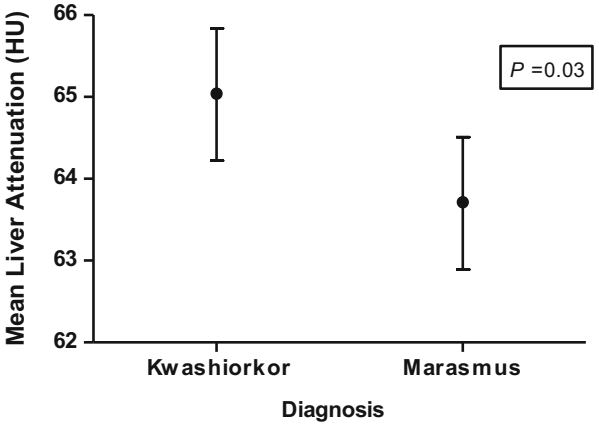

Fig. 4 Regression of mean liver attenuation against diagnosis of severe acute malnutrition. The mean attenuation of the liver and SD (as *bars*) in Hounsfield units is shown for adult survivors of marasmus and kwashiorkor after adjustment for age, sex, and birth weight. Marasmus adults had a significantly lower liver attenuation indicating that they have more liver fat (Data are from Thompson et al. 2015)

Based on these data, it is conceivable that the pathogenesis of fatty liver in individuals exposed to SAM is different along the life course. So, marasmus infants may have less liver fat accumulation as they are more effective in utilizing nonesterified fatty acids as a metabolic fuel (i.e., more efficient beta-oxidation) than kwashiorkor infants. In later life, marasmus survivors can accumulate more liver fat as during weight gain (especially if it is rapid during catch-up growth or later childhood), more fat is partitioned into abdominal and ectopic depots rather than subcutaneous compartment ("the fat overflow hypothesis"). In the Jamaican adult cohort, the pathogenesis apparently did not involve insulin resistance or inflammation. However, it is also possible that as the participants were relatively young and lean, they have more liver fat but have not yet developed inflammation. It remains to be seen if markers of inflammation would emerge with aging or weight gain.

Changes in Appetite Control in Later Life

Increased appetite induced by an episode of SAM may be one mechanism to promote obesity and cardiometabolic risk in later life. In animals, restriction of protein or calorie during gestation and/or suckling induces hyperphagia in postnatal life, probably through changes in the orexigenic peptides agouti-related peptide and neuropeptide Y, with simultaneous decreased hypothalamic levels of the anorexigenic peptide pro-opiomelanocortin (Orozco-Solis et al. 2009). It is unknown if prenatal and/or postnatal malnutrition causes similar changes in humans. Ghrelin, an orixogenic peptide, is higher in the serum of children in the acute stages of SAM, especially in those with marasmus, compared to healthy children (Altinkaynak et al. 2008). Leptin levels are correspondingly lower and are similar in kwashiorkor and marasmus children (Kilic et al. 2004). There are no data, to our knowledge, if these changes are persistent through the life course.

In a feeding trial of adult SAM survivors, there were no changes in appetite control (for protein and total energy) or satiety regulation based on whether they had marasmus or kwashiorkor as infants. However, there was a significant association of lower birth weight with higher protein targeting. This effect of birth weight may be mediated through increasing body weight, which then in turn increases protein leveraging (Campbell et al. 2016).

It is also possible that cognitive changes induced by SAM affect future lifestyle choices. In Dutch women, postnatal exposure to famine during both childhood (ages 0–9 years) and during adolescent years (ages 10–17 years) was associated with more physical inactivity and tobacco use, but there were no changes in diet or alcohol use (Fransen et al. 2016). No changes were seen in the men.

Mortality and Fitness

It is not known if mortality is increased or if reproductive fitness is altered in survivors of SAM and if there is any difference between marasmus and kwashiorkor survivors. It is possible that exposure to famine in utero may increase mortality risk

in future famines experienced in postnatal life (Hayward et al. 2013) although this is controversial. However, one would expect that marasmus survivors living in calorie-surfeit environments would have lower life expectancy (van Abeelen et al. 2012b) and changes in reproductive capacity (Yarde et al. 2013) based on their potential for glucose intolerance, sarcopenia, and fatty liver compared to their kwashiorkor counterparts, but this remains to be proven.

Possible Epigenetic and Genetic Factors

While the mechanism behind these "thrifty phenotype" changes in marasmus survivors is not clear, epigenetic changes are the most likely explanation (Hochberg et al. 2011). In the skeletal muscle of adult marasmus and kwashiorkor survivors, 63 genes were recently found to be differentially methylated (Sheppard et al. 2017). Most of the critical gene nodes were associated with immunity (e.g., HLA-DRB1), musculoskeletal growth (e.g., PITX2), and glucose metabolism (e.g., p21 protein (Cdc42/Rac)-activated kinase PAK1, C-reactive protein CRP1, and hexokinase (HK2)), as well as cardiovascular and neuronal pathways. The variance in methylation in adulthood was related to both prenatal and postnatal nutritional insults. However, the effect, especially for glucose metabolism, was stronger for antenatal insults. In a Bangladeshi study, young adults who were exposed to famine in gestation and/or infancy had abnormal glucose tolerance which was associated with differential methylation at several metastable epialleles in the blood,that is, VTRNA2–1, PAX8, PRDM-9, near ZFP57, near BOLA, and EXD3 (Finer et al. 2016). Most of the variance was also explainable by prenatal exposure, but postnatal nutrition also played an important role.

Obviously, these studies in marasmus and kwashiorkor survivors deserve replication as well as to be expanded to describe the epigenomic profiles in other tissues, since they may be different from muscle. Regardless, combining these data with other peri-conception studies from the Gambia (Dominguez-Salas et al. 2014) and the Dutch Hunger Winter cohort (Tobi et al. 2014), they suggest that maternal diet during pregnancy can cause changes in fetal metastable epialleles that persist into adult life. These epigenetic changes then can account for the observed phenotype of increased cardiometabolic risk in SAM (especially in marasmus survivors). The changes that relate to immunity also imply that the diversity of gut microbiota, which can be different in marasmus and kwashiorkor infants (Smith et al. 2013) may play a lasting role in body composition and cardiometabolic risk.

It is unknown if genetic factors can play a role as there is a significant lack of genetic studies in marasmus and kwashiorkor survivors. Genetic factors could contribute to the development of small for gestational age, edema, and low GSH levels. In a small study of 136 SAM survivors (Marshall et al. 2006), glutathione S-transferase polymorphisms was associated with the risk of developing kwashiorkor. GSTP1 Val(105) homozygotes were significantly more common among the former kwashiorkor patients (OR 3.5; 95%CI: 1.1–10.8) and there was a tendency

for an association between nondeletion GSTT1 genotypes and the presence of nutritional edema (OR 2.4; 95% CI: 1.0–5.9). These polymorphisms may explain some of the variance in glutathione levels, but they do not readily explain the other cardiometabolic changes.

Areas to be Explored

Obviously, the issue of the long-term cardiometabolic risk of SAM survivors requires more study and there are important questions to be answered.

- Is the mortality of adult marasmus survivors definitively increased because of their increased cardiovascular risk?
- Childhood stunting (a more moderate and chronic case of malnutrition) is associated with increased cardiometabolic risk in adults. Do they have the same pathophysiological pathways as those seen in the severe wasting of SAM?
- What is the best nutrient composition for therapeutic feeds for infants with SAM, and what rates of catch-up growth are safe for optimal, long-term cardiometabolic health?
- What happens to these SAM survivors as they gain weight or become more sedentary in their later life?
- Despite epigenetic data giving insight into the pathophysiological pathways, more studies are needed including the role of inflammation, stress responses, metabolic flexibility, growth factors, etc.
- What is the specific role of the gut microbiome on the development of cardiometabolic risk?
- Is there an increased risk of polycystic ovary syndrome in female survivors?
- There are almost no data on effective interventions in adult SAM survivors; whether primary to prevent cardiometabolic risk, or secondary after cardiometabolic disease has occurred.

Policies and Protocols

Oral Glucose Tolerance Test (OGTT)

All subjects were asked to fast for 10–12 h from the night before testing as well as to avoid strenuous exercise and consuming alcohol/caffeine the day before. We measured body composition by dual x-ray absorptiometry using a Lunar Prodigy machine (GE Health Care, USA). Participants then had a 75-g anhydrous OGTT. Five milliliter of blood was taken at 0, 30, 60, 90, and 120 min through an antecubital cannula into fluoridated and heparinized chilled tubes for plasma glucose and insulin measurements.

The whole body insulin sensitivity index (WBISI) was calculated using the method of Matsuda et al. (Matsuda and DeFronzo 1999) as:

$$\text{WBISI} = 10000/\sqrt{(G_0.I_0.G_m.I_m)}$$

where G_0 and I_0 are plasma glucose and insulin concentrations at 0 min, and G_m and I_m are the mean concentrations of glucose and insulin.

Beta-cell function was estimated using the oral disposition index (oDI), which is the ability of the beta cell to compensate for a given level of insulin sensitivity. This was calculated as:

$$\text{oDI} = \text{WBISI} \times \text{insulinogenic index}$$

i.e., $\text{oDI} = \text{WBISI} \times ([I_{30} - I_0]/[G_{30} - G_0])$
where I_{30} and I_0 are insulin concentrations at 30 and 0 min, and G_{30} and G_0 are glucose concentrations at 30 and 0 min.

Cardiac Measurements

Measurements were made using a GE Vivid *i* ultrasound machine with cardiac 3S probes and vascular 8 L probes. Pulse wave velocity was measured from ECG-gated flow waveforms, at 1–2 cm proximal to the carotid bulb and femoral bifurcation. 2D, M-mode and Doppler transthoracic echocardiography was done with the participants lying in the left lateral recumbent position using standard parasternal short and long axis, apical, subcostal, and suprasternal views. All measurements were ECG gated and sweep speeds for M-mode, pulsed wave (PW) or continuous wave (CW), Doppler was set at 100 mm/s. Images and loops were exported in DICOM format. Cardiac output, stroke volume, left ventricular mass, and left ventricular outflow tract internal diameter were then measured using standard techniques. With the neck in slight hyperextension and tilted approximately 30° to the left, the intima-medial thickness was measured in the right carotid and femoral arteries at 1–2 cm proximal to the carotid bulb or femoral bifurcation.

CT Scanning for Liver Fat

Liver fat was assessed using single slice, cross-sectional abdominal CT scanning at T12- L1 intervertebral disc space. Total, subcutaneous and intra-abdominal fat area, volume and mass were measured with one cross-sectional scan at the L4–5 inter-space using a Phillips Brilliance 64-slice scanner and using QCT Pro software. Participants were examined in the supine position with arms outstretched overhead with the scanner set at 120 kV, 100 mA exposure and 5 mm slice thickness. Liver fat data was analyzed using E-Film software. Three regions of interest (ROIs) were placed on the liver (posterior right lobe, anterior right lobe and left lobe, and 1 ROI was placed on the spleen. Each ROI measured a minimum of 1 cm^2 and excluded all major blood vessels. For each region of interest, attenuation was documented (Hounsfield units- HU).

CT images were analyzed with the commercial software package: "Tissue Composition Module" Beta 1.0 (Mindways, Austin, TX, USA). Measurements of total adipose area and visceral adipose tissue were completed by the commercial software package.

Dictionary of Terms

- **Insulin sensitivity** – the ability of insulin to increase glucose uptake in tissues.
- **Beta-cell function** – the ability of the beta-cell in the pancreas to secrete insulin in response to plasma glucose.
- **Disposition index** – a measure of the pancreas' ability to secrete insulin in response to the level of whole body insulin sensitivity.
- **Systemic vascular resistance** – also known as the total peripheral resistance, is the resistance by the body's vasculature to blood flow. This excludes the pulmonary vasculature.
- **Sarcopenia** – the loss of lean tissue as a part of aging.
- **Epigenetics** – the study of changes in gene expression that are not due to alterations in the DNA sequence and which can produce heritable characteristics during development of an organism.
- **Metabolomics** – techniques that identify and quantify the small-molecular metabolic chemicals of a biological system.
- **Orexogenic** – describes any molecule or process that stimulates appetite.
- **Euglycemic hyperinsulinemic clamp** – a procedure to measure the rate of glucose uptake under steady state conditions and therefore is regarded as the gold standard method to calculate insulin sensitivity.

Summary Points

- Children who are born with lower birth weights tend to develop marasmus rather than kwashiorkor if they experience postnatal undernutrition.
- Infants who have marasmus have increased cardiometabolic risk in later life (less lean mass, glucose intolerance, and more fatty liver).
- Both marasmus and kwashiorkor survivors are at risk of cardiovascular changes, including higher systemic vascular resistance and diastolic blood pressure, hypertension and lower cardiac output in adulthood.
- Developmental plasticity is the most likely mechanism in these marasmic children resulting in lower lean mass in later life, beta-cell dysfunction, higher systemic vascular resistance, cardiovascular changes, and fatty liver.
- Preliminary studies indicate that the epigenotype expressed in the skeletal muscle of adult survivors can explain much of the observed phenotype in adult life.
- These epigenetic changes mostly occur in the prenatal period but also extend into the postnatal period.
- There is a lack of intervention studies to ameliorate the increased cardiometabolic risk especially in marasmus survivors.

Abstract

Protein energy malnutrition is a prevalent nutrition public health problem affecting mainly developing countries including Iraq. Malnutrition could be a deficiency or an excess nutrient intake, but in this chapter it will refer to deficiency states.

Usually deficiency of energy and protein in the diet is accompanied by mineral and vitamin deficiency simultaneously resulting in both macro- and micronutrient deficiency. Body size and composition will be affected by malnutrition; body organs are affected too. The heart had been thought to be spared from malnutrition ill effects but later on proved to be one of the many organs impacted by this public health problem.

Many types of studies, chronologically, including animal experiments, autopsy for individuals who died of malnutrition, hospital-based observational studies among severely malnourished children, and community-based observational studies among apparently healthy moderately malnourished school children provided evidence of the impact of malnutrition on the heart.

The impact of protein energy malnutrition on heart structure and function is not only seen in severe malnutrition but also in moderate cases as shown in the study of apparently healthy moderately malnourished school children. Structural manifestations as decreased size of the heart, thinner left ventricular wall muscle, and thinner interventricular septum have been documented by different studies. Function of the heart on the other hand has not been affected as measured by ejection fraction and fiber fractional shortening, while stroke volume, blood pressure, and cardiac output have been affected according to the apparently healthy moderately malnourished children study.

Keywords

Protein energy malnutrition · Heart · Cardiovascular · Macronutrients · Micronutrients · Minerals · Vitamins · Starvation · Famine · Malnutrition · Cardiac mass

List of Abbreviations

HAZ	Height for age z-score
IVSD	Interventricular septum thickness during diastole
IVSS	Interventricular septum thickness during systole
LVEDD	Left ventricular end diastolic dimension
LVEDV	Left ventricular end diastolic volume
LVESD	Left ventricular end systolic dimension
LVESV	Left ventricular end systolic volume
PEM	Protein energy malnutrition

PWD	Posterior left ventricular wall during diastole
PWS	Posterior left ventricular wall during systole
WAZ	Weight for age z-score
WHO	World Health Organization

Introduction

Malnutrition

The WHO defines malnutrition as "the cellular imbalance between supply of 'nutrients and energy' and the body's demands for them to ensure growth, maintenance and specific functions." The imbalance could be an excess or deficiency; however this chapter will use malnutrition as deficiency state only. Effects of malnutrition on growth and development of children are extensively investigated and documented. Morbidity and mortality statistics related to malnutrition is huge.

Malnutrition affects the whole body through reduction in the supply of energy, protein, and other nutrients that will alter cell metabolism, structure, and function progressing to organ and system affection (WHO 2003; Suskind et al. 2011).

Muscle mass and bone mass are reduced as a result of chronic PEM, which in turn will predispose individuals to future health problems and alteration in normal body composition. With age people add weight which is mainly adipose tissues. They will develop obesity faster than do individuals with normal muscle and bone mass. Obesity is defined as more adiposity of the body and with altered body composition in terms of low muscle mass, and low bone mass adiposity will be reached faster and at lower increase in body weight.

Malnutrition in Iraq

In developing countries, PEM is one of the major health problems affecting their populations in general and children in particular. Iraq is one of these developing countries where PEM is prevalent. United Nation sanctions imposed on Iraq in 1990 caused progressively increasing numbers of children getting malnourished. A series of nutrition status assessment of under-5 children have been carried thereafter on national and international levels. High prevalence rates for underweight, stunting, and wasting have been documented. Iodine deficiency also showed high prevalence as documented by a survey including Baghdad, Mosul, and Basra in 1992. Total goiter rate and urinary iodine levels were assessed by the first author in collaboration with UNICEF who had sponsored urinary iodine level estimation in Virginia or the USA (Swidan 1994).

Currently millions of people are displaced within Iraq (for years) due to insecurity crisis and invasion by ISIS. Surveys are lacking for many reasons, but malnutrition along with many infectious diseases is affecting those people of course with children on top of victims as reported by the media and seen in hospitals and even in

schools. Currently prevention and correction of malnutrition in Iraq are extremely difficult.

The Heart

The heart is a specialized part of the cardiovascular system. It is the first organ to complete its development during fetal growth.

Heart wall is composed of three layers, pericardium, myocardium, and endocardium. These cover all the chambers except the left atrium which is extra-pericardium (Standring 2008).

The mass of the heart varies in normal adult males from 280 to 340 grams and in normal adult females from 230 to 280 (Standring 2008).

Cardiac muscle differs from skeletal muscle and smooth muscle in cell structure, cell biology, histology, physiology, and metabolism.

Metabolism of the Heart

Cells need energy to carry their specific functions like contraction of muscle cells including cardiac muscle. They capture energy, store it, and release it on need. Fatty acids are the basic energy source for heart contributing (60–100%); in contrast, lactate and glucose contribute much less as energy sources for the heart (0–40%). During fasting, plasma free fatty acid concentrations increase and result in increased myocardial glycogen. Lucien concentration in plasma increases during fasting which contributes to the maintenance of heart mass.

Malnutrition and the Heart

In the first half of the twentieth century, the hypothesis (the heart is spared from the effect of malnutrition) had been well accepted. Earlier doctors used to believe that the effects of malnutrition on the cardiovascular system were nonexistent and the heart was not affected in malnutrition. However, they thought that the cause of this sparing is the special heart metabolic characteristics and body feedback mechanisms that compensate for body needs and heart protection (Webb et al. 1986).

Effects of malnutrition on the heart have been identified following World War II. Keys and colleagues in 1947 reversed this hypothesis and highlighted a new one that the heart is not spared in undernutrition (Webb et al. 1986). Then the study of the effects of malnutrition on the cardiovascular system started.

Those studies indicated that nutrition has a major impact on the heart and in turn affects the way the heart functions and its ability to pump blood efficiently (Kothari et al. 1992). In chronic malnutrition manifested as stunted growth, the heart will never attain normal size. The smaller body will not place sufficient demands on the

heart to induce additional cardiac growth on one hand, and macro- and micronutrients necessary for growth are lacking on the other hand.

Several researchers performed studies to prove this new hypothesis and the type of effect and its extent. At the beginning, researchers depended on postmortem studies of individuals who died of malnutrition by comparing their left ventricle mass with other subjects who died from other causes in Costa Rica study (Regan 1985).

Some researchers used experimental animals to study the effects of malnutrition on mammalian heart especially rats (Pissaia et al. 1980; Freund and Holroyde 1986; Vandewoude 1995; Fioretto et al. 2001) and dogs (Alden et al. 1987) by exposing them to programmed food deficient in protein and energy and matched them with control group with normal nutrition. The hearts of the two groups were studied structurally and functionally by noninvasive and invasive investigations and then postmortem study.

In relation to acute malnutrition, Fabiansen et al. induced acute malnutrition in a group of 5-week-old piglets by feeding them certain poor diet for 7 weeks. Researchers concluded that acute malnutrition is associated with cardiac dysfunction in this pediatric porcine model decided by the increased myocardial performance index (MPI) and pro-atrial natriuretic peptide. Acute malnutrition was also associated with cardiac injury evidenced by elevated levels of cardiac troponin T (Fabiansen et al. 2015).

The above study was stimulated by the fact that severe acute malnutrition (SAM) is responsible for half million mortalities annually among children and that cardiac dysfunction may play a role in these mortalities. Acutely and severely malnourished children have organ atrophy, and their physiology and metabolism are altered. Changes in fluid and electrolytes in addition to impairment of cardiac function among acutely and severely malnourished children are important examples that led World Health Organization (WHO) to develop special guidelines for the management of shock, dehydration, and blood transfusion that differ from standard treatment used for well-nourished children. These WHO recommendations include small volume therapy and low sodium fluids to avoid overload and heart failure in children with severe acute malnutrition. Evidence behind these recommendations is controversial, and WHO called for more research to produce sound evidence-based ones (Fabiansen et al. 2015).

Other researchers studied the effects of malnutrition on hospitalized malnourished children and matched them with the control group (Olivares et al. 2005; Abufaddan et al. 2010). Those hospitalized children were severely malnourished either edematous or non-edematous.

Morphometric data showed that the cardiac muscle mass growth was impaired to the same extent as the body weight, supporting the concept that the heart is not spared in chronic PEM. This concept was first described by Keys et al. in 1947 (Webb et al. 1986), and it was later validated by others (Penpargkul et al. 1980). Cardiac sparing has been observed with shorter-duration PEM protocols limited to hours or days (Drott et al. 1986).

Malnutrition (PEM) Impact on the Heart in Active Children

In hospital malnutrition is seen with very high prevalence in comparison with the general population, and usually these are severe cases with different comorbidities. Mild and moderate cases of malnutrition may pass unnoticed and mistakenly considered as normal children especially in developing countries with poor healthcare systems. For this reason apparently active, primary-school-age children have been targeted for nutrition status assessment using anthropometry and then their heart structure and function assessed to see the impact of PEM. Children have been classified accordingly for the sake of inclusion in the following study done in Iraq in 2011 by Al-Samerraee and Thamer.

A community-based comparative study (retrospective cohort) has been carried by the authors to study some heart structural and functional indicators in malnourished primary school children as exposed and compared them with normally nourished matched non-exposed from the same community.

Children whose height for age (chronic malnutrition indicator) and/or their weight for age were equal to or less than – 2SD have been included as exposed group. Wasting (acute malnutrition) was probably masked by the presence of stunting which reflected chronicity of malnutrition. Non-exposed group had zero or positive z-scores for all anthropometric indicators.

This study differed from the previous ones by selecting physically active school-age children. In this study, anemia as a source of left ventricular morphometric modification has been excluded. Clinical examination, biochemistry, electrocardiographs, and echocardiography have been performed for all participants with the exclusion of children with congenital heart disease (Al-Samerraee and Thamer 2014).

Interventricular septum thickness during diastole (IVSD), interventricular septum thickness during systole (IVSS), posterior left ventricular wall during diastole (PWD), posterior left ventricular wall during systole (PWS), left ventricular end diastolic dimension (LVEDD), and heart mass showed that all of these variables were significantly lower in the exposed group. The following are mean values of the above parameters: exposed group versus non-exposed, respectively, IVSD (0.53 ± 0.05 cm) (0.67 ± 0.08 cm) $\rho < 0.000$, IVSS (0.87 ± 0.10 cm) (0.98 ± 0.16 cm) $\rho = 0.001$, PWD (0.51 ± 0.05 cm) (0.67 ± 0.08 cm) $\rho < 0.000$, PWS (0.78 ± 0.11 cm) (0.97 ± 0.11 cm) $\rho < 0.000$, LVEDD (3.55 ± 0.37 mm) (3.8 ± 0.35 mm) $\rho < 0.000$, and heart mass (44.30 ± 7.24 g) (71.90 ± 17.95 g) $\rho < 0.000$.

These parameters were strongly and positively correlated with anthropometric indicators HAZ and WAZ (Figs. 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, and 12).

Heart function was affected too as mean left ventricular end diastolic volume (LVEDV) showed lower values among exposed (malnourished) group (54.43 ± 13.42 ml) than that of the non-exposed (65.24 ± 14.49 ml) $\rho = 0.001$.

Mean left ventricular end systolic volume (LVESV) was lower among exposed (malnourished) group (17.41 ± 4.92 ml) than that of the non-exposed (20.95 ± 5.20 ml) $\rho = 0.003$.

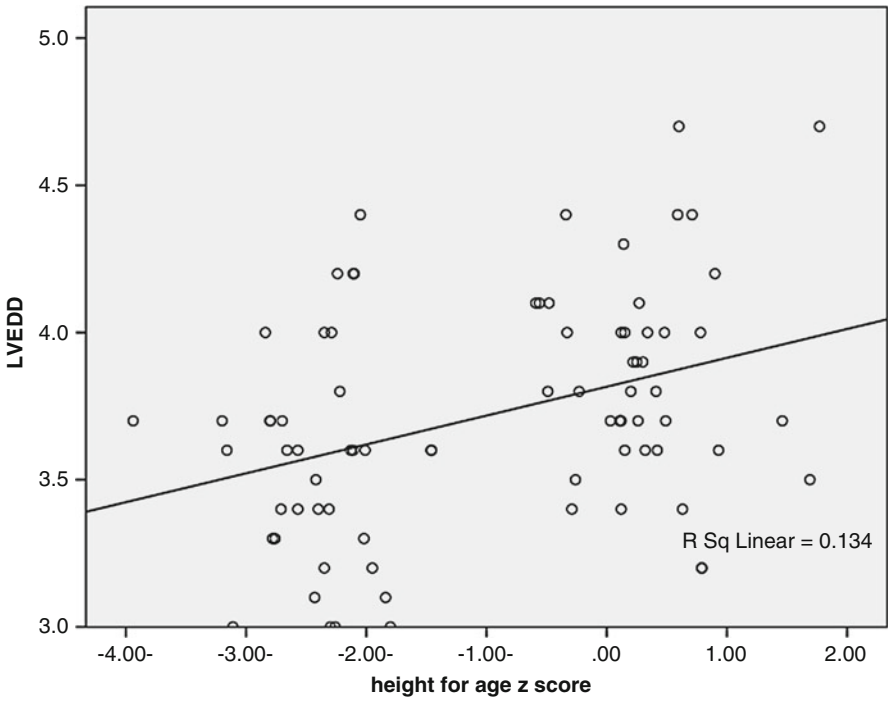

Fig. 1 Correlation between LVEDD and HAZ R = 0.367 $p = 0.001$

Mean left ventricular stroke volume was lower among exposed (malnourished) group (37.62 ± 10.60 ml) than that of the non-exposed (44.55 ± 11.44 ml) $\rho = 0.007$.

Ejection fraction did not differ significantly between the two groups.

Some echocardiography studies in malnourished children report overall preserved pumping function; other studies report systolic dysfunction.

Policies and Protocols

Echocardiography

Echo-Doppler-color Doppler hospital-type apparatus was used. Multi-probe frequency and size included cardiac probe for adult, neonatal, coronary, vascular, M-mode, 2D, and Doppler P and C waves. This was of three frequencies: 2.5, 3.5, and 5 KHz. The new American Society of Echocardiography standards were used as reference values for echocardiographic measurements. The examination was done through all the four major windows, longitudinal long axis, short axis, apical, and epigastric. Starting the examination through the left parasternal long axis is very beneficial because of the major landmark, the mitral valve which will be in the center

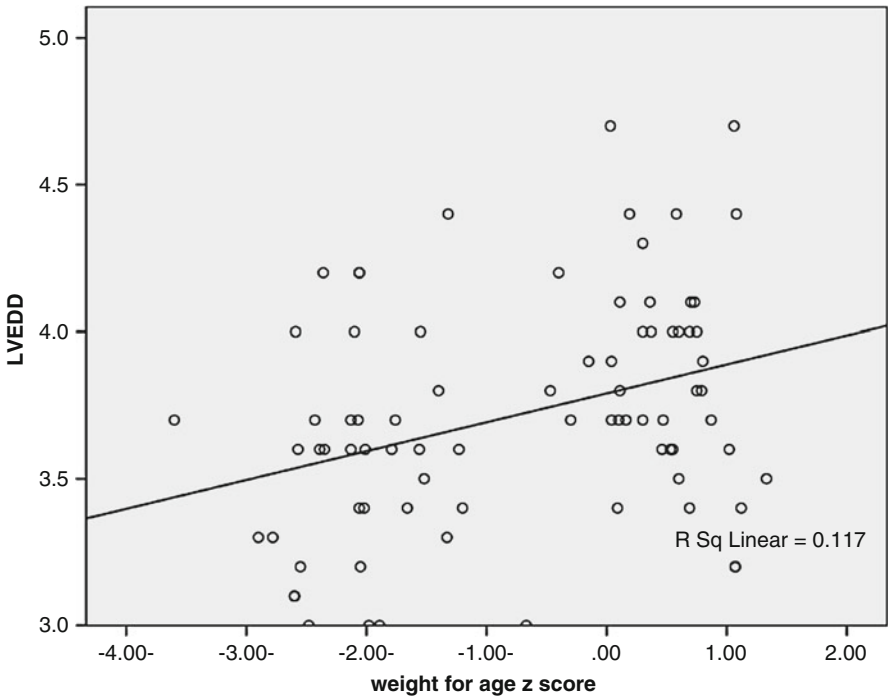

Fig. 2 Correlation between LVEDD and WAZ R = 0.342 $p = 0.002$

of this view. Diagnosis of any organic heart disease and exclusion of such children were done. After that, parasternal long axis was used for obtaining the following measurements:

1. Interventricular septum thickness both systolic and diastolic (IVSS and IVSD)
2. Posterior left ventricular wall both systolic and diastolic (PWS and PWD)
3. Left ventricular end systolic and end diastolic volumes (LVESV and LVEDV)
4. Left ventricular end systolic and end diastolic dimensions (LVESD and LVEDD)
5. Stroke volume
6. Ejection fraction and fiber shortening ratio
7. Mitral valve a wave/E wave ratio

All of the above measurements can be displayed automatically, and from these measurements left ventricular mass for each participant has been calculated.

In South Africa (Bantu population), a common form of heart disease had been based on chronic malnutrition (Higginson et al. 1952). Affected people had poor nutritional background and suffered from recurrent attacks of congestive heart failure. The heart showed gross enlargement, evidenced by chest X-ray. The enlargement affected all chambers by being dilated and hypertrophied. The heart's range of

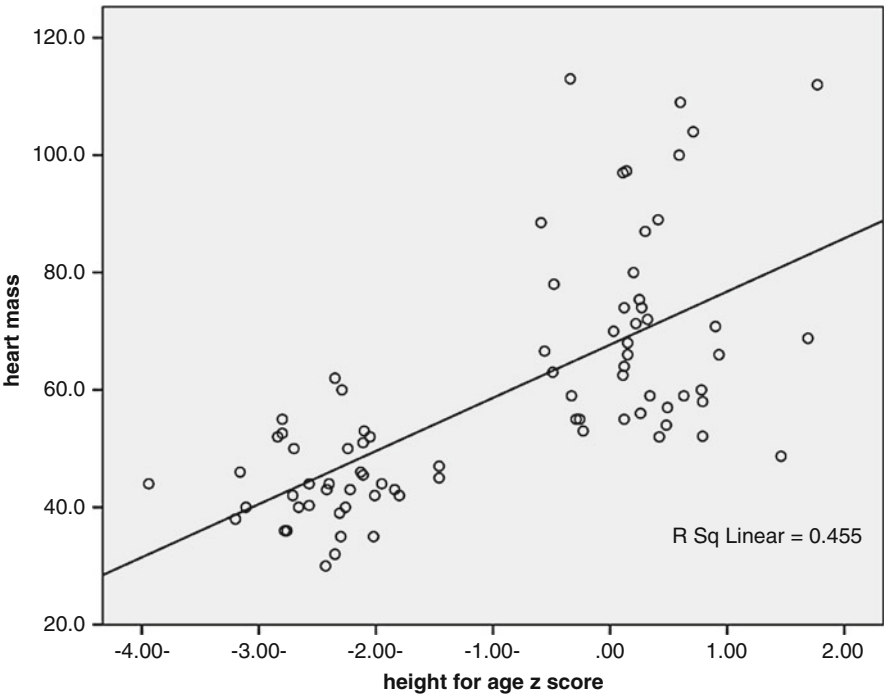

Fig. 3 Correlation between heart mass and HAZ R = 0.675 $p = 0.000$

pulsation was proportionately small, and the circulation was hypokinetic. (Higginson et al. 1952). Postmortem findings were in accord with chronic malnutrition as the etiological background.

Micronutrients and Cardiovascular System

When a diet is deficient in macronutrients (energy and protein), it is also expected to be deficient in micronutrients (minerals and vitamins). Some of micronutrient deficiencies cause specific disease entities. Examples are iron deficiency anemia, iodine deficiency disorders (e.g., goiter, cretinism, and hypothyroidism), rickets and osteomalacia, beriberi, pernicious anemia, pellagra, scurvy, and xerophthalmia.

Deficiencies of specific micronutrients such as iron and vitamin B_1 can cause heart failure. Poor diet may underlie such deficiencies especially in elderly patients in developed countries but mostly children in developing ones. Poor diet is the primary cause of worldwide malnutrition affecting millions of children suffering

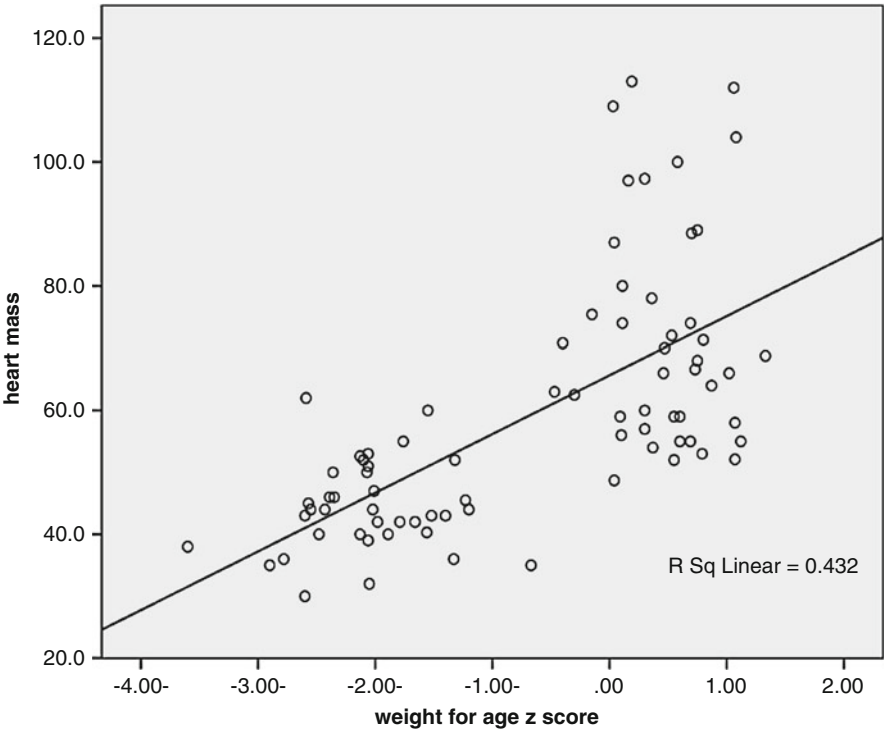

Fig. 4 Correlation between heart mass and WAZ R = 0.657 $p = 0.000$

from both acute (wasting) and chronic (stunting) malnutrition. Studies of specific nutrient levels among such populations are still lacking.

Calcium and Vitamin D

Calcium deficiency may come from lower intestinal absorption after the age of 70 years caused by less calcitriol-sensitive gut and lower renal synthesis of calcitriol.

Low calcium intake has been linked to higher mortality rates from ischemic heart disease in postmenopausal women.

Hypocalcemia-induced cardiomyopathy in children with congenital etiology and hypocalcemia responds dramatically to calcium supplementation. Low calcium levels are proarrhythmic. They have been associated with QT interval prolongation and hypocalcemic ventricular fibrillation (Witte Klauss et al. 2001).

Vitamin D plays a role in cardiovascular system functioning. Experimental studies on rats fed with vitamin D-deficient and calcium-sufficient diets showed

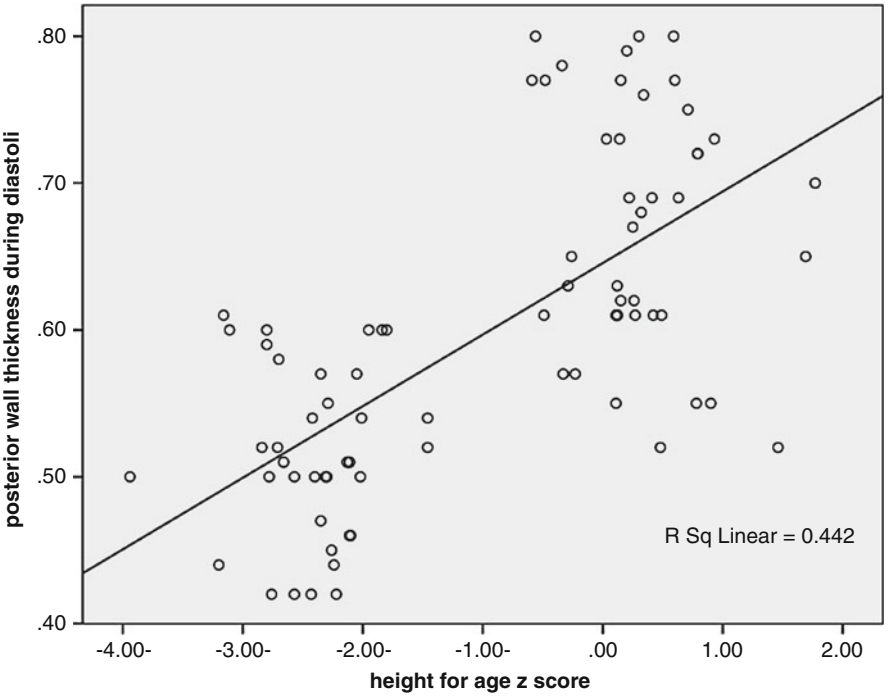

Fig. 5 Correlation between PWD and HAZ R = 0.665 $p = 0.000$

deterioration of myocardial contraction. Supplementation with vitamin D reverted myocardial contraction to normal (Witte Klauss et al. 2001).

Magnesium

Hypomagnesemia is related to worse prognosis for patients with heart failure and an increase in the rate of ventricular ectopics in patients with left ventricular dysfunction and those with normal cardiac function. Replacement with magnesium decreased the rate of ventricular arrhythmias.

Magnesium deficiency can lead to cardiac failure in rats. This can be inhibited by sufficient doses of ascorbate suggesting the possibility of free radical involvement. Heart failure as a consequence to hypomagnesemia has been observed in humans, and left ventricular function has been improved by correcting magnesium low levels. Hypomagnesemia is common in elderly patients with atrial fibrillation and heart failure and can precipitate digoxin toxicity. Ventricular arrhythmias seen in idiopathic cardiomyopathy may respond to magnesium therapy (Witte Klauss et al. 2001).

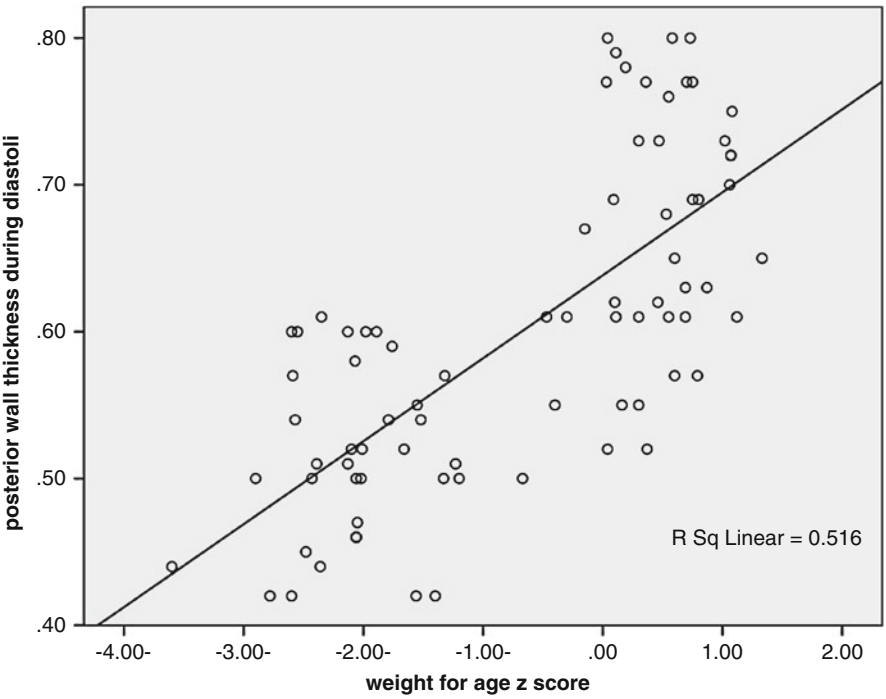

Fig. 6 Correlation between PWD and WAZ R = 0.718 $p = 0.000$

Zinc

Zinc deficiency is common in elderly. It correlates with cardiovascular drug intake and with dietary protein low intake. Low serum zinc with high urinary zinc levels are seen in those with heart failure and may be due to diuretic therapy.

Maternal severe zinc deficiency can cause developmental impairments to the heart. Prenatal zinc status may influence fetal cardiovascular autonomic function through unknown mechanism as stated by a study from Pero. Pregnant women with moderate zinc deficiency were supplemented and fetuses monitored. They had a lower mean heart rate at 20 weeks of gestation and greater heart rate variability and acceleration at 28 weeks, suggestive of greater parasympathetic control of the heart (Christian and Stewart 2010).

Copper

Copper has a role in the regulation of oxidative free radicals; its deficiency increases the susceptibility of lipoprotein peroxidation. Copper deficiency increases the risk of myocyte oxidative damage and may elevate plasma cholesterol concentrations.

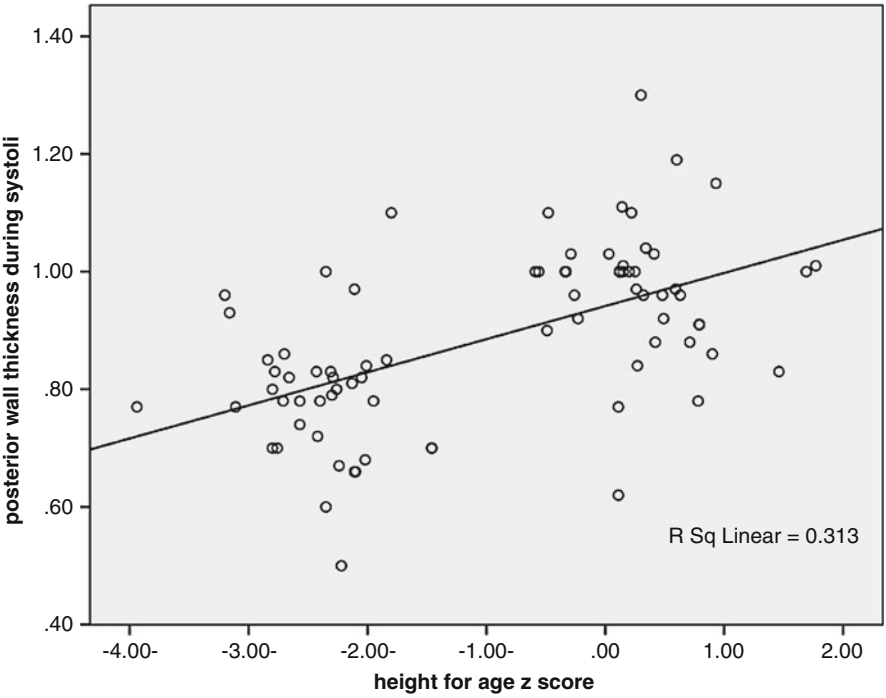

Fig. 7 Correlation between PWS and HAZ R = 0.559 $p = 0.000$

In rats chronic copper deficiency can lead to myofibrillar disarray and mitochondrial fragmentation. Copper deficiency decreases cytochrome C oxidase activity; this may lead to mitochondrial impairment and contribute to cardiac dysfunction. Copper-deficient cardiomyopathy is a recognized entity, and the identification of the genetic basis for defects in the copper-dependent ATPases has highlighted the possibility that copper deficiency has a role in experimental and human cardiomyopathy (Witte Klauss et al. 2001).

Selenium

Selenium is a constituent of the antioxidant enzyme glutathione peroxidase. Pure selenium deficiency is rare, but deficiency symptoms may occur when there is an additional dietary stress such as a vitamin E deficiency. An endemic cardiomyopathy in China, Keshan disease, is a consequence of selenium deficiency, which is also a risk factor for peripartum cardiomyopathy. In western countries, selenium-deficient cardiomyopathy has been described in patients on long-term total parenteral nutrition (Witte Klauss et al. 2001).

Ischemic heart disease and peripheral vascular disease have been linked to low selenium levels. In pig models of myocardial infarction, selenium reduced the

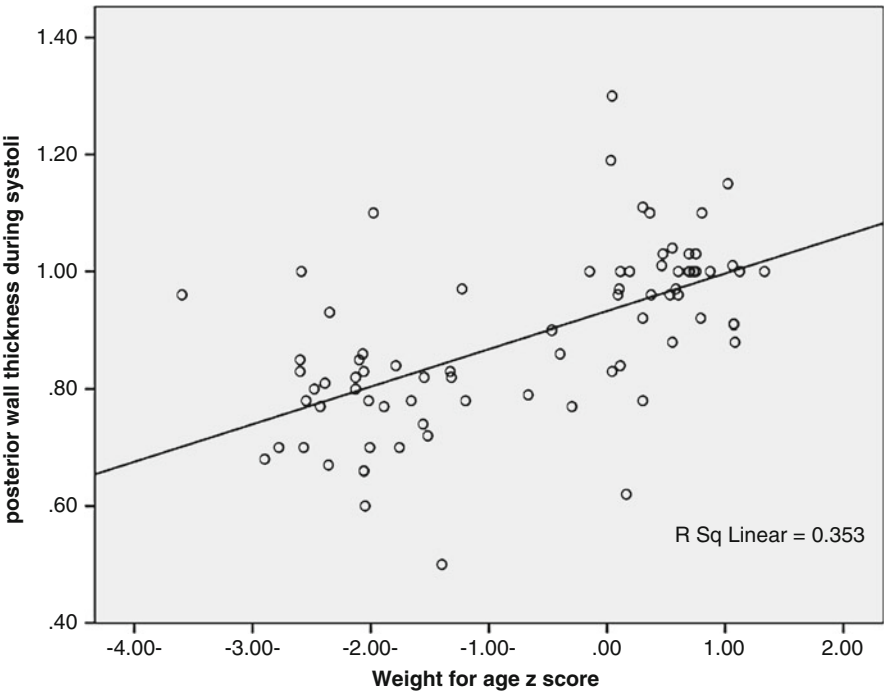

Fig. 8 Correlation between PWS and WAZ R = 0.594 $p = 0.000$

occurrence of late ventricular potentials in the border zone. This may be explained by the fact that selenium deficiency leads to increased levels of lipid peroxidation and, as a consequence, an increase in oxidative stress. Selenium has a role in protecting tissues from oxidative damage, which maintains the ability of cells to produce ubiquinone and preserves it from breakdown by oxidative degeneration. Deficiency leads to mitochondrial ultrastructural changes such as loss of cristae.

Thiamine

Thiamin deficiency occurs in malnourished individuals, in patients with chronic disease, in chronic alcoholics, in intestinal malabsorption, in anorexia, and in cases with high demand for this vitamin. High demand occurs during nutrition therapy with high carbohydrate diets for malnourished patients whose thiamine stores are marginal.

Beriberi, the well-known thiamine deficiency-induced disease, is characterized by cardiac failure. It is a high-output failure, with wide pulse pressure, tachycardia, enlarged heart, vasodilatation, pulmonary congestion, venous distention, and

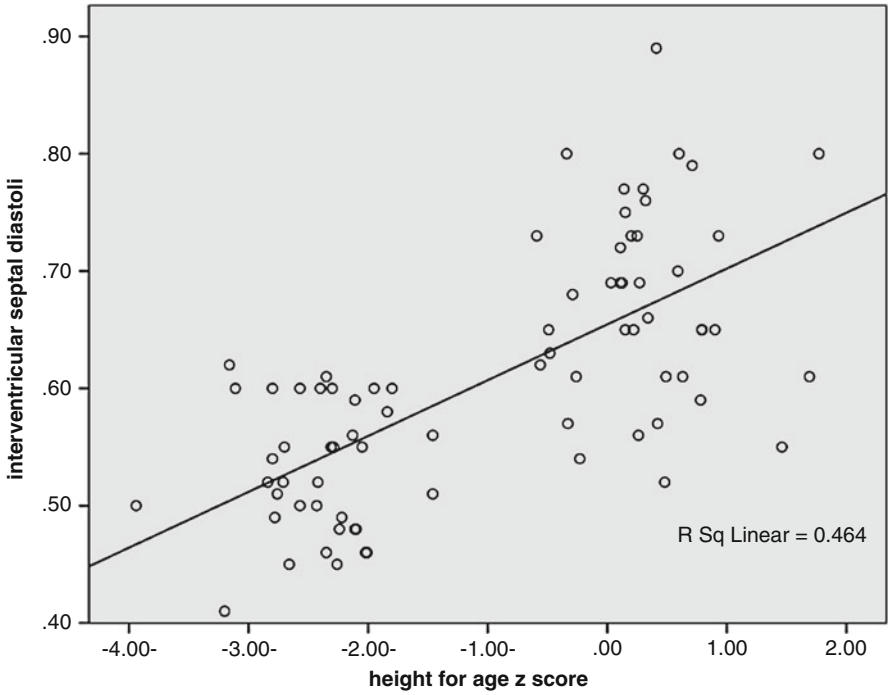

Fig. 9 Correlation between IVSD and HAZ R = 0.681 $p = 0.000$

peripheral edema. Vasodilatation is due to the accumulation of pyruvate and lactate. Response to thiamine is brisk and often with full recovery.

Vitamin (B_1) or thiamine is a coenzyme for decarboxylation in carbohydrate metabolism. Deficiency leads to impaired oxidative metabolism through inhibition of the citric acid cycle and the hexose monophosphate shunt (Witte Klauss et al. 2001).

Vitamins a and E

"Carotenoids, including β-carotene, lycopene, lutein, and α-carotene, are thought to prevent the oxidation of LDL cholesterol and other cell membrane lipids and thus prevent or slow the development of atherosclerosis. However, α-tocopherol (vitamin E) may be more effective than β-carotene in inhibiting LDL oxidation. Supplementation with 800 IU vitamin E, 1000 mg vitamin C, and 24 mg β-carotene in people with coronary artery disease effectively reduces LDL susceptibility to oxidation. Yet the effectiveness of carotenoids alone in preventing or treating heart disease has not been established, and, at present, carotenoid supplementation is not recommended" (Gropper et al. 2009).

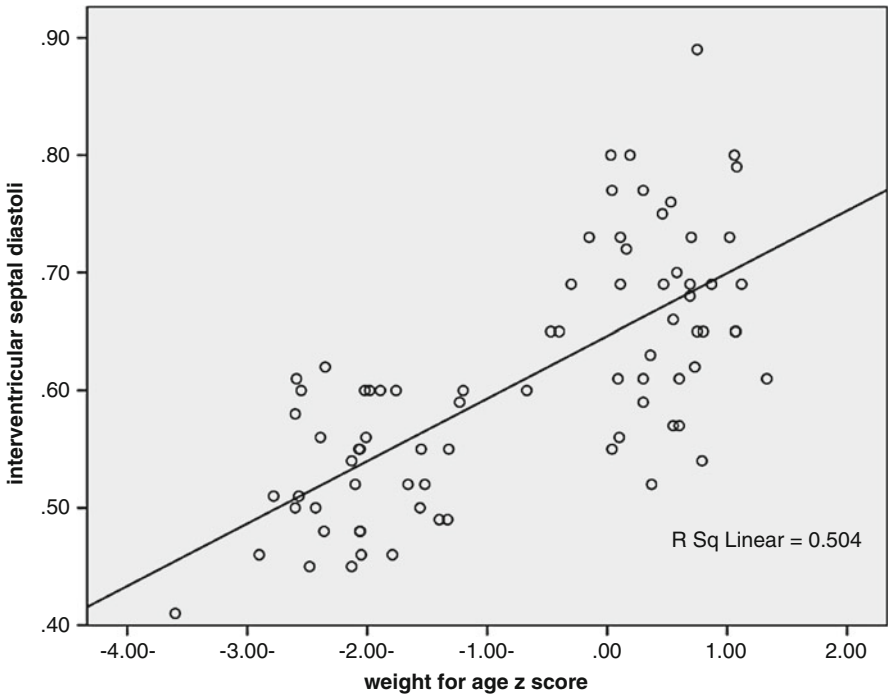

Fig. 10 Correlation between IVSD and WAZ R = 0.710 $p = 0.000$

Riboflavin (B_2)

Experimentally riboflavin deficiency has resulted in abnormal lipid metabolism, with a reduction in the beta-oxidation of fatty acids. It is not known whether riboflavin deficiency has any detrimental effect on cardiac functioning. Children with CHF due to congenital heart disease have an increased risk of riboflavin deficiency.

Vitamin B_6

Low pyridoxal-5′-phosphate is a risk factor for coronary artery disease and extracranial carotid artery disease mediated, in part, by elevated homocysteine levels. However, low B_6 levels are an independent risk factor for coronary artery disease even when homocysteine is taken into account. There are no reports of pyridoxal-5′-phosphate levels in HF.

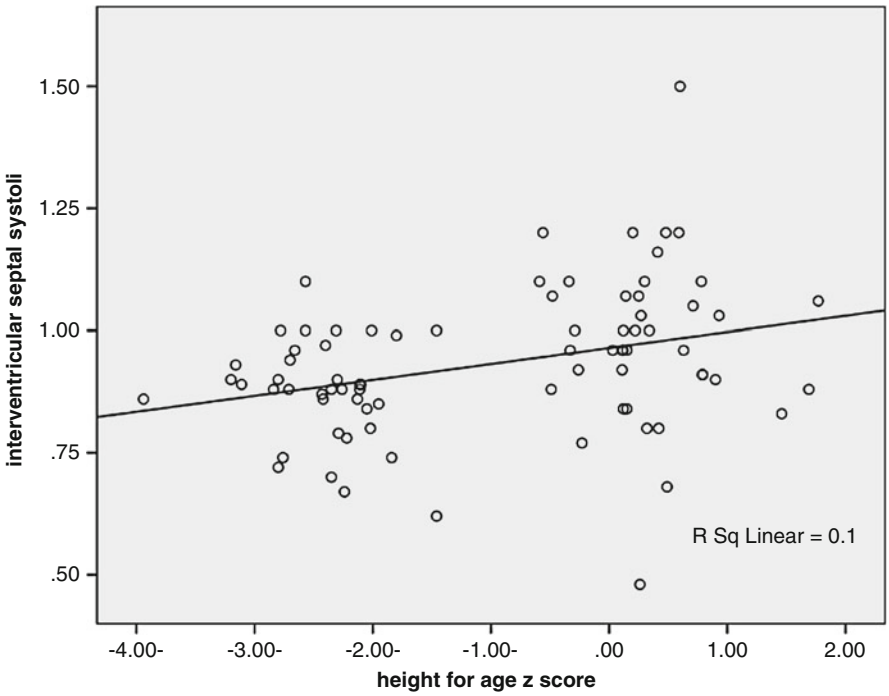

Fig. 11 Correlation between IVSS and HAZ R = 0.316 $p = 0.005$

Folate

The conversion of homocysteine to methionine requires folate, and a strong inverse relationship exists between folate consumption and homocysteine levels among patients with and without hyper-homocysteinemia. Tissue levels of vitamins B_{12}, B_6, and folate are not closely related to blood levels, and many more elderly patients may be deficient than are recognized. There is epidemiological evidence of an inverse link between folate consumption and risk of coronary heart disease (Witte Klauss et al. 2001).

Vitamin B_{12}

Vitamin B_{12} deficiency is associated with elevated levels of homocysteine. High homocysteine means an elevated risk for coronary artery disease. Data about B_{12} status in patients with heart disease will add to scientific knowledge in this regard.

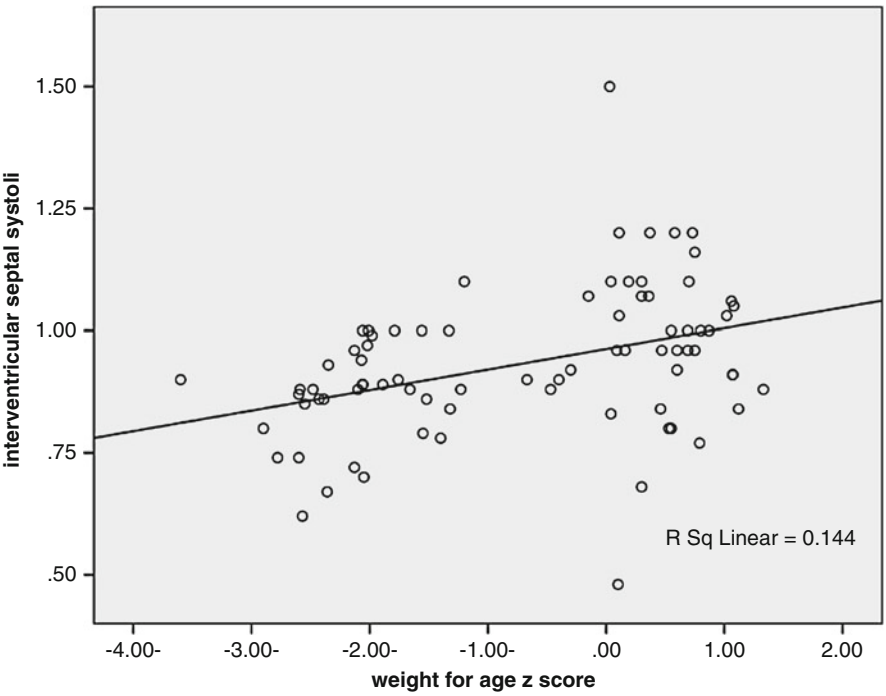

Fig. 12 Correlation between IVSS and WAZ R = 0.379 $p = 0.001$

Vitamin C

High intake of vitamin C has been correlated closely with a reduced risk of death from stroke through long-term follow-up study. The strength of the association was similar to the association of death and diastolic blood pressure. Vitamin C intake has no relation with deaths from heart disease. A study from Finland showed an increased risk of death from coronary heart disease, over 8 years of follow-up on middle-aged men, in those with low plasma ascorbate concentration.

In patients with hypertension, vasodilatory response to acetylcholine is attenuated. This attenuated response is partially reversed by vitamin C, and ascorbic acid supplementation can significantly lower blood pressure in hypertensive patients. Vitamin C improves endothelial function in diabetics and smokers when infused intra-arterially (cigarette smokers have lower plasma and leukocyte levels of vitamin C). Vitamin C infusions improve endothelial dysfunction associated with hypercholesterolemia and possibly caused by oxidative stress. Oral treatment with vitamin C for 30 days improves endothelium-dependent vasodilation in patients with coronary artery disease, and even a single dose of 2 g can improve vasomotor function after 2 h (Witte Klauss et al. 2001).

In heart failure it is unknown whether vitamin C levels are reduced, but improvements of endothelial dysfunction have been seen with vitamin C.

Vitamin E

In middle-aged subjects, high vitamin E intake is associated with a lower incidence of coronary heart disease. Among individuals with high intake of vitamin E, men had a lower risk of developing coronary artery disease by 40% and women by 34%. Similar results are seen in those 65-year-olds and more with additional benefits if they use both vitamin E and vitamin C supplements. Vitamin E for healthy volunteers led to a reduction of platelet stickiness, an effect that has also been seen in diabetics and heart transplant recipients (Witte Klauss et al. 2001).

Dietary Recommendations for Cardiovascular Health

From the above paragraphs, we can conclude that macro- and micronutrient deficiencies affect cardiovascular health in general and the heart structure in particular. On the other hand, high calorie and high fat diets as well as physical inactivity have been considered as causes for obesity and ischemic heart disease and many other chronic noncommunicable diseases. Costs incurred by different societies for the management of these diseases and health problems are expanding continuously. Exploration of future outcomes of protein energy malnutrition on the heart may need more longitudinal studies. Virtual research question may include vulnerability to ischemia, post-myocardial infarction complications, susceptibility to cardiomyopathy, and electrophysiologic abnormalities.

Prevention of cardiovascular diseases and promotion of cardiovascular health are being approached through the following: evaluating the diverse dietary risk pathways rather than just blood lipids or obesity; foods and diet pattern rather than isolated specific nutrients; complex influences of different foods on weight control instead of just counting calories; and implementing strategies for lifestyle change.

Evidence-based dietary recommendations include increase intake of the following food: fruit vegetables (other than starchy ones like potatoes), nuts, legumes, fish, vegetable oils, yogurt, and whole grains. These recommendations also include limiting intake of red meat, processed meats, foods rich in refined grains, starch, added sugars, salt, and trans fat (Mozaffarian 2016).

Health system reforms may be essential to foster health promotion through well-designed policies. Healthy diets as recommended by international associations and increase physical activities should be applied practically in addition to special education programs about their importance in relation to heart and cardiovascular system as a whole.

In our Arab world, promoting cardiovascular health is challenging. Diet rich in calories, refined sugars, starchy food, and fat is preferred. Inactive sedentary life is a prevailing style especially for females. Still health education programs regarding healthy diet and physical activity are developing.

Dictionary of Terms

- Malnutrition means on one hand food intake that exceeds human body needs and results in obesity or increased body weight.
- Malnutrition means on the other hand food intake that does not meet human body needs and results in decreased body size/weight.
- Stunting means short stature in relation to age; it happens when food insufficiency persisted for more than 6 months.
- Wasting is thinness of the human body determined by relating body weight to body height. This is the earliest bad effect of food shortage.
- Echocardiography is an examination and imaging of the heart using ultrasound waves.

Summary Points

- PEM is a public health problem affecting millions of people mainly those in developing countries with children on top of the list.
- Malnutrition may be clinical (severe) or subclinical mild and moderate where children are considered normal with poor healthcare systems.
- PEM causes decrease in body size including internal organs, and the heart is one of them.
- Heart involvement is correlated with severity of PEM determined by anthropometry.
- Studies included laboratory experiments, postmortem studies, hospital-based observational studies, and community-based comparative study.
- Micronutrients like vitamins and minerals are essential for cardiac health as their deficiencies result in many diseases and health impairment.
- Micronutrients can be used to counteract cardiovascular ill health and control degenerative changes of the cardiovascular system.
- The field needs more research that may be longitudinal studies to assess long-term impact of childhood malnutrition on heart health and disease.
- Nutrition as a medical discipline may help, through more focused research work, to control the widespread of heart disease.
- Current knowledge highlighted new areas of concerns for health policies in terms of healthy diet and lifestyle for better cardiovascular health.

Intermittent Fasting Effects on the Central Nervous System: How Hunger Modulates Brain Function

63

Fernanda M. Cerqueira, Bruno Chausse, and Alicia J. Kowaltowski

Contents

Abstract

Fasting has been present throughout human history and is a regular practice in many cultures and religions. Currently, findings regarding beneficial effects of fasting on body mass control and health have largely stimulated the practice. The number of studies investigating intermittent fasting effects on different pathological states has grown steadily. Evidence suggests that this dietary intervention can delay or even prevent the onset of pathologies, such as neurodegenerative diseases. Indeed, several studies have reported intermittent fasting actions on brain integrity and function. However, fasting may also affect hunger control in less desirable manners. Indeed, the brain is highly sensitive to fasting practice due

to its pronounced energy demand and its central role in the control of whole body energy balance. In this chapter, the effects of intermittent fasting on brain function are discussed along with a description of the history of human fasting practices.

Keywords
Intermittent fasting · Caloric restriction · Energy homeostasis · Brain function · Hypothalamus · Appetite control · Energy expenditure · Reproductive function · Aging · Cognition · Neurogenerative diseases

List of Abbreviations

AD	Alzheimer's disease
AGRP	Agouti-related peptide
CART	Cocaine- and amphetamine-regulated transcript
GnRH	Gonadotropin-release hormone
HDL	High-density lipoprotein
IF	Intermittent fasting
LDL	Low-density lipoprotein
NPY	Neuropeptide Y
PD	Parkinson's disease
POMC	Pro-opiomelanocortin
VLDL	Very-low-density lipoprotein

Introduction

Fasting is the act of abstaining from food for a specific period of time. It is practiced in many cultures and religions, as well as for weight loss purposes and even political statements. Many types and subtypes of fasting exist (Table 1), with a wide range of changes in net calorie intake and physiological effects in humans and laboratory animals.

In 1994, 14% of US adults had tried fasting as a strategy to control body weight (French and Jeffery 1994), and this number may have risen quite largely in recent years, stimulated by anecdotal beliefs in health benefits of this practice. In fact, overweight and obesity are major global health concerns related to disorders including coronary heart disease and type 2 diabetes. More than 50% of the population in the UK and US, for example, are considered overweight or obese (National Center for Health Statistics 2016; The NHS Information Centre 2012). Caloric deficit is an obvious approach to promote weight loss, achieved by increasing the metabolic demand through physical exercise and/or decreasing calorie intake (Wu et al. 2009). Although a very successful strategy to promote weight loss and reduce disease risk, adherence to caloric restriction decreases over time and is inversely proportional to the degree of restriction (Wing and Phelan 2005). Thus, one to few days a week fasting with ad libitum feeding breaks has become more popular as a supposedly easier way to limit caloric ingestion (Varady 2011).

Table 1 Types and subtypes of fasting

Fasting (types and subtypes)	Description
Dry fasting	Also called absolute fast or complete fast. Consists of total absence of food and liquid intake, including water. Usually practiced for a shorter periods of time. Dry fasting is used by religious practitioners of Hinduism, Judaism, Islam, and Jainism as well as in traditional Chinese Medicine (Fredricks 2013)
Water-only fasting	Allows the ingestion of water, while abstaining from any type of food and other liquids (Fredricks 2013)
Therapeutic fasting	"Therapeutic fasting" is a water-only fast with medical supervision. It was well accepted as an inpatient treatment for morbid obesity during the 1950s and 1960s. More recently, spas and fasting retreats are offering similar activities (Fredricks 2013)
Modified fasting	
- Juice fasting	Juice fasting refers to the consumption of juice only. Juice fasters believe it enhances the body's elimination of metabolic byproducts. It is followed from home or specialized retreats. Certain rules may apply, such as exclusive raw vegetable juice and consumption up to 30 min after production (Fredricks 2013)
- Specific fasting	Specific and exotic types of fasting normally refer to the abstinence or consumption of a given food (Fredricks 2013)
- Intermittent fasting (IF)	Intermittent fasting (IF) is a focus of many recent studies and consists of a repeated pattern of fasting and refeeding (Mattson et al. 2017)
• Every other day fasting	A type of IF, also called alternate day fasting, where 24 h fasts are followed by 24 h ad libitum refeeding
• 5:2 Fasting	Two fast and five feasting days per week (Mattson et al. 2017)
• 20/4	A type of IF where 20 h fasts are followed by 4 h nonfasts
• Time-restricted feeding	Described by Chaix et al. (2014) as limiting daily feeding hours to 9–12 h

Animal models have shown that caloric restriction effects go beyond weight loss and disease prevention. In mammals, caloric restriction modulates several cellular pathways (Table 2) associated with lifespan extension such as insulin signaling, inflammation, hunger, autophagy, gene expression, mitochondrial biogenesis, and function. Ultimately, caloric restriction is a useful model to understand longevity-regulating genes; the National Institute of Aging, Max Planck Institute for Biology of Aging, and other Federal Agencies around the world have heavily invested in research to find drugs which can mimic it (Ingram et al. 2006).

Caloric restriction animal models are, however, labor-intensive. As a result of its relative ease, many studies have substituted caloric restriction (a daily decrease in food intake) for intermittent fasting (IF, often 24 fasting followed by 24 ad libitum feeding, or every other day feeding, Cerqueira and Kowaltowski 2010); unfortunately, both terms are often used interchangeably. Although IF reproduces some of caloric restriction effects, such as decreased body weight (Table 2), criticism has been raised from observations that IF does not necessarily decrease the net caloric

Table 2 Main metabolic and health-related effects of calorie restriction and intermittent fasting (*IF*)

	Calorie restriction	Intermittent fasting
Similar findings in rodents and humans	- Significant and standardized restriction of dietetic calories - Weight loss - Well-documented reduction in blood triglycerides, growth hormone, and insulin (Lee and Longo 2011; Barnosky et al. 2014) - Substantial improvement in insulin sensitivity (Barnosky et al. 2014) - Improved mitochondrial biogenesis (Civitarese et al. 2007) - Regulation of "nutrient-sensing" pathways (Civitarese et al. 2007) - Reduced blood pressure and atherosclerosis risk (Fontana et al. 2004)	- Effects on net calorie consumption depending on ad libitum intake on feasting days - Different reports on body weight: loss, no effect or gain (Lee and Longo 2011; Barnosky et al. 2014) - Differences in short-term and long-term effects (Lee and Longo 2011; Cerqueira et al. 2011) - Marked reduction in blood IGF-1 (Lee and Longo 2011; Fontana et al. 2008) - Reduction in blood insulin and triglycerides (Lee and Longo 2011; Barnosky et al. 2014)
Research findings in rodents (Adapted from Lee and Longo 2011)	- Lifespan extension - Reduced nitrogen excretion - Reduction in body temperature - Extended reproductive span - Reduced cancer incidence; for a subset of malignancies, progression is reduced - Decreased oxidative imbalance markers - Effects observed within weeks or months - Reduction in blood IGF-1 levels	- Arguable effects on lifespan - Divergent effects on diabetes prevention (Dorighello et al. 2013) - Reduced fertility - Increased nitrogen excretion - Varying effects on oxidative markers (Cerqueira et al. 2011) - Reductions in body temperatures - Effects observed after 2–3 days - Use of ketone bodies as energy sources
Research findings in humans	- No reduction in IGF-1 levels (Fontana et al. 2008) - No clear reduction in fasting blood glucose (Barnosky et al. 2014)	- No clear reduction in fasting blood glucose (Barnosky et al. 2014) - May be protective during chemotherapy (Dorff et al. 2016) - Improvement in insulin sensitivity associated with weight loss in obese individuals (Barnosky et al. 2014)

intake in rats (Cerqueira et al. 2011; Chausse et al. 2014). Classical caloric restriction protocols, on the other hand, promote 30–60% reduction in calories, keeping the proportion of macronutrients and correcting the micronutrients levels (Cerqueira and Kowaltowski 2010). During IF, some studies have reported compensation through overeating on the refeeding days (Cerqueira et al. 2011; Chausse et al. 2014).

Importantly, IF effects on rodent lifespan are debatable (Cerqueira and Kowaltowski 2010). Curiously, a parallel can be made with fasting during Ramadan, which promotes more eating during the refeeding period, resulting, in some cases, in weight gain (Bakhotmah 2011).

Indeed, fasting deeply affects brain function promoting neuronal remodeling to counteract nutritional stress. These adaptations are pronounced in the hypothalamus, the brain area that controls whole body energy balance. Hormones and nutrients signaling energy deficits activate compensatory sensor-behavioral responses that are coordinated by hypothalamic neurons (Morton et al. 2014). Therefore, prolonged periods of food deprivation, such as IF, induce marked modulation in hypothalamic function and consequently in feeding behavior. These changes may also be related to beneficial effects of fasting on cognition and brain disease prevention. Indeed, IF has long been recognized to delay cognitive decay and the onset of neurodegenerative diseases (Murphy et al. 2014). Here, the history of fasting in humans will be explored along with discussions about how IF impacts brain function, focusing on its effects on the hypothalamic control of energy balance, cognitive function, and neurodegenerative diseases.

The History of Human Fasting

Fasting has been practiced since the dawn of humankind, when it was imposed by food scarcity. As humanity and food availability evolved, feeding habits shifted from eating when food was available to a limited amount of times per day (main meals) to what recently became a scientifically unsupported nutritinal gold-standard recommendation of eating every 3 h (Mattson et al. 2017). As a result, people in the Western World are constantly in the postprandial state (Lopez-Miranda and Marin 2010), while the human body evolved to endure periods of fasting/starvation, and thus accumulates excess calories, stored mainly as lipids, with ease (Mattson et al. 2017).

Interestingly, throughout history, organized religions and cults embraced periods of fasting as part of their rituals. Indeed, fasting is still a tool for spiritual purification or atonement for the largest known religions (Table 3). Important spiritual leaders such as Gandhi, Jesus, and Buddha fasted for over a month, thus providing evidence that fasting is well within the the capabilities of a healthy adult. Despite the variability in frequency and type, religion-associated fasting has given us hints about the impact of fasting on human health. Muslims undergo long fasts each year throughout the length of Ramadan (and beyond). During the Ramadan month, those practicing fasting present lower total cholesterol, LDL cholesterol, VLDL cholesterol, and triglyceride levels, while HDL levels are markedly increased (Adlouni et al. 1997; Maislos et al. 1993), even without a significant reduction in body weight (Temizhan et al. 2000). During Ramadan, acute coronary heart diseases reduced compared to pre-Ramadan months (Temizhan et al. 1999). One case study of a man undergoing 1 week fast during the Japanese Buddhist ritual Danjiki also showed lower triglycerides levels after fasting (Tanaka et al. 2016).

Table 3 Fasting in the main religions

Religion	Fasting practice
Hinduism	Fasts once a week in addition to other religious observances Fasting before yoga practice is common (Fredricks 2013)
Buddhism	Half-day and 3-day fasts Fasting after noon is a common practice in Tibetan Buddhism (Fredricks 2013)
Judaism	Some holidays involve 25-h fasting periods, while others involve fasts from sunrise to sunset (Fredricks 2013)
Islam	Ramadan involves fasting from sunrise to sunset during a month every year (Fredricks 2013)
Christianity	Many examples of one-day, three-day, and forty-day fasts in the new testament. Abstention from meat on certain holidays. Mormons often fast the first Sunday each month (Fredricks 2013)

Renowned physicians and scientific icons also reinforced this practice due to earlier observations on health and concentration capacity; Socrates, Plato, and Aristoteles fasted for mental clarity, and Pythagoras fasted for 40 days before teaching advanced students. Hippocrates believed fasting assisted the body in healing itself and stated *Our food should be our medicine and our medicine should be our food. But to eat when you are sick is to feed your sickness* (Fredricks 2013). Another Greek Physician, Paracelsus, concluded, nearly 500 years ago, *Fasting is the greatest remedy – the physician within!* (Bragg and Bragg 2004). In fact, fasting is one of the oldest known medical therapies, dating from the Stone Age (Goscienski 2005). Fasting was regularly prescribed to treat and prevent diseases, preserve health, and prolong life. In the 1950s and 1960s, fasting and very-low calorie diets were a well-accepted inpatient treatment for morbid obesity. This is no longer recommended since it has been linked to serious complications such as ventricular fibrillation, lactic acidosis, vitamin and electrolyte deficiency, and sudden death either during fasting or refeeding (Johnstone 2007). Despite this specific criticism, fasting has strong worldwide appeal, and is considered a no cost therapy associated with disease prevention and treatment. It is thus not surprising that healthy individuals follow this practice, without any close monitoring, contributing to a lack of more robust data on the effects of this intervention on human health.

Indeed, IF is becoming an ever more popular strategy to lose weight (Carlson and Hoelzel 1946; Fredricks 2013). IF is actually a pattern of fasting and feeding which alternates between periods of fasting and refeeding (Mattson et al. 2017) which has branched into different subtypes (Table 1). Some studies have demonstrated that calories are often reduced during IF (e.g., weekly calorie intake in an individual on the "5:2" diet is reduced by 25%; Harvie et al. 2013), although the question remains as to what extent physiological responses to IF are mediated by overall caloric restriction.

The earliest IF studies in laboratory models date from the 1880s: The effects on growth and nutrition were tested in chickens (Von Seeland 1887) and salamanders (Morgulis 1913). In 1945, different fasting strategies were tested in rats (fasting to nonfasting days of 1:2, 1:3, and 1:4) and were suggested to impact on lifespan; 1:3

was found to be the most effective. Interestingly, the strongest effects on the reduction of tumor incidence were directly associated with the frequency of fasting days (Carlson and Hoelzel 1946). The shortest window between fasting and non-fasting days (1:2) resulted in a larger number of individuals with higher food intake during the nonfasting days, a result which was reproduced in rats fed every other day (Cerqueira et al. 2011; Chausse et al. 2014). Interestingly, many caloric restriction studies in rodents are, in fact, some form of fasting, as pointed out by Mattson and colleagues (Mattson et al. 2017): rodent caloric restriction models normally involve offering daily allotments of food once or twice a day, or even every 3 days, and the animals consume it all within few hours. Indeed, IF mimics daily caloric restriction in many aspects (Table 2), although there is controversy whether IF and caloric restriction result in similar net calorie intake reduction. While IF effects on lifespan are still arguable, caloric restriction has consistently been shown to extend life spans in rodents since 1935 (McCay 1935; Sohal and Weindruch 1996).

In humans, most caloric restriction and IF interventions are not performed continuously throughout the life, and there is no data regarding the effect on human lifespan. Indeed, most of the research has been focusing on the beneficial aspects of ongoing IF and caloric restriction, or how long the metabolic effects last when they are ceased. Although it is known caloric restriction and fasting affect hunger and other brain and autonomic nervous system characteristics, the behavioral aspects are less explored. These are important, since hunger triggered by caloric restriction or fasting is a central component of weight gain after these interventions cease (Franklin et al. 1948; Stice et al. 2008).

Intermittent Fasting Effects on Brain Function

The brain coordinates complex physiological and behavioral responses to endogenous and environmental stimuli. Indeed, different signals modulate its function inducing neuronal activity remodeling. These changes involve high energy-expending processes such as neurotransmitter synthesis and reuptake, which result in elevated brain energy consumption (Amigo and Kowaltowski 2014); nutrient availability must therefore be accurately regulated to avoid neuronal dysfunction and death. In addition to its high-energy demand, the brain controls whole body nutritional state by regulating energy intake and waste. Fasting-feeding signals are sensed by different neuronal populations that, together, modulate appetite, food reward, locomotor activity, and energy expenditure (Morton et al. 2014). These features make the brain highly sensitive to alterations in feeding patterns such as those introduced by dietary restriction.

Given the brain's susceptibility to fasting, a growing number of studies have been performed to understand how IF affects neuronal function, mostly within an aging perspective. Evidence suggests that fasting cycles can delay brain aging, preventing neurogenerative diseases and cognitive functional decay. Moreover, fasting diets have been related to improvements in brain plasticity, learning, and memory. IF also modulates the central control of energy balance, since this regimen alters the

circadian regulation of the body's nutritional state. The next sections contain discussions about IF effects on neuronal function, focusing on its actions on energy homeostasis control, cognition, and neurodegenerative diseases.

Intermittent Fasting Impacts on Hypothalamic Function

Energy homeostasis is primarily controlled by the hypothalamus. This cerebral area has a permeable blood–brain barrier that allows the entrance of hormones and nutrients signaling body nutritional state. These signals are integrated by distinct neuronal populations which adjust energy balance regulating feeding and energy usage (Morton et al. 2014). In response to energy deficits, hypothalamic orexigenic neurons induce increases in appetite and energy conservation. Anorexigenic neurons, in turn, counteract positive energy balance inhibiting food ingestion and stimulating energy expenditure. The alternating activation of these pathways finely regulates fasting-feeding cycles, ensuring adequate body mass control (Barsh and Schwartz 2002). Changes in feeding patterns should therefore modulate hypothalamic function, adapting physiological responses to the body's nutritional state (Fig. 1).

Dietary regimens that involve fasting have been found to alter hypothalamic control of appetite and body mass. Indeed, IF promotes hyperphagia along with marked activation of hypothalamic orexigenic pathways (Chausse et al. 2014). Several groups have observed increases in the expression of orexigenic neuropeptides neuropeptide Y (NPY) and agouti-related protein (AGRP), using different fasting protocols (Kumar and Kaur 2013; Chausse et al. 2014; Gotthardt et al. 2016; Méquinion et al. 2017). This effect could be related to IF-induced reduction in circulating leptin levels. Minor changes in hypothalamic anorexigenic neuropeptide contents have been reported. Due to enhancements in orexigenic signaling, IF subjects can compensate fasting periods presenting similar cumulative caloric ingestion of nonrestricted groups (Cerqueira et al. 2011; Chausse et al. 2014; Wahl et al. 2016). This suggests that IF outcomes can be a consequence of changes in feeding frequency as well as restrictions in caloric intake, when they occur (Anson et al. 2003). However, it is important to highlight that, in some studies, IF-treated subjects present 10–20% reduction in overall food consumption. In a short-term study, Lauzurica and collaborators observed that IF animals present progressive increases in caloric intake during the first week. Curiously, appetite and NPY neuropeptide levels remained elevated for days after the treatment ended (Lauzurica et al. 2010). This agrees with data showing that orexigenic neurotransmitter expression continues increasing even when IF-treated rats are fed (Chausse et al. 2014). Despite overeating, IF animals display low body mass, indicative of a decrease in energy conversion efficiency, as a result of increases in lipid oxidation and metabolic rates (Chausse et al. 2014). However, the alterations in hypothalamic function underlying IF-induced reduction in feed efficiency are not yet well understood.

The beneficial effects of fasting have been attributed to metabolic and physiological adaptations induced by nutritional stress. These changes include activation of the stress-linked hypothalamic axis that engage sensory-motor responses to food

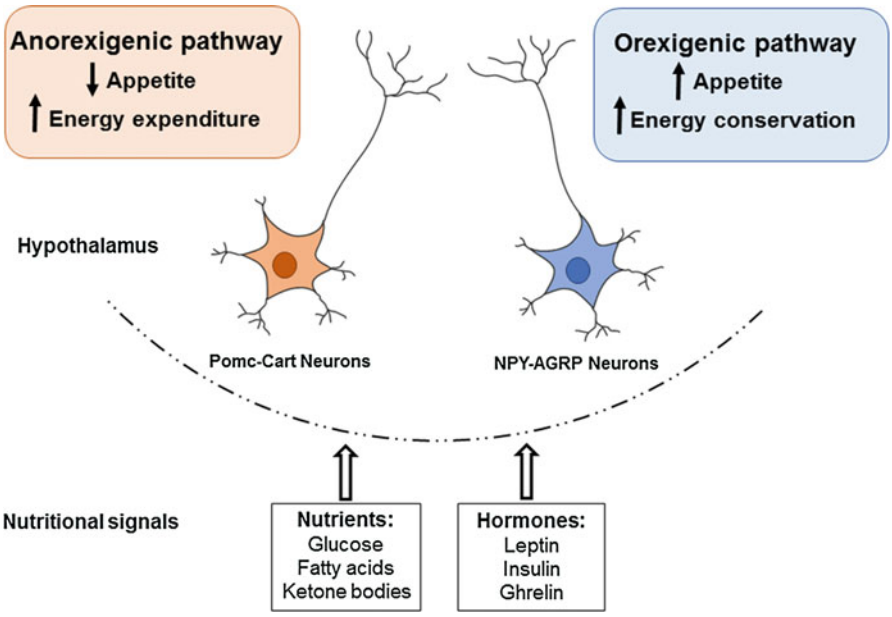

Fig. 1 Hypothalamic pathways controlling body energy balance. Energy balance is controlled by alternating the activation of hypothalamic orexigenic and anorexigenic neurons. Nutritional deficits activate orexigenic neurons (characterized by the expression of NPY and AGRP neuropeptides) inducing increases in appetite and energy conservation. Nutrients and hormones signaling positive energy balance, in turn, activate anorexigenic neurons (characterized by the expression of POMC and CART neuropeptides), promoting decreases in appetite and increases in energy expenditure. Key: *NPY* neuropeptide Y, *AgRP* agouti-related peptide, *POMC* pro-opiomelanocortin, *CART* cocaine- and amphetamine-regulated transcript

scarcity (Mattson 2015). Studies in rodents show that fasting cycles activate the hypothalamic–pituitary–adrenal axis, increasing plasma corticosterone levels (Lauzurica et al. 2010). Moreover, IF promotes an enhancement in norepinephrine content in the medial hypothalamus followed by increases in NPY expression and hyperphagia (Gotthardt et al. 2016). Hypothalamic alterations determining IF-induced voracious feeding should include enhancements in the hedonic and nutritional value of food. Indeed, the hypothalamus orchestrates the activity of different brain areas controlling energetic and sensory aspects of feeding (Morton et al. 2014). Studies in humans suggest that intense dietary restraint is followed by changes in food perception, anxiety, and mood (Green et al. 1994). Nonetheless, the integration between the hypothalamus and other brain areas supporting IF effects on feeding behavior is still incompletely understood.

In parallel to energy balance, the hypothalamus regulates energy-sensitive processes such as reproduction. Fasting-induced alterations in energy availability can promote physiological adaptations or even interrupt this process (Hill et al. 2008). In fact, famine and starvation have long been related to changes in

reproductive cycles and impairments in fertility. For instance, clinical cases of anorexia nervosa comprise nutritional infertility and amenorrhea (Estour et al. 2010). IF impacts on the hypothalamo–hypophysal–gonadal axis have been described in detail in rodents. IF-induced changes in leptin and NPY levels have been linked to reductions in gonadotropin-release hormone (GnRH) expression and its release in the hypothalamus of male and female rats (Kumar and Kaur 2013). Since this neuropeptide is a master regulator of reproduction, changes in GnRH were followed by decreases in testosterone and luteinizing hormone content along with interruption in reproductive function. In a long-term study, approximately 50% of female rats presented alterations in the estrous cycle after 6 months of IF (Martin et al. 2007). These data suggest that the perturbations in energy balance promoted by fasting diets directly impact the neuroendocrine control of reproductive function leading to reductions in fertility. IF effects on hypothalamic function are outlined in Table 4.

Table 4 Intermittent fasting effects on hypothalamic function

Animal model	Dietary intervention	Effects	Reference
Female Sprague-Dawley rats	2 h daily food access (7 days) plus refeeding (14 days)	Hyperphagia ↓ Body mass during restriction time ↑ NPY, corticosterone ↓ POMC, leptin	Lauzurica et al. 2010
Female/male Wistar rats, 3–4 months	24-h fast/24-h fed, 12 weeks	Body mass ↑ NPY ↓ GnRH, testosterone ↓ LH, leptin	Kumar and Kaur 2013
Male Sprague-Dawley rats, 8 weeks old	24-h fast/24-h fed, 3 weeks	Hyperphagia ↓ Body mass ↓ Feed efficiency ↓ Leptin ↑ NPY, AgRP, orexin	Chausse et al. 2014
Male C57BL/6 mice	8 weeks high fat diet followed by 4 weeks 24-h fast/24-h fed	Body mass ↑ Norepinephrine, NPY	Gotthardt et al. 2016
Female C57BL/6 J, 8 weeks old	2 h daily food access, 10 weeks	Hyperphagia ↓ Body mass ↑ NPY, AGRP	Méquinion et al. 2017
Male C57BL/6 J, 4 weeks	22 weeks of high fat diet followed by 12 weeks of mild IF	Hyperphagia ↑ POMC	Seimon et al. 2016

Major effects of intermittent fasting on hypothalamic function are summarized. In general, IF increases hypothalamic orexigenic signaling followed by hyperphagia, even when different fasting protocols were used. Key: *NPY* neuropeptide Y, *POMC* pro-opiomelanocortin, *AGRP* agouti-related peptide, *GnRH* gonadotropin-release hormone, *LH* luteinizing hormone

Intermittent Fasting Effects on Cognition and Neurodegenerative Diseases

Brain function is sustained by the coordinated activity of neurons and nonneuronal cells, which are highly sensitive to perturbations in organism homeostasis. Physiological challenges introduced by alterations in lifestyle and aging, for example, can directly affect brain performance (Mattson 2015). Indeed, aging-related changes in cerebral structure and function are associated with the appearance of neuronal disorders and increased brain vulnerability to diseases. The mechanisms behind brain functional decline have long been investigated and include alterations in neuronal physiology, cell-to-cell interaction, brain volume, and microscopic morphology (Wahl et al. 2016).

Fasting diets delay or even prevent aging-induced neuronal dysfunction. Extensive research regarding IF impacts on the brain have suggested that fasting cycles can delay cognitive decay and neurogenerative diseases (Murphy et al. 2014). IF beneficial effects are supported by reductions in cellular oxidative stress and enhancement in mitochondrial function (Amigo and Kowaltowski 2014; Raefsky and Mattson 2016). IF further maintains brain homeostasis by improving neurogenesis and synaptic plasticity (Murphy et al. 2014). Recent findings about IF effects on cognition and neurodegenerative pathologies are shown in Fig. 2 and will now be discussed.

Changes in behavior and cognition in aged mammals have been associated with a decline in brain function (Anderton 2002). In fact, aging-induced neuronal deterioration in the hippocampus and prefrontal cortex is followed by impairment in memory and learning (Weber et al. 2015). These effects are a consequence of increased neuronal death accompanied by marked decreases in neurogenesis and brain plasticity (Murphy et al. 2014). IF protects the brain against dysfunction and degeneration by increasing neuronal resistance to cellular stress. Findings in rodents suggest that IF enhances neuronal resilience to excitotoxic stress, preventing learning deficits (Qiu et al. 2012). Fasting cycles further induce increments in neurotrophic factors and anti-inflammatory cytokine contents, which prevent hippocampal cell death and stimulate neurogenesis (Arumugam et al. 2010; Marosi and Mattson 2014). Indeed, Lee and colleagues showed that IF can increase the survival of newly generated neurons in the hippocampus (Lee et al. 2000). Learning and memory have been improved by fasting treatment even when the diet is introduced at advanced ages. IF-induced attenuation in spatial learning and motor coordination deficits was observed in old rats at 70% of their lifespan. This effect was a consequence of the increased expression of synaptic proteins regulating calcium homeostasis (Singh et al. 2012). Although beneficial impacts of IF on brain aging have long been demonstrated, some evidences suggest that alternative fasting patterns can compromise cognitive function in humans. Daylight fasting, such as adopted during Ramadan, has been related to impairments in cognitive capability and decision making (Cherif et al. 2016). In addition, long-term food restriction to lose weight promoted self-reported decreases in memory and intellectual function, accompanied by poor sustained attention task results (Green et al. 1994).

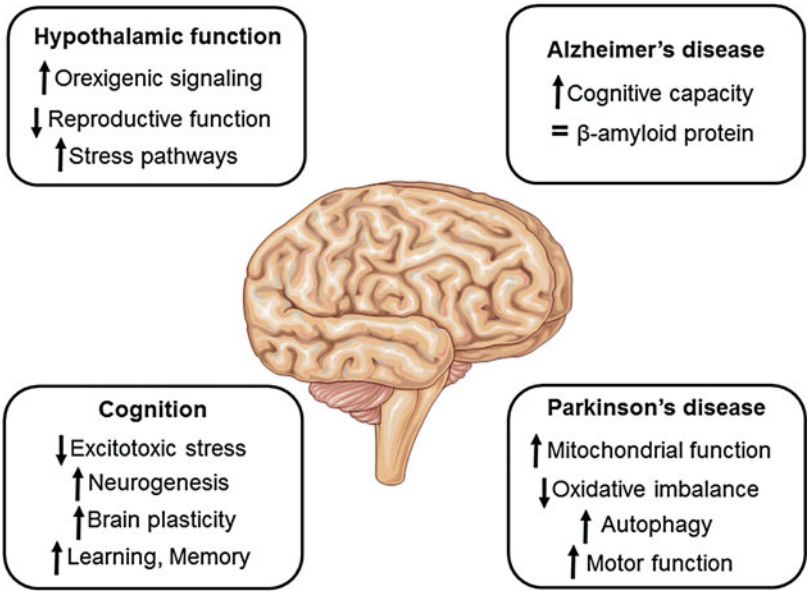

Fig. 2 Intermittent fasting effects on brain function. The main effects of IF on brain function are summarized. IF-induced changes in energy balance are followed by increases in orexigenic signaling in the hypothalamus, in parallel with alterations in hypothalamic axis control of reproduction and stress responses. IF improvements in cognitive capacity are supported by increased neuronal resistance to excitotoxic stress, neurogenesis, and brain plasticity, resulting in preserved learning and memory. IF can delay Alzheimer's disease progression independently of changes in neuronal β-amyloid peptide accumulation. IF also prevents Parkinson's disease development through enhancements in mitochondrial function and autophagy, along with reduction in oxidative imbalance. Of note, IF can hasten the progression of some brain diseases such as amyotrophic lateral sclerosis

Deterioration in cognitive capability is often followed by the onset of neurogenerative diseases. Indeed, Alzheimer's disease (AD) is present in many cases of learning and memory deficits and is considered a major factor causing dementia. AD is associated to neuronal degeneration in brain areas controlling cognition and emotional behaviors (Castellani et al. 2010). This disease is characterized by the aggregation and extracellular accumulation of β-amyloid peptide plaques and by neuronal intracellular aggregation of hyper-phosphorylated forms of the tau protein. AD etiology also includes mitochondrial dysfunction and oxidative imbalance (Mattson 2004). While caloric restriction effects on AD progression have been extensively addressed, only one study has reported IF impact on AD. Using a triple transgenic AD mouse model, Halagappa and collaborators showed that long-term IF treatment could prevent cognitive declines in mice. Differently from caloric restriction, IF effects were not associated with reductions in β-amyloid protein and phospho-tau levels (Halagappa et al. 2007). This suggests that fasting effects on neuronal function are dissociated from cellular morphological alterations present in AD and could be a consequence of metabolic adaptations induced by nutritional stress.

Parkinson's disease (PD) is characterized by alterations in motor function involving rigidity, resting tremors, and walking disability. PD etiology comprises intracellular aggregation of α-synuclein protein followed by marked neurodegeneration in the *substantia nigra* (Jankovic 2008). PD progression is also associated to mitochondrial dysfunction, oxidative imbalance, and accumulation of oxidized and nitrated proteins. This effect is a consequence of decreases in cellular autophagic capacity (Hu and Wang 2016). Different groups have reported IF impacts on the prevention of neuronal dysfunction in PD. These effects include motor function gain along with reduction in neuronal α-synuclein accumulation and death (Duan and Mattson 1999; Holmer et al. 2005; Griffioen et al. 2013). The mechanisms by which fasting cycles attenuate PD symptoms involve enhancements in autophagy and mitochondrial function (Raefsky and Mattson 2016). Notably, IF did not avoid neuronal degeneration in the *substantia nigra* and striatum of rats treated with 6-hydroxidopamine, a chemical-induced model of PD (Armentero et al. 2008). Fasting was also unable to delay the emergence of amyotrophic lateral sclerosis, a neurodegenerative disease promoting motor function decay, and, in fact, hastened its progression (Pedersen and Mattson 1999). IF ineffectiveness in the prevention of some neuronal disorders challenges data collection regarding beneficial fasting effects on brain function. Therefore, further studies should be conducted to uncover IF actions in details, in order to understand and avoid undesirable side effects when used for human treatment.

Conclusion

Fasting has long been practiced by humans, determined by food scarcity or for ritualistic reasons, and is an important selective pressure driving human evolution; cyclic famine episodes introduced positive selection for genes favoring energy storage in human ancestors (Sellayah et al. 2014). Fasting-induced adaptations in neuronal function are further suggested to determine human survival when an individual experiences hunger and is required to obtain food (Mattson 2015). The mechanisms behind these changes are the probable basis for IF effects on brain homeostasis.

Evidence for the beneficial impact of IF on health, along with popular literature supporting fasting cycles to lose weight, has promoted an increase in the practice of diets containing food abstinence. Nevertheless, some concerns arise from studies evaluating IF effects on body homeostasis. First, the activation of hypothalamic orexigenic pathways following IF treatment can induce feeding disturbances or even promote treatment interruption. In fact, the use of IF protocols in humans comprises increases in aversive states on the fasting day, indicating that this diet cannot be tolerated over a prolonged period (Heilbronn et al. 2005). Second, different sets of data suggest that IF can generate deleterious effects. For instance, studies indicate that IF is associated with metabolic impairment in hypercholesterolemic mice (Dorighello et al. 2013). IF has also been related to increases in adiposity accompanied by alterations in insulin sensitivity in rats (Cerqueira et al. 2011). Moreover,

evidence suggests that IF can affect oxidative balance in a tissue-specific manner (Chausse et al. 2015). Third, despite its positive effects on health, IF is not recommended for individuals in physical development, such as young children and pregnant woman, due to their high sensitivity to nutritional deficits (Murphy et al. 2014).

Dictionary of Terms

- **Anorexigenic signaling** – A set of metabolic pathways and physiological processes activated during positive energy balance. Usually comprises increases in energy expenditure and appetite suppression.
- **Autophagy** – Intracellular process by which damaged and dysfunctional organelles and proteins are degraded releasing amino acids for the synthesis of new cell components. It controls cell function and viability.
- **Energy conversion efficiency (feed efficiency)** – Indicates the proportion of ingested calories that is converted into body mass. This index is usually calculated as the ratio between weight gain and total food consumption.
- **Orexigenic signaling** – A set of metabolic pathways and physiological processes activated during energy deficits. Comprises increases in food consumption along with increments in energy conservation.
- **Oxidative imbalance** – Occurs when cellular oxidant production exceeds its removal. Frequently associated with increases in damaged molecules.

Summary Points

- This chapter reviews the effects of intermittent fasting on brain function in parallel to a description of human fasting practice history.
- Fasting has long been practiced by humans and is considered a therapeutic intervention since the Stone Ages.
- Positive effects attributed to intermittent fasting have prompted the practice of diets containing food abstinence as well a number of studies investigating its impacts on health.
- Despite present differences in protocols and in some effects, caloric restriction and intermittent fasting have been recognized to induce improvements in rodents and human health.
- The brain is highly susceptible to fasting diets due to its elevated energy demand and its role in the control of energy homeostasis.
- Intermittent fasting activates hypothalamic orexigenic pathways inducing hyperphagia and disruption in reproduction.
- Intermittent fasting prevents cognitive functional decay and neurodegenerative diseases. These effects are mediated by improvements in neuronal function and in brain plasticity.
- Despite its positive impacts on brain function, intermittent fasting can hasten the progression of some neuronal diseases, such as amyotrophic lateral sclerosis.

- Evidence suggests that fasting cycles can be deleterious in specific genetic backgrounds and affects cell metabolism in a tissue-specific manner.
- The practice of intermittent fasting is not recommended in subjects sensitive to nutritional deficits, such as children and pregnant women and during convalescence.

Contents

Abstract

Brain functioning requires glucose utilization; however, glucose is a limited resource for the organism, by depending mainly on our food consumption. Prolonged fasting can inevitably reduce the amount of glucose necessary to maintain neuronal activities and therefore, can negatively affect cognitive

processes. To date, fasting for esthetical reasons or for unhealthy habits are the common behaviors that lead to low blood glucose levels; however, their effects on brain functioning, such as memory processes, attention levels, and self-control are still poorly investigated. The present work wants to summarize some of the most recent evidences on prolonged fasting effects on brain functioning and attempts to integrate these evidences in a recent model of self-regulation. Additionally, the consequences of low blood glucose levels on neuronal activities (fMRI) are described and discussed from the practical and clinical point of view. Overall, prolonged fasting and subsequent low blood glucose levels seem to decrease self-regulation abilities and negatively affect the attentional system. These results suggest that glucose levels need to be taken in account in fMRI protocols and monitored in circumstances where brain functioning is already compromised, such as in dementia and psychiatric conditions.

List of Abbreviations

ATP	Adenosin triphosphate
BGL	Blood glucose levels
BOLD	Blood-oxygenation level dependent
CBF	Cerebral blood flow
CBV	Cerebral blood volume
CMRglu	Cerebral glucose consumption
CMRO2	Cerebral metabolic rate of oxygen
CPT	Continuous performance test
DMN	Default mode network
fMRI	Functional magnetic resonance imaging
HRF	Hemodynamic response function
ICA	Independent component analysis
pACC	Pregenual anterior cingulate cortex
PCC	Posterior cingulate cortex
PET	Positron emission tomography
V1	Primary visual cortex

Introduction

Glucose is the principal fuel of each single neuron of our brain. Its metabolism is indispensable for brain functioning: production of neurotransmitters, information processing, maintenance of homeostatic plasticity, and other vital neuronal and glial activities (Mergenthaler et al. 2013). Additionally on a cognitive level, optimal blood glucose levels are essential for virtually any cognitive process, such as for example memory and attention. Human physiology has evolved an elaborate system aimed to

maintain homoeostasis of the glucose system. Normal blood glucose levels are kept by daily food consumption; logically, our eating behaviors but also specific diseases such as diabetes can affect blood glucose levels and our cognitive processes.

For instance, disequilibrium between food intake and energy expenditure or prolonged fasting, often precipitate hypoglycemic states with consequent drastic effects on physiology (Roh et al. 2016). Indeed, recurring hypoglycemia has been linked to structural and functional brain changes (Warren and Frier 2005).

From the perspective of a cognitive neuroscientist, two aspects are important regarding glucose metabolism and eating behavior. Firstly from a psychological perspective, fasting or simply irregular eating behavior may have an influence on blood glucose levels, which in turn affects brain functioning but also cognitive, affective, and motivational processes. From this point of view, low blood glucose levels might have additional impairing effects in circumstances where cognition is already compromised, such as in case of brain diseases (i.e., Parkinson, Alzheimer). Secondly from a methodological perspective, whether low glucose levels due to prolonged fasting have influences on the signal most often applied in functional neuroimaging examinations in the MRI (BOLD-signal) is a problem which has so far not sufficiently been investigated (Anderson et al. 2006). From this latter point of view, providing evidence and understanding the relation between glucose levels and brain activations may indeed increase the reliability of the research practice, especially in functional magnetic resonance imaging (fMRI) designs.

Consequently, the present chapter aims to contribute to a better comprehensive understanding of these psychological and methodological considerations. The first part of the chapter provides an overview on how glucose levels are regulated at central level and the relation between glucose metabolism and BOLD signal. Subsequently, the second part describes a series of studies that focus on the effects of prolonged fasting on vision, memory, and emotional processes to elucidate the psychological and methodological issues from a cognitive neuroscientists' perspective.

The last part of the chapter summarizes the most important findings and outlines future directions and considerations.

Glucose Regulation and Distribution in the Brain

Blood glucose level homeostasis, with a normal range between 70 and 110 mg/dl, is maintained mainly via two hormones, insulin and glucagon, and by the parasympathetic nervous systems activities (Sprague and Arbelaez 2011). Both, the activation and deactivation of the autonomic nervous system are centrally regulated by complex mechanisms at the level of the hypothalamus and brain stem (Thorens 2011).

For instance, recent studies report how neuronal cells of specific hypothalamus nuclei and vagal complex show different glucose sensitivities: neurons inhibited by the decrease of extracellular levels of glucose, and neurons excited by the increase of extracellular levels of glucose (Burdakov et al. 2005; Routh 2010). In return,

glucose-sensitive neurons activities would modulate neurotransmitters and autonomic nervous system activity, in a series of complex mechanisms (Burdakov et al. 2005; Routh 2010; Grayson et al. 2013). Thus, neurons effectively have the leverage to very substantially modulate whole brain functioning.

Critically, our physiological system ensures the optimal distribution of glucose to all the brain regions under a broad variety of conditions: motor and cognitive activity and tasks, affective and motivational processes, resting attentional and meta-cognitive processes, and also switch and interaction between these instances. Neuroimaging studies have shown that during cognitive processes, our organism maintains the optimal supply of glucose for task-related brain activations by several means, for instance by withdrawing glucose from other task-unrelated regions (Sokoloff 1999). Additionally, cerebral glucose consumption (CMRglu) increases or decreases differently across functionally connected sets of brain regions when switching from rest conditions to task-dependent activity and *vice versa.* This means that the functional relations within areas of the same networks (and probably also between brain areas of different networks) are regulated in a complex and engagement-associated way (Sokoloff 1999; Riedl et al. 2014).

The principal implication from this evidence is that the amount of glucose in our brain is quantitatively limited and has to be optimally distributed across brain circuits. Given that the brain cannot generate or store glucose (in sufficient quantities), the peripheral blood glucose circulation, peripheral energy storage, and our eating behavior are essential for an optimal brain functioning (Cryer 2007).

Glucose and Its Relation with the Most Common Functional Neuroimaging Signal

Glucose metabolism requires 20% of our daily amount of calories. Aerobic oxidative phosphorylation and glycolysis are the main metabolic processes for glucose synthesis. The principal outcome of these processes is represented by Adenosin Triphosphate (ATP), the energy necessary for neuronal and glia functioning (Magistretti and Allaman 2015). Neuronal functioning, mainly action potentials and synaptic potentials (both pre and post), together with the preservation of the ion gradients, need 75–80% of the total amount of ATP available (Hyder et al. 2013). Neuronal functioning, during for example different kinds of cognitive processes, is investigated via neuroimaging techniques that take advantage of the relation between neuronal functioning and glucose necessity. Neuronal groups involved in definite tasks or states increase their demand of ATP in order to activate and maintain the cognitive processes necessary to the organism to obtain optimal functioning.

The vast majority of fMRI studies rely on measurement of the blood-oxygenation level dependent (BOLD) signal. The BOLD-signal is dependent upon several physiological changes: rate of blood oxygenation, cerebral metabolic rate of oxygen (CMRO2), cerebral blood flow (CBF), and cerebral blood volume (CBV) (Buxton

2010). These changes are all linked to ATP (Buxton et al. 2014). However, the relation between glucose request and BOLD-signal is not direct and causal.

Nevertheless, the recruitment of certain brain regions in particular cognitive processes usually is related to higher glucose metabolism levels and elevated BOLD signal. Yet, how the two relate under various conditions is up to now unclear.

Low Blood Glucose Levels and Brain Functioning

Blood circulation ensures sustained supply of glucose to the brain. Changes in our diet can affect the amount of glucose necessary and available in time to maintain brain functioning (Cryer 2007).

Low glucose states in the brain only occur under pathological conditions or due to prolonged nutrient deficiency, because a stable provision of glucose to the brain is maintained as long as possible (Paulson et al. 2010). In case of prolonged fasting and persistent hypoglycemic state, impairment on cognitive processes in healthy adults has been shown at below 55 mg/dl (Warren and Frier 2005). However, when low BGL persists, compensatory processes are triggered in order to preserve a normal cognitive ability, but how the brain can adapt in low BGL circumstances is still unclear (Warren and Frier 2005). In extreme situations, between a range 41–49 mg/dl, hypoglycemia can cause coma and death (Ben-Ami et al. 1999).

It is now well established that hypoglycemic state negatively affects cognitive processes and also brain functions (Warren and Frier 2005). For instance, hypoglycemic effects have been investigated with several neuroimaging techniques like functional Magnetic Resonance Imaging (fMRI), Positron Emission Tomography (PET) (Rooijackers et al. 2016), and their combination (Wehrl et al. 2013). Especially fMRI experiments are effective in detecting cognitive impairment during hypoglycemic states given the link between glucose levels of specific task-related regions and magnitude of the BOLD-signal (Driesen et al. 2007).

Nevertheless, much less is known about the effects of low but still normal blood glucose levels on brain functioning in the healthy population. Even in nonclinical conditions prolonged fasting such as fasting or being on a diet for aesthetic reasons could lead to a cognitive impairment that has the potential to interfere with the normal functioning and safety of the individual (for instance during driving a motorized vehicle and working in professions that require high levels of concentration).

Effects of Fasting During Task-Related Brain Activity

The following section mainly describes results from a set of studies investigating the influence of prolonged low normal blood glucose levels in healthy individuals in a naturalistic setting. The focus is on brain functioning, cognition and affect, as well as basal attention processes (Chechko et al. 2015; Kohn et al. 2015, 2016).

The conceptual aim of the reported studies was to elucidate the interaction of mood regulation and variations in energy availability as are apparent in fasting and which are operationalized in this context as a manipulation of blood glucose levels. All studies are conducted in a double-blind, placebo-controlled, cross-over design on 40 subjects (20 male and 20 females). Each participant was tested twice with 4 weeks between the two measurements. Measurements took place between 12 a.m. and 1 p. m. All subjects were studied after overnight fasting (>16 h. In one condition, subjects received an infusion of glucagon (0.5 mg/h) to stabilize blood glucose levels and simulate a re-feeding situation. In the second condition subjects received an infusion of sodium chlorite (50 ml) as a placebo control. Both conditions were administered in counter-balanced order. The infusion in both conditions in total lasted for an hour during which several experiments were conducted. Blood was additionally drawn at several time-points during the experiment to investigate a set of food intake and glucose metabolism related blood parameters (epinephrine, norepinephrine, insulin, and cortisol) to better characterize potential effects of the manipulation (Fig. 1). Importantly, the condition in which the placebo was administered is the actual condition of interest as this is the low BGL condition. The project included three fMRI experiments per condition started after 6 mins after the injections, plus two resting state measurements at the beginning and the end of each measurement. The resting state measurements were implemented to investigate changes in the functional connectivity of the brain at rest. The experiments were not only designed to investigate mood regulation, but the project included two levels of control experiments. One level was a basal visual stimulation experiment as a means of basic visual control, one working memory experiment (CPT, 2-back) as a means of higher level cognitive control, and a mood regulation experiment with a mood induction task (Fig. 1). Briefly, mood induction tasks are usually used in research, and especially fMRI experiments, to evaluate the neuro-correlates that reflect positive or negative effects (Westermann et al. 1996) while the continuous performance test (CPT) with a 2-back condition is a well-validated working memory task (Beck et al. 1956). The experiments are described in detail in the respective publications. Manipulation of blood glucose levels was successful in the conditions (high BGL: 114.5 mg/dl; low BGL: 73.9 mg/dl) and hormonal state reflected a re-feeding situation in the glucagon condition.

Effects of Low Blood Glucose Levels on Visual Processing

In the first experiment the basal visual stimulation in a fasting situation was studied. It was investigated whether the presentation of a lateralized, flickering checkboard is associated to differential brain activation patterns in the elevated blood glucose versus the non-modulated fasting condition. Small but reliable differences in the prolonged fasting condition compared to the elevated glucose condition in higher order occipital brain areas were found. The modulation of brain activity in higher order occipital areas in comparison to early visual processing areas such as V1 can be seen as indication that low normal blood glucose levels after overnight fasting do

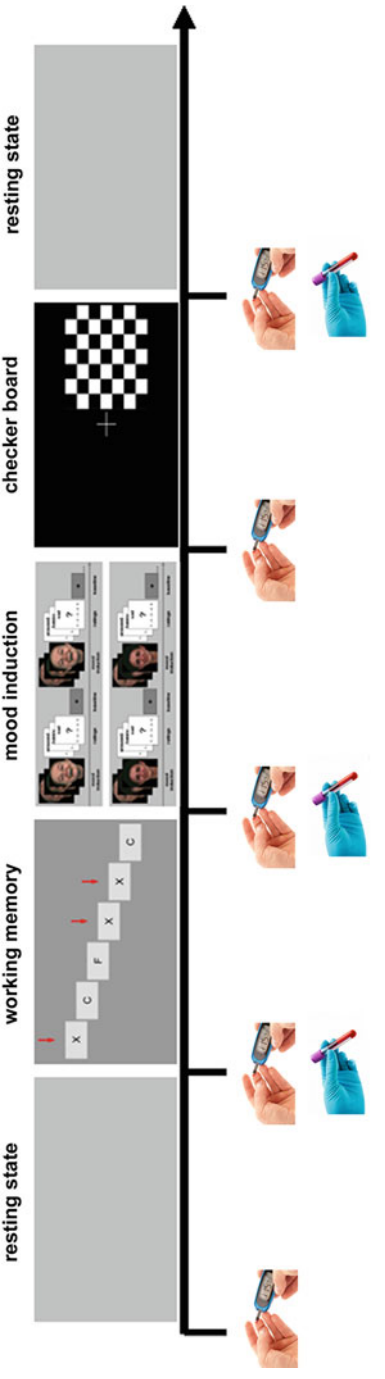

Fig. 1 Design of the study. This figure displays one randomization of the experiments conducted after the start of the infusion at the time of the first blood glucose measurement. The experiments took about one hour. After the final resting state an anatomical scan was measured. The order of working memory and mood induction experiments was counter balanced between participants

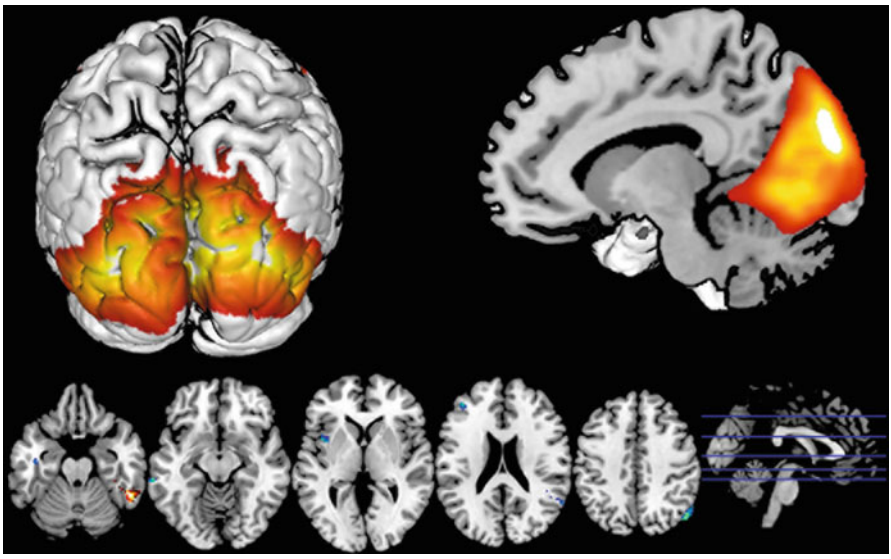

Fig. 2 Blood glucose levels effects on brain activity during visual processing. In high blood glucose levels conditions the visual component is strongly coupled with parietal, frontal, temporal gyrus, and Insula (in hot). Subjects with lower blood glucose levels showed stronger activity/connectivity in the ventral attentional pathway (*lower panel*, hot and *blue*) (Adapted from figure in. Kohn et al. (2016). Brain Struct Funct. 221:147–158, Springer-Verlag Berlin Heidelberg 2014)

not impact the blood-oxygenation level dependent (BOLD) signal that is measured in fMRI. Such a modulation would invariably (or at least with unsystematic variation) affect voxels with the strongest signal the most; the strongest signal is measured in this case in V1. As there was no difference in these voxels, yet differences were observed in brain areas that subserve higher-order visual processes, which are also known to covary with attentional processes (Fig. 2), an influence of overnight fasting on attentional processes was proposed. For instance, during right-sided stimulation, higher normal BGL were associated to higher activity in the left middle occipital gyrus. During left-sided stimulation higher normal BGL were associated to higher activity in high order visual areas too, like the right middle occipital gyrus, right temporal gyrus, left cuneus, and right lingual gyrus (Fig. 2).

To analyze if fasting leads to a general modulation of visual processing, additionally functional connectivity patterns at rest were investigated via Independent Component Analysis (ICA, (Beckmann and Smith 2004)). Here we analyzed large scale brain networks that can be reliably extracted in a data driven fashion and which have previously been well characterized (Smith et al. 2009). Template maps of visual networks were projected into the experimental data and tested. Interestingly, differences between the two conditions were found supporting the findings from the task activity study. The observed modulation by fasting was partially overlapping with the dorsal and ventral stream of attention as proposed by Goodale and Milner (Goodale and Milner 1992; Corbetta and Shulman 2002). Both the streams originate

from the primary visual cortex (V1), but while the dorsal path passes through the occipital lobe in the direction of the parietal lobe, the ventral stream follows a different path, by passing through the occipital towards the inferior temporal lobe. Briefly, the ventral pathway is involved in identification and recognition of objects while the faster dorsal pathway is involved in spatial vision, space-based attention and seems responsible for attentional deployment (Itti and Koch 2001). In low BGL conditions, subjects showed stronger activity and connectivity to areas that can be assigned to the ventral attentional pathway. This stronger connectivity could reflect a switch in a more basal (conservative) functioning of the brain, where an internal focus (or object-based focus) would be preserved at the face of general attentive processes (Goodale and Milner 1992). This switch may arguably be more ideal in terms of energy consumption and/or subserves the identification of potential food sources more goal-orientated.

Conversely, in the high BGL condition the visual component was found as strongly coupled with parietal, frontal, temporal gyrus and the insula. It might be speculated that the strong functional connectivity between visual areas and the dorsal stream and regions belonging to the salience network (i.e., the insula) (Menon and Uddin 2010) may reflect an enhanced general attentional processing in the high BGL condition. Additionally, the high BGL condition was associated with higher arousal, which generally suggested a possible indirect and beneficial effect of higher epinephrine levels on attentional processes.

In summary, low BGL was associated to a decreased activity in brain regions involved in general attentional processes but not to a general decreased activity at the level of the primary visual input into the brain. These results speak against direct influences of low normal BGL on the intensity of the BOLD signal and also against a systematic impact of low normal BGL on the latency and temporal propriety of the HRF.

Effects of Low Blood Glucose Levels on Working Memory and Mood

The next task was a continuous performance task in which subjects saw a succession of letters on a computer screen and were in two different conditions required to respond to a target letter with a button press. In one condition, subjects were asked to press every time they saw an X on the screen and in the second condition subjects were required to respond every time they saw a letter that had been displayed two letters before. This task is also commonly referred to as n-back task (Riccio et al. 2002; Rottschy et al. 2012). In our experiment we had a 0-back and a 2-back condition.

The working memory performance between the low BGL and the high BGL condition did not significantly differ. Yet differences in brain activation in the thalamus and hypothalamus were observed. Specifically, the low BGL group was associated to a decreased recruitment of the bilateral thalamus, the bilateral basal ganglia, the posterior cingulate cortex (PCC), and the rostral prefrontal cortex (Fig. 3).

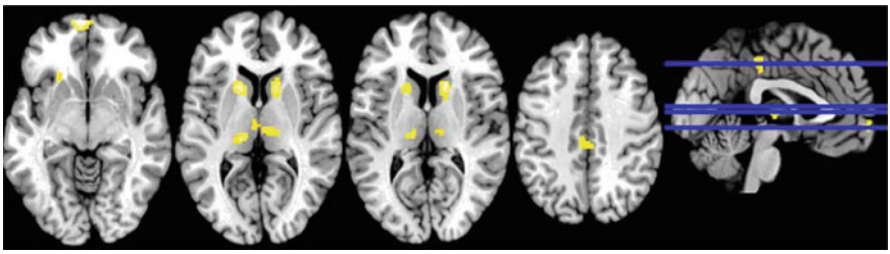

Fig. 3 Blood glucose levels effects on brain activity during working memory task. During the two-back task (working memory task) the low blood glucose levels group showed decreased activation of the bilateral thalamus, the bilateral basal ganglia, the posterior cingulate cortex (*PCC*), and the rostral prefrontal cortex (in *yellow*) (From: Chechko et al. 2015. Copyright: 2014 Wiley Periodicals, Inc.)

Thalamus nuclei are one of the regulators of BGL (Cho et al. 2011) and together with the basal ganglia are involved in working memory processes (McNab and Klingberg 2008), and transmission of information to the prefrontal cortex (McNab and Klingberg 2008; Chechko et al. 2015). The posterior cingulate cortex is, however, a region with a higher glucose uptake at rest, by showing a decrease in glucose consumption during demanding cognitive tasks (Greicius et al. 2007). Thus, decreased activation in these areas might indicate an impaired ability of the brain to switch from resting conditions to working memory-related activations in low BGL conditions compared to high BGL conditions. These brain areas thus seem to respond to small changes in peripheral blood glucose, which are still in the normal range.

Interestingly, additional analyses looking into the effect of order of the working memory experiment and the mood regulation showed that prior cognitive effort (having completed the mood regulation task before the working memory task) lead to further decreased activation of the abovementioned brain regions. Nevertheless, the changes in working memory-related brain activations were not associated with changes in working memory performances. This suggests neurobiological changes (e.g., compensatory increase of brain activity) might precede behavioral impairments. That is, the brain's activity may show alterations before differences in behavioral parameters are observable.

Yet, as the previous study related brain activation changes to changes in catecholamines rather than blood glucose itself and no direct relation to blood glucose was observable in this sample, the results could also hint at effects that relate to self-regulation failure (Heatherton and Wagner 2011). A relatively recent theory that links glucose brain metabolism to cognitive effort (such as performing a working memory test) and mood regulation is represented by the "strength model" of self-regulation (Gailliot et al. 2007). In detail, this model sustains that every action that we take, every thought or external information that we need to elaborate, requires energy, which in terms of the model very literally means glucose. Glucose as the central resource for self-regulation underlies every act of regulation according to this theory and depletion of glucose is identified as the process behind failures in self-

regulation (Gailliot and Baumeister 2007). Recent meta-analyses question the reliability of the strength model itself and show that self-regulation failure empirically is not very strongly associated to glucose (Carter and McCullough 2014; Dang 2016). Yet, the importance of glucose for self-regulation *per se* has been supported empirically (Kurzban 2010; Beedie and Lane 2012; Orquin and Kurzban 2016). Glucose allocation and hormonal processes that are triggered by glucose rather than general and physical glucose depletion has been proposed to underlie self-regulation failure (Hagger and Chatzisarantis 2013; Kohn et al. 2016). That is, a crucial determinant of self-regulation failure may be the cognitive resources available in a particular state or in other terms, the situational "challenge" level. Self-regulation failure may only be apparent when we are challenged to a sufficient degree. In terms of the current publication, one could argue that low BGL following prolonged fasting might negatively affect working memory processes in the brain, especially after previous cognitive efforts. However, the 2-back paradigm before or after a cognitive demanding task did not challenge the subjects sufficiently to show a detrimental behavioral effect.

To determine influences of low blood glucose on mood regulation, a combined mood induction procedure with facial expressions and recruitment of autobiographical memories have been used. Thus, the subjects were asked to try to generate a happy and a sad mood state. Results show that also for the mood induction procedure, behavioral differences represented by the subjective affective state of the participants could not be observed when collapsing over the order. Similar as in the working memory task, brain activation differences are nevertheless observable. In this experiment, high BGL were associated to stronger brain activation in the pregenual anterior cingulate cortex, the posterior cingulate cortex, and the thalamus. These brain regions are involved in emotional processing (Vogt 2009; Lindquist et al. 2012).

Comparison of the order of the experiments revealed that subjects, who had to work on the working memory paradigm before the mood induction procedure, were less good at generating a sad state and this was only apparent in the non-modulated fasting condition (Fig. 4). Brain activity in this condition was also in comparison to the elevated condition strongly increased (Fig. 5). For instance, strong brain activity was found in the orbitofrontal and frontal cortex, temporal pole, and the dorsal anterior cingulate gyrus, brain areas usually involved in emotional processing and emotion regulation (Fitzgerald et al. 2008; Dyck et al. 2011; Lindquist et al. 2012) and often found to be linked to depressive symptoms and sad mood state (Habel et al. 2005; Killgore et al. 2007) (Fig. 5). One explanation of this effect relates to effort. Similar to the explanation in the working memory task, stronger brain activity is observed in the absence of behavioral differences; the effort account assumes that the stronger activity patterns in emotional processing areas of the brain observed in the non-modulated fasting condition are caused by higher effort to reach a similar level of performance. In line with the assumption that blood glucose leads to failure of regulation only in a sufficiently challenged state, behavioral differences (e.g., regulation failure) can only be observed in the un-modulated fasting condition in which stronger recruitment of brain areas supporting the task fail to balance performance.

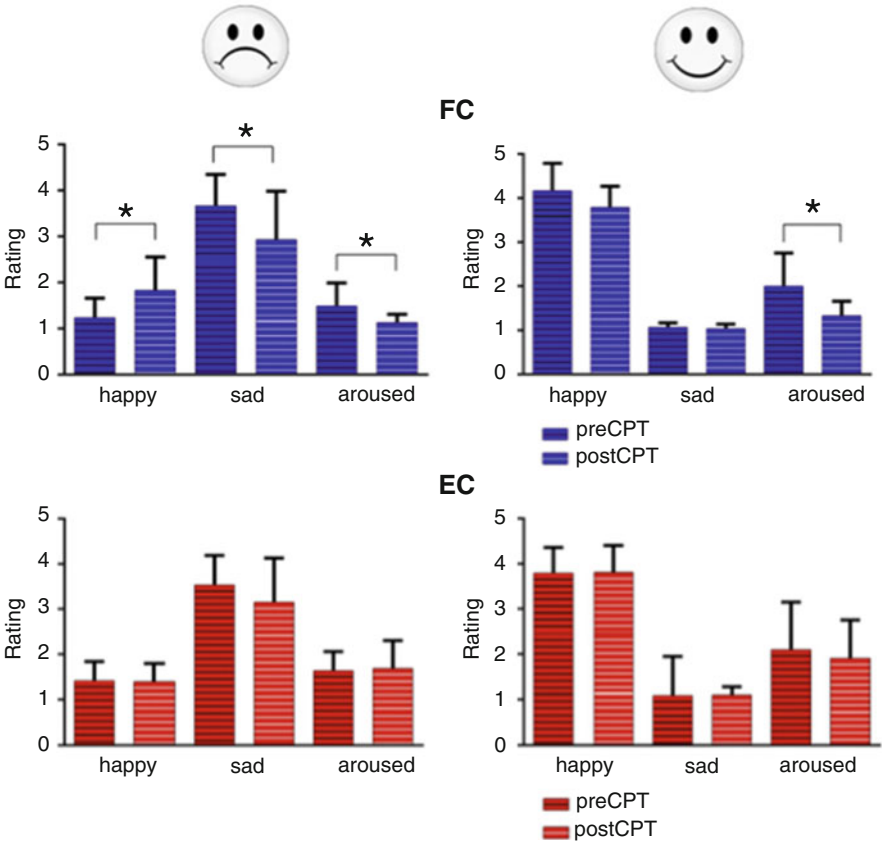

Fig. 4 Mood induction tasks. The figure shows the performance of the two groups (low blood glucose levels group –FC- in *blue*, and high blood glucose levels group –EC- in *red*), at the mood induction task, before (*darker bars*) and after the working memory task CPT (*lighter bars*). The results showed FC group was less able to induce a sad mood (*left side* of the panel) compared with the EC group, after the working memory task. The FC group did show lower arousal rating after CPT in both the sad and happy conditions of the mood induction task (From: Kohn et al. 2015. Neuroimage 113: 246–256. Copyright: Elsevier Inc.)

Thus, the results partially support the strength model of self-regulation. However, given that no drop in glucose levels was registered after the first cognitive effort task (but only at the end of the whole experiment), the diminished self-control capacity does not directly relate to peripheral blood glucose levels and thus depletion of glucose per se in this setup was not the cause for self-regulation failure. The association of low BGL to arousal levels (related to decreased epinephrine levels) could potentially explain ego-depletion effects on self-control.

An alternative complementary interpretation relies on the involvement of the pre-genual anterior cingulate cortex as one of the main hubs of the default mode network (Smith et al. 2009; Uddin et al. 2009; Callard and Margulies 2014) and the default mode

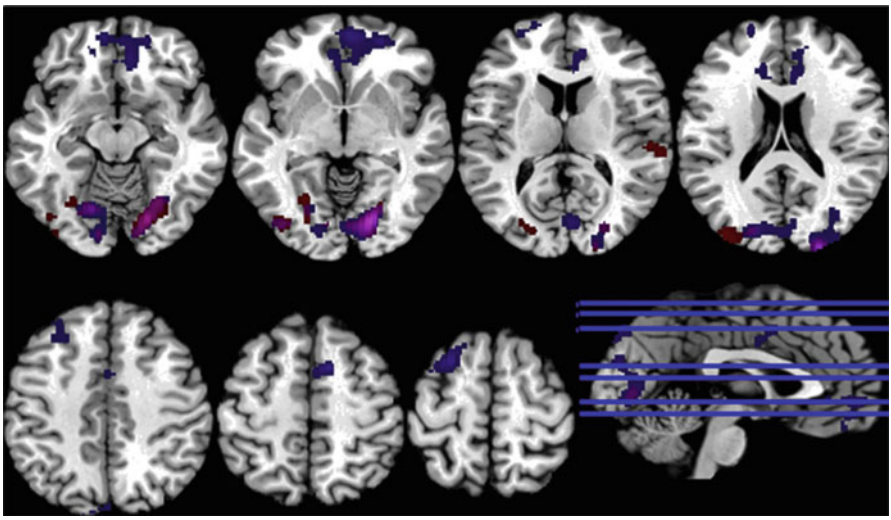

Fig. 5 Effects of glucose levels on brain activations during mood induction task after working memory task. Strong brain activity is found into the orbitofrontal and frontal cortex, temporal pole, and the dorsal anterior cingulate gyrus (in *blue*) in low blood glucose levels circumstances. Higher blood glucose levels are associated to stronger brain activation in the pregenual anterior cingulate cortex, the posterior cingulate cortex and the thalamus (in *red*). Brain activations during mood induction after the working memory task are showed in *violet* (From: Kohn et al. 2015. Neuroimage 113: 246–256. Copyright: Elsevier Inc.)

network has been shown to be strongly related to glucose metabolism (Passow et al. 2015). Therefore, a functional connectivity analysis using the template map of the default mode network (Smith et al. 2009) on the fMRI data of the task indeed revealed a stronger connectivity of the default mode network in anterior subsystems in the non-modulated fasting condition. This pattern of elevated connectivity to the anterior part of the default mode network in fasting, and also stronger connectivity in posterior subsystems in the elevated condition, could potentially be interpreted as a sign for a segregation of anterior and posterior parts of the default mode network in the low BGL group (Laird et al. 2011).

Policies and Protocols

To date, the negative consequences of behaviors of prolonged fasting for aesthetical reasons or simply because of time pressure are extremely underestimated and undervalued by the general population. Additionally, such effects are scarcely taken in account by educational programs as well as in psychopathological circumstances. The present manuscript reports and discusses how prolonged fasting can potentially affect higher cognitive processes like emotional and attentional processes, especially after cognitive efforts. One main position is that cognitive, attentional, and emotional processes are not per se affected by fasting behavior. Yet, empirical evidence points to the

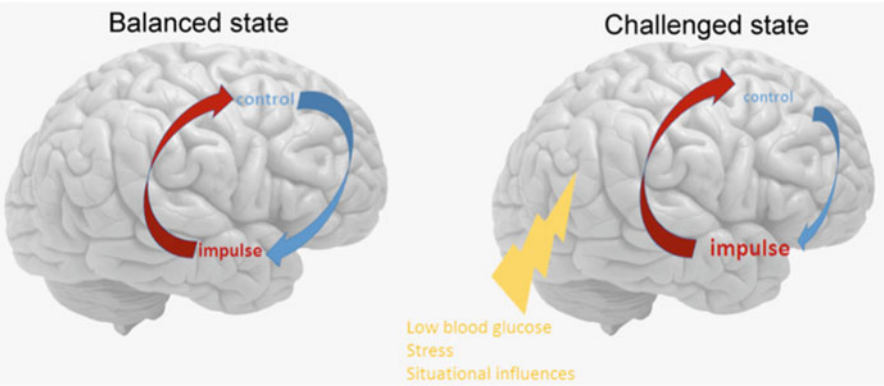

Fig. 6 The role of glucose in self-regulation and stressful circumstances. The model shows how the combination of several factors, such as low blood glucose levels, cognitive effort and stress occurrence might drive loss of control and cognitive-attentive decline (in *left panel*). This combination might potentially increase psychopathological symptoms. Stress, cognitive effort and low blood glucose can be seen as a challenge to the system, which in response may be more prone to self-regulation failure

possibility that fasting may render the individual in an "elevated risk state" in which certain cognitive, attentional, or emotional processes are performed and maintained under strong pressure to the whole system.

In prolonged fasting, cognitive effort can furthermore lead to a critical state in which the relative scarcity of glucose may pose a sufficient challenge to the organism to lead to self-regulation failure (Fig. 6). This may in consequence lead to emotional dysregulation, loss of cognitive control capacity, and attentional decline. A similar process can be observed in stressful contexts (Hermans et al. 2014). Stress, by activating catecholaminergic and endocrine systems, is thought to have negative effects on executive functions and attentional processes in general. These stress-induced hormonal changes have been proposed to give rise to characteristic large scale brain network modulations: The executive control network is decreased and its proposed counterpart, the salience network, is increased in activity under stress (Hermans et al. 2014). Similar processes as proposed in the large scale brain network dynamics of stress might be elicited by prolonged fasting and in consequence lie at the heart of fasting induced self-regulation failure. Consequences of challenged states and subsequent regulation failure may be far ranging and potentially life threatening. Also they may explain a part of what is in police reports or accounts of accidents usually referred to as "human error" (Hagger et al. 2009).

A more practical, specialized advice derived from the results presented here pertains to neuroimaging research. Based on the presented set of studies, we would advise to check participants for fasting state and ideally also include screening of blood glucose levels. A level of above 80 mg/dl seems to be sufficient to serve as a guideline. Yet, future research should aim at further elaborating on this suggestion.

Dictionary of Terms

- **Adenosine Triphosphate (ATP)** – is a molecule that consists of one adenin nucleotide, ribose, and three phosphate groups. Metabolic processes, for instance the oxidative phosphorylation, use the energy produced by losing of one or two phosphate groups from the ATP molecule, in order to keep each cell alive.
- **Rate of blood oxygenation** – is the fraction of hemoglobin binding to oxygen relative to the total amount of hemoglobin in the blood. Optimal human rates are between 95–100%. Hypoxemia state follows a blood oxygenation rate below 95%.
- **Cerebral metabolic rate of oxygen (CMRO2)** – refers to the quantity of oxygen consumed by the brain necessary to support the activity of neurons cells.
- **Cerebral blood flow (CBF)** – is the volume of blood (milliliters) passing through some brain regions (gray or white matter) per time unit (minutes).
- **Cerebral blood volume (CBV), or relative CBV (rCBV)** – is the volume of blood (milliliters) presents in a brain region (usually 100 g of brain tissue).
- **Continuous performance test CPT** – neuropsychological task to evaluate "executive function" such as working memory and attention (and the relative deficits). Repetitive stimuli (sounds, letters, numbers) are presented in series over the time. The task of the subject is to respond to specific target (for instance, to a specific letter) or inhibit responses to other stimuli.
- **Functional Magnetic Resonance Imaging (fMRI)** – measures brain functional activity associated to changes into the blood flow. Changes into the blood flow are coupled with change in neuronal activity while the subject is involved in a particular task or setting. Brain activities are shown as bright, by indicating functional association between those areas and the cognitive processes involved in the task used.
- **Blood-Oxigen-Level Dependent contrast (BOLD)** – reflects the changes in oxygen levels of particular brain regions involved in a specific task that can be detected with MRI technologies.
- **Salience Network (SN)** – network that trigger visceromotor responses to stimuli that attract our attention (salient stimuli). The fronto-insular and the anterior cingulate cortex play a major role in integrating the top down and ascending signals that are relate to salient stimuli.
- **Default Mode Network (DMN)** – network of brain regions activated during wakeful rest conditions and deactivated during task-related activities (for instance, goal-direct tasks).
- **Working memory** – is brief-term capacity. It retains and regulates information.
- **Mood induction task** – task used to manipulate mood. Movies, pictures, and unpleasant odors can be used in order to induce positive or negative emotional states.
- **Independent Component Analysis (ICA)** – method to delineate each single component of a multivariate complex signal. This computational method requires the components to be independent to each other and with a non-Gaussian distribution.

Summary Points

The work presented in this chapter attempts to give to the reader an overview on how prolonged fasting can negatively affect brain processes. Particularly,

- Certain eating habits, such as uncoordinated fasting, has been shown to have negative influences on visual attention, by decreasing BOLD-signal in high order occipital regions during visual stimulation.
- Low normal BGL decrease the activation of working memory-related regions. The weak response of the thalamus during working memory task after a cognitive effort is even more accentuated. Therefore, certain eating habits that result in low normal BGL can potentially and negatively interfere with our daily performances.
- Low normal BGL can negatively affect self-control-related brain regions. This effect is reflected in increased activations in brain areas involved in emotional processing. Clinically, low glucose levels might have additional deleterious effects on psychopathological conditions were compromised emotional processes already exist.
- Negative effects of low normal BGL on self-control-related regions are even more extended after a cognitively demanding task. However, no empirical link to the amount of glucose consumed has been found. Low normal BGL possibly via attentional and/or catecholamergic processes modulate self-regulation.
- Low BGL is potentially able to compromise the validity of neuroimaging studies that involve attentive, mnemonic, and emotional processes. Particularly, the control of the glycemic state (i.e., metabolic diseases) of the participants during the recruitment phase in fMRI studies is recommended.

Contents

Abstract

The central nervous system plays a key and important role in regulating dietary energy consumption. Studies in the literature have shown that high calorie intake is deleterious to the physiological function of neurons. On the other hand, low-calorie intake has demonstrated to be beneficial, protecting neurons against harmful effects that could lead to the development of neurodegeneration. This chapter aimed to review the main aspects of dietary energy restriction protocols, such as intermittent fasting and calorie restriction, in relation to neuronal plasticity, cognition, and neurodegeneration.

List of Abbreviations

Aβ	Amyloid-β peptide
AD	Alzheimer's disease
ADAM10	A disintegrin and metalloproteinase 10
APP	Amyloid precursor protein
BDNF	Brain-derived neurotrophic factor
CaM	Ca^{2+}/calmodulin-sensitive
CNS	Central nervous system
CR	Caloric restriction
CREB	Cyclic AMP response element-binding protein
DAT	Dopamine active transporter
DER	Dietary energy restriction
DG	Dentate gyrus
FOXO	Forkhead box O
GDNF	Glial cell line-derived neurotrophic factor
Grp78	Glucose-regulated protein 78
GLUT3	Glucose transporter 3
HO1	Heme oxygenase 1
Hsp70	Heat-shock protein 70
IF	Intermittent fasting
LPS	Lipopolysaccharide
MPTP	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MWM	Morris water maze
NF-κB	Nuclear factor κB
NMDAR	N-Methyl-D-aspartate receptor
PD	Parkinson's disease
PGC-1α	Peroxisome proliferator-activated receptor gamma coactivator 1-α
PPARs	Peroxisome proliferator-activated receptors
ROS	Reactive oxygen species
SIRT	Sirtuin
SN	Substantia nigra
SOD2	Superoxide dismutase 2
TrkB	Tropomyosin receptor kinase B
VMAT	Vesicular monoamine transporter
VTA	Ventral tegmental area
WHO	World Health Organization

Introduction

The central nervous system (CNS) plays a central role in regulating dietary energy consumption. Those individuals that are capable to overcome others in the acquisition of food (calorie) are evolutionary selected (Mattson 2002). Nevertheless, studies consistently show that persistent excessive calorie intake can impair cognitive performance. On the other hand, long-term restriction in calorie consumption, at lower levels than the habitual *ad libitum* intake, could improve cognitive function (Fig. 1) (Fontan-Lozano et al. 2007; Mattson 2010).

Dietary energy restriction (DER) stimulates neurogenesis and cognitive function. These beneficial effects of energy deprivation on the CNS are due to the induction of adaptive response pathways in a process called hormesis, which involves many mechanisms, including mitochondrial biogenesis, reduction of oxidative stress and inflammation, and increase of brain-derived neurotrophic factor (BDNF) levels, among others (Fig. 2) (Abrous et al. 2005; Mattson 2008a, b; Vasconcelos et al.

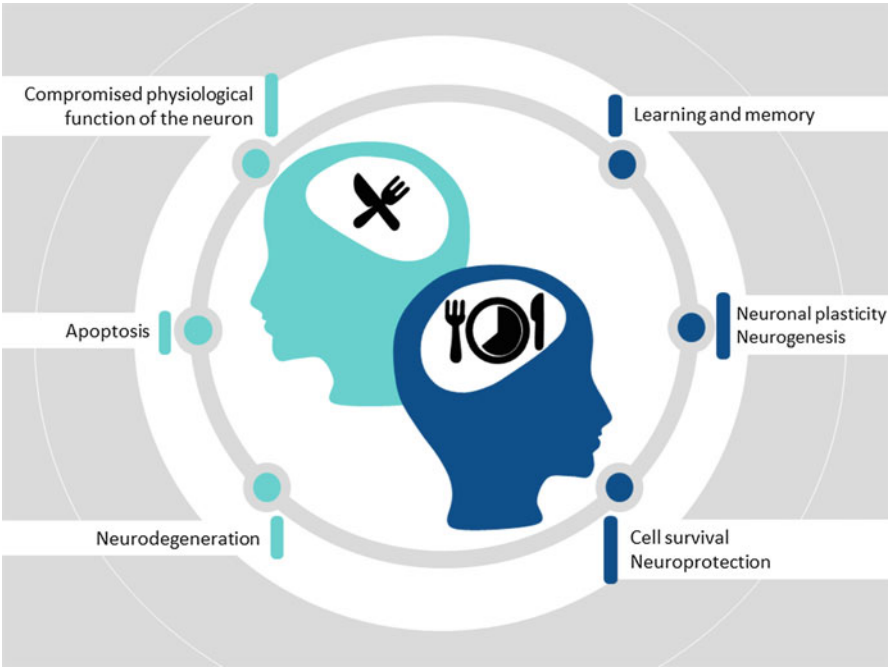

Fig. 1 A schematic view of DER effects in neuronal plasticity, cognition, and neurodegeneration. High calorie intake (light blue scheme) is deleterious to physiological function of neurons. On the other hand, DER (dark blue scheme) has demonstrated to be beneficial, protecting neurons against harmful effects, which could lead to neurodegeneration (DER, dietary energy restriction) (Fontan-Lozano et al. 2007; Mattson 2010)

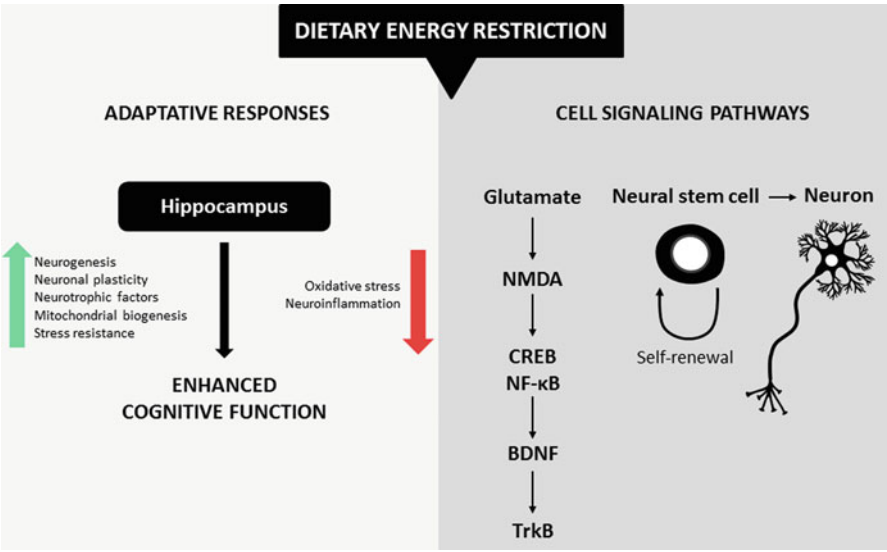

Fig. 2 DER-related adaptive responses and cellular signaling pathways on the CNS that contribute to enhancement of cognitive function. In the left, DER changes brain signaling and neuronal network activity resulting in improved cognition. The hippocampus, a brain region responsible for cognitive processing, is particularly important for the adaptive responses to DER. In the right, the hippocampus neurons play central roles in learning and memory. These neurons have an increased activity in response to DER, resulting in augmented glutamate neurotransmitter release. NMDA receptors, leading to Ca^{2+} influx followed by CaM kinases activation which, in turn, can modulate activity of transcription factors such as CREB and NF-κB which induce an increase of BDNF levels and enhanced association with its receptor, TrkB (CaM, Ca^{2+}/calmodulin-sensitive; CREB, cyclic AMP response element-binding protein; DER, dietary energy restriction; NMDA, N-methyl-D-aspartate; NF-κB, nuclear factor κB; TrkB, tropomyosin receptor kinase B) (Marosi and Mattson 2014; Longo and Mattson 2014)

2014). The remarkable DER effects are often viewed as a response of adaptation to food deprivation (Mattson 2008a, b).

There are two main protocols of DER that have been extensively studied due to promising effects on cognition and longevity: intermittent fasting (IF) and caloric restriction (CR) (Horne et al. 2015), the first associated with a restriction in frequency of feeding and the latter associated with restriction of calories ingested. While IF is a protocol that intercalates fasting periods with free access to food, CR refers to a chronic 20–40% decrease in calorie intake without malnutrition, both resulting in extended longevity, improved metabolic health and fitness, and improved physiological and molecular markers (Horne et al. 2015). Also, it has been demonstrated that DER could counteract many age-related diseases, such as reduction of the risk of metabolic deregulation, atherosclerosis, and neurological and cognitive diseases (Halagappa et al. 2007; Vasconcelos et al. 2014; Horne et al. 2015).

Although the term fasting is frequently interchanged by starvation, they do not have the same meaning. Starvation is a chronic nutritional insufficiency usually

meaning extreme fasting, causing deterioration and death. On the other hand, fasting was shown to optimize general health and stress resistance and prevent many age-related diseases through ketogenesis and changes in metabolic signaling pathways (Muller et al. 2001; Hartman et al. 2013).

Many studies have indicated that DER protocols also enhance neuroplasticity, cognition, and behavioral outcomes (Zainuddin and Thuret 2012), as reviewed below.

Effects of DER on Neurogenesis and Neuroplasticity

The hippocampus is an essential brain region for cognitive functions like learning and memory, in which neurogenesis occurs through life. During this process, proliferative cells form novel neurons in dentate gyrus (DG) region of the hippocampus, and these neurons integrate into the existing neuronal circuitry (Abrous et al. 2005). Another critical brain region involved in cognitive function is prefrontal cortex (Martinet et al. 2011), and it was shown a direct pathway communicating this brain area to the CA1 region of the hippocampus as a mechanism of memory and learning (Soares-Simi et al. 2013).

It has been shown a strong correlation between learning and memory abilities and the number of new neurons, pointing to a link between cognitive function and neurogenesis. For instance, Drapeau et al. (2003) evaluated in the same animals the amount of novel neurons and spatial navigation learning and found a positive correlation between these measurements.

Hormetic stimulus (mild stressors that induce hormesis), such as exercise, enriched environment, and DER were shown to increase new neuron formation (Lee et al. 2000; Abrous et al. 2005). Corroborating the association between cognition and neuroplasticity, Kaptan et al. (2015) showed that CR increased proliferation and the amount of neuronal cells in DG accompanied by an improvement in spatial learning and memory. Moreover, CR also mitigates the progressive neuronal loss, which is frequently associated with cognitive deficit (Graff et al. 2013).

BDNF is a neurotrophin that plays widespread roles in neuronal plasticity, survival, and differentiation, which is essential for learning and memory processes. It has been demonstrated that IF and CR can enhance BDNF expression in the hippocampus and other brain regions, which mediates adaptive responses. In turn, this neurotrophin seems to positively influence processes such as neurogenesis and cognition through stimulation of novel neuron survival and preventing cognitive dysfunction (Lee et al. 2000, 2002a; Marosi and Mattson 2014; Vasconcelos et al. 2014). Cyclic AMP response element-binding protein (CREB) transcription factor is the main regulator of BDNF expression (Lipsky and Marini 2007). Indeed, activation of CREB by phosphorylation was proven to be essential for memory formation. Furthermore, BDNF was shown to increase, in neurons, levels of N-methyl-D-aspartate receptor (NMDAR), which under physiological stimulation could contribute to induce plastic changes in synapses which are fundamental for memory and learning processes (Fig. 2) (Marosi and Mattson 2014).

Kaptan et al. (2015) showed that restriction of only 15% of calories during adolescence can increase cell proliferation in DG and BDNF levels in the prefrontal cortex and hippocampus, accompanied by an enhancement of learning and memory in female rats.

Effects of DER on Cognitive Function

Cognitive function can be defined as the ability to realize, memorize, and manage information from the environment (Shettleworth 2009). Cognitive abilities, such as learning and memory, play a central role in the success of a subject to continuously adapt to its changing surroundings (Morand-Ferron et al. 2016).

Severe DER results in a decrease of most organs size in mammals, except for the brain (Weindruch and Sohal 1997). This fact, from an evolutionary point of view, suggests that maintaining the cognitive function is of primordial importance under periods of limited food availability. Indeed, not only mammals are more active during periods of fasting, but also DER can improve cerebral functionality, as shown by a better execution of behavioral tasks of motor, sensory, learning, and memory abilities (Fontan-Lozano et al. 2007; Singh et al. 2012). These adaptive effects have been mostly associated with augmented generation of novel neurons from neuronal progenitor cells and improved synaptic plasticity (Lee et al. 2002b).

Although extremely important for adaptation, cognitive function and plasticity are very energetically costly (Kennedy et al. 1978; Leybaert et al. 2007). Brain consumes 20 to 25% of the glucose and oxygen, mostly for synapses and to restore resting membrane potential of axons (Attwell and Iadecola 2002), and it represents only 2% of the body weight (Clarke and Sokoloff 1999). Therefore, it is not surprising that changes in energy availability can impact cognition.

Numerous animal and human projects have attempted to study the effects of DER on cognition, as described below. Although the vast majority of DER research was performed with animals, there is also preliminary evidence in humans pointing to health enhancements (Horne et al. 2015).

Neurodegeneration

The neurodegenerative diseases consist of a group of neurological disorders that can affect different subsets of neurons in specific cerebral areas with no determined cause and slow progression. The neural degeneration can disrupt many levels of neuronal activity starting with molecular pathway impairment, disruption of synapses, and changes in local circuits and finally affecting higher-order neuronal networks (Fig. 3) (Palop et al. 2006). Regarding molecular level, some mechanisms seem to be more relevant to neural degeneration such as mitochondrial dysfunction, oxidative stress, and apoptosis (Przedborski et al. 2003). The most studied benefits of DER on neurodegenerative diseases include Alzheimer's disease (AD) and Parkinson's disease (PD), which will be the focus of this topic.

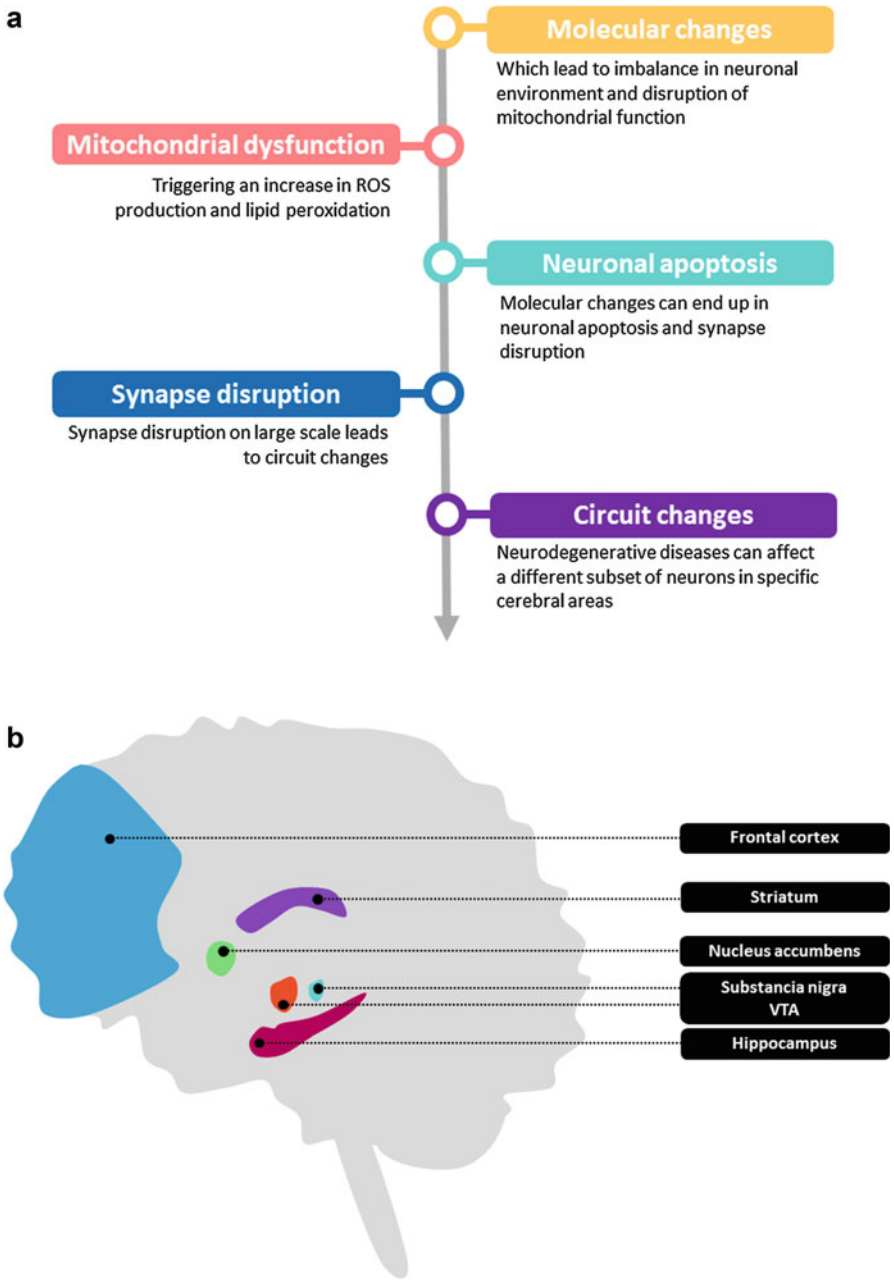

Fig. 3 General changes observed in neurodegeneration: from molecular to circuit disruption. (**a**) The neuronal degeneration can start with molecular pathway impairment that leads to an imbalance in neuronal environment and disruption of mitochondrial function triggering an increase in ROS and lipid peroxidation. All of these changes can result in neuronal apoptosis, synaptic

The beneficial effects of DER on neurodegenerative process are mainly focused in its ability (1) to modulate some of the molecular pathways that are impaired in these illnesses and (2) to enhance neurogenesis and synaptic plasticity as previously presented in this chapter.

It is well established that along normal CNS aging numerous modifications occurred to nucleic acids, proteins, and lipids together with a cumulative burden of excitotoxic, metabolic, and oxidative stress. All these changes are intensified in the neurodegenerative process. However, animal studies have proposed that dietary changes such as in alimentary frequency and calorie intake could alter the incidence and severity of these disorders (Mattson et al. 2003). The mechanism proposed to the observed benefits of reduced dietary intake is based on energy availability changes that are perceived by neurons as mild cellular stress stimulus leading neurons to react increasing the production of stress resistance response proteins. The insulin-like/forkhead box O (FOXO) signaling pathway, sirtuins (SIRTs), and peroxisome proliferator-activated receptors (PPARs) are among the principal switches that stimulate the synthesis of neurotrophic factors such as BDNF, chaperones, and antioxidant enzymes (Gillette-Guyonnet and Vellas 2008).

Some studies performed in animal model of either excitotoxicity or metabolic insults as well as AD have proposed that short-term CR or IF could be neuroprotective and alleviate amyloid-β (Aβ) peptide aggregates and microglia activation, respectively (Patel et al. 2005; Halagappa et al. 2007). AD is histologically characterized by two well-known pathological hallmarks: senile plaques composed of Aβ peptide and the neurofibrillary tangles of abnormally phosphorylated tau. Both protocols (IF or CR) increase the expression of some key proteins such as sirtuin-SIR2 (first identified in yeasts subjected to CR with expanded lifespan) or SIRT1 (in mammals) (Fig. 4). This protein can regulate DNA repair, gene silencing, aging, and programmed cell death. In vitro studies suggest that increased levels of SIRT1 protect cells from apoptosis triggered by reactive oxygen species (ROS) generated by Aβ aggregates (Gillette-Guyonnet and Vellas 2008). Higher levels of SIRT1 lead to increased generation of catalytically active A disintegrin and metalloproteinase 10 (ADAM10) proteins that can maintain an anti-amyloidogenic activity either in rodent brains (Wang et al. 2005) or in monkey brains (Qin et al. 2006). ADAM10 is a constitutive α-secretase protein that cleaves the amyloid precursor protein (APP) generating a secreted and non-amyloidogenic product. Some studies have demonstrated that active ADAM10 not only reduces Aβ but

Fig. 3 (continued) disruption, and dysfunction of neuronal circuits. (**b**) Neurodegenerative diseases can affect different subsets of neurons in specific cerebral areas, such as dopaminergic neurons from mesolimbocortical pathways, including neurons from VTA to nucleus accumbens, hippocampus and frontal cortex or mesostriatal pathway, from substantia nigra to striatum in Parkinson's disease and can affect cholinergic neurons and to a lesser extent non-cholinergic neurons in the hippocampus, in Alzheimer's disease (ROS, reactive oxygen species; VTA, ventral tegmental area) (Przedborski et al. 2003)

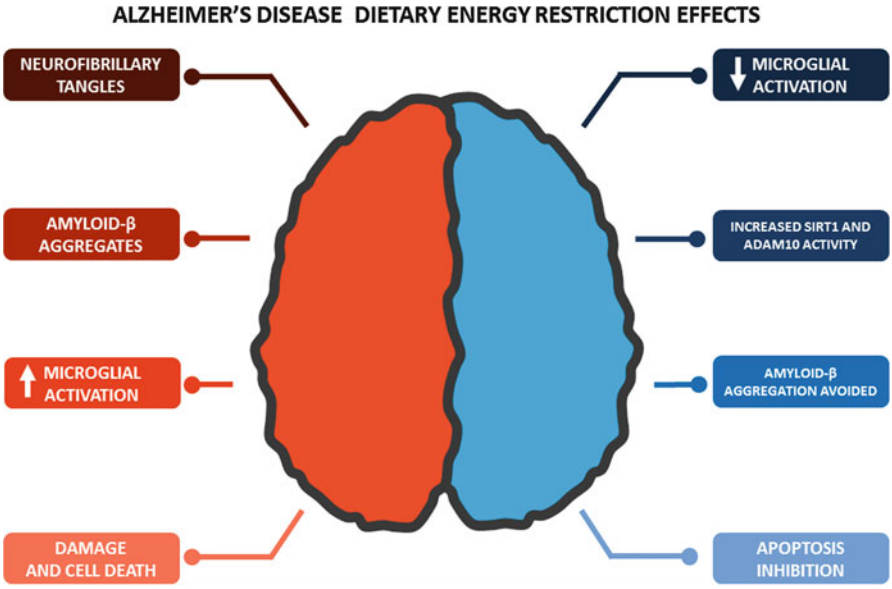

Fig. 4 DER effects in Alzheimer's disease animal models. In red, neurofibrillary tangles in cytosol and Aβ peptide aggregates that intensify microglia activation. In blue, DER can decrease microglia activation and due to an increase in SIRT1 can modulate ADAM10 activity avoiding Aβ peptide aggregation (Yuan et al. 2017). Furthermore, SIRT1 seems to inhibit apoptosis (Aβ, amyloid β; DER, dietary energy restriction; ADAM10, A disintegrin and metalloproteinase 10; SIRT1, sirtuin 1)

also can reduce tau pathology, increase hippocampal neurogenesis, and help to maintain normal physiological synaptic functions (Yuan et al. 2017).

Notwithstanding the PD can be characterized by pathologic accumulation of presynaptic protein α-synuclein or microtubule-associated protein tau within vulnerable dopaminergic neurons and often glial cells, as well as in striatum (Fig. 5). In experimental models of PD, DER has also been associated with a reducing death vulnerability of substantia nigra (SN) dopaminergic neurons (Duan and Mattson 1999). A study performed in nonhuman primate rhesus monkey that received 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a neurotoxin that selectively degenerates dopaminergic neurons leading to PD-like motor, neurochemical, and histopathological alterations in humans and primates, showed that monkeys that were at a reduced caloric diet for up to 6 months before receiving neurotoxin injection had an increase in neurotrophin levels such as glial cell line-derived neurotrophic factor (GDNF) and BDNF in striatum that protected dopaminergic neurons from degeneration measured by less motor deficits and higher levels of dopamine (Maswood et al. 2004). The same protection was also observed in mouse model (Duan and Mattson 1999).

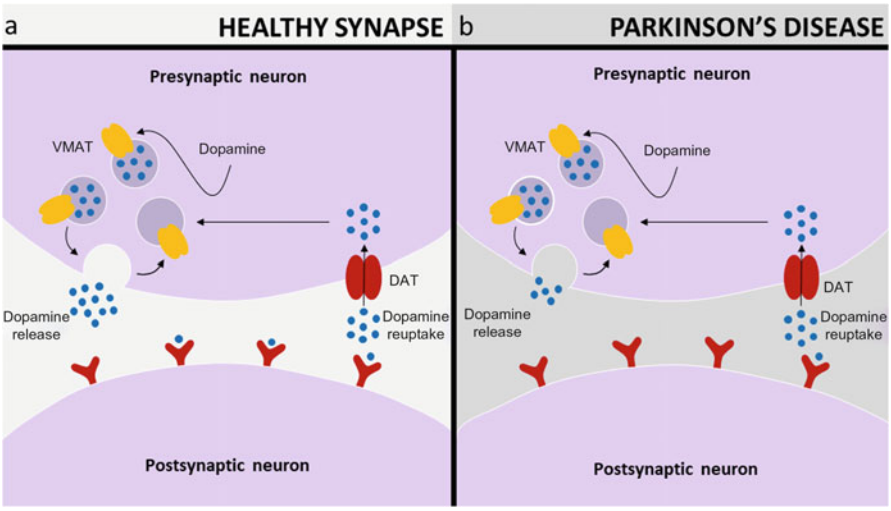

Fig. 5 Role of normal and mutated α-synuclein in synapse. (**a**) Presynaptic terminal of a dopaminergic neuron represents the well-known hallmark of Parkinson's disease: α-synuclein is an important protein for presynaptic dopaminergic vesicle release. (**b**) The loss of normal function of this protein promotes the accumulation of dopamine in the cytoplasm that together with α-synuclein oligomers is toxic to neuron (DAT, dopamine active transporter; VMAT, vesicular monoamine transporter) (Duan and Mattson 1999)

Similar to exercise effect, DER, especially IF, upregulates the antioxidant enzyme expression such as superoxide dismutase 2 (SOD2), glutathione peroxidase and heme oxygenase 1 (HO1), chaperones such as heat-shock protein 70 (Hsp70) and glucose-regulated protein 78 (Grp78), proteins involved in stress resistance and mitochondrial bioenergetics, antiapoptotic proteins, and neurotrophins (Camandola and Mattson 2017) (Fig. 6). Increased levels of BDNF can, in turn, raise the glucose transporters expression in neurons (GLUT3) stimulating neuronal energy metabolism. Furthermore, BDNF can also induce mitochondrial biogenesis through peroxisome proliferator-activated receptor gamma coactivator 1-α (PGC-1α) (Camandola and Mattson 2017). It is well established that in PD there are an increase in membrane lipid peroxidation, protein nitration and oxidation, and a remarkable decrease in mitochondrial activity (Duan and Mattson 1999).

Although no safe protocol of DER had already been established for humans, it is becoming clearer that this challenge induces a complex array of molecular mechanisms that seems to optimize brain function and protect against neurodegenerative diseases and injuries (Camandola and Mattson 2017).

Animal Studies

Animal studies are very critical to evaluate the potential effects of DER at the cellular level on CNS, which could guide us to a better understanding of its impact in clinical

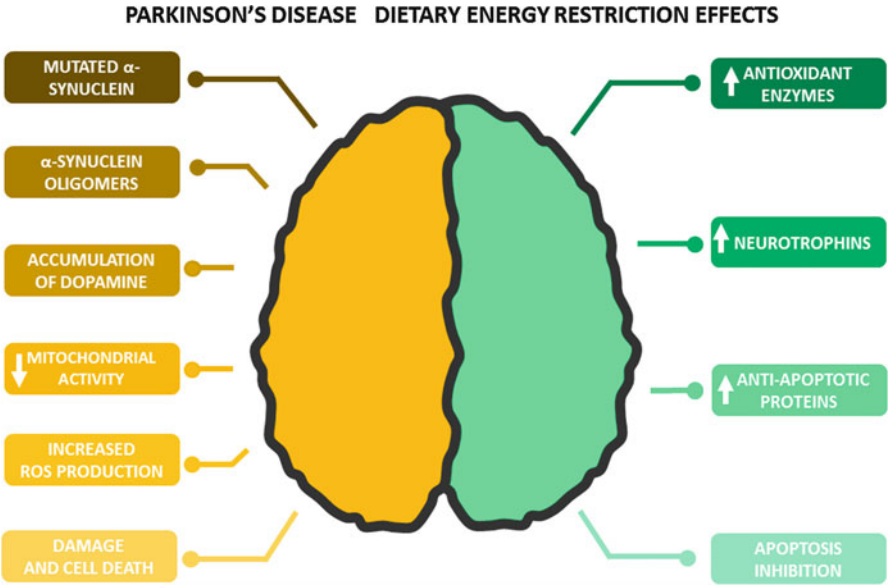

Fig. 6 DER effects in Parkinson's disease animal models. In yellow, mutated α-synuclein promotes the accumulation of dopamine in the cytoplasm that together with α-synuclein oligomers is toxic and can decrease mitochondrial activity as well as increase ROS production. All this cellular changes can lead to neuronal apoptosis. In green, DER can increase antioxidant enzymes, anti-apoptotic proteins, and neurotrophins protecting neurons from apoptosis (DER, dietary energy restriction; ROS, reactive oxygen species) (Duan and Mattson 1999)

trials (Mattson 2010). Several animal studies have consistently shown that DER enhances cognitive function, as some of them described ahead.

Literature data have provided evidence that a lifelong CR in mice is able to increase memory and prevent age-related decline in long-term potentiation (LTP) (Eckles-Smith et al. 2000; Kuhla et al. 2013). Likewise, CR started at midlife promoted an extension of life and of cognitive function in aged mice (25-month-old) (Means et al. 1993).

Ferreira et al. (2006) showed that 7-week-old rats subjected to mild (30%) or strong (60%) CR presented improved learning compared to rats in ad libitum diet, although memory was ameliorated in rats fed a 30% CR diet only. Moreover, 10% to 30% CR improved learning ability of mice in the Morris water maze (MWM) test (Ma et al. 2014).

Xu et al. (2015) showed that 30% CR in mice, unlike 30% caloric enhancement, improved learning and memory abilities, also evaluated in the MWM test. Accordingly, mice in high calorie diet (30% higher calorie intake) for 10 months had decreased memory capacity and neurodegeneration, while 30% CR resulted in improved memory in the MWM test (Dong et al. 2015). It was also investigated the effects of 20 and 35% CR on cognitive function in mice, and improved learning was observed in male but not in female, which suggests a sex-dependent DER effect on cognitive function (Wu et al. 2003).

It is well known that inflammation can induce cognitive dysfunction. Vasconcelos et al. (2014) demonstrated that IF is able to mitigate memory impairment associated with neuroinflammation, induced by lipopolysaccharide (LPS, a component of gram-negative bacteria membrane) stimulus. These results seem to be due to the anti-inflammatory effects of this DER protocol, which involves reduction of circulating inflammatory cytokines and pro-inflammatory gene expression.

Obesity is an inflammatory disease associated with increased systemic inflammation and cognitive deficits. Jeon et al. (2016) showed that CR in obese mice promoted weight loss and reversed learning, metabolic, and brain glucose dysfunctions. Accordingly, dietary-induced obesity rats subjected to CR for 28 days had improved cognitive function and BNDF signaling (Kishi et al. 2015).

Human Studies

Numerous religious groups have to fast during specific periods of the day or of the year, including Christians, Buddhists, Jews, Hindus, and Muslims (Longo and Mattson 2014). In many clinics, patients are being advised to adopt a very low-calorie diet (less than 200 calories per day) or even water-only diet under medical supervision in order to prevent diseases or for weight control (Longo and Mattson 2014). In fact, many studies have confirmed the beneficial effects of DER in improving general health in humans, including reduction of body weight in obese subjects (Harvie et al. 2011, 2013), hypertension (Goldhamer et al. 2001; Al-Shafei 2014), rheumatoid arthritis (Kjeldsen-Kragh et al. 1991; Muller et al. 2001), and asthma (Johnson et al. 2007).

Although DER was shown to increase cognitive function in different species, studies in humans are limited and with conflicting results (Rashotte et al. 1998; Qasrawi et al. 2017). In one study, nonobese volunteers subjected to a controlled experimental underfeeding during 1 week showed, during fasting, enhanced concentration, energy during the day, and emotional balance (Michalsen et al. 2003). Witte et al. (2009) showed that 30% CR in elderly humans resulted in memory improvement. Conversely, Green et al. (1994) showed that women students under DER had impaired cognitive performances in vigilance and short-term memory parameters. Moreover, the same group showed 1 year later that meal skipping had no effect on cognition of women (Green et al. 1995).

One month a year, during the holy month of Ramadan, around 1.6 billion Muslims practice intermittent fasting, in which they are refrained to eat and drink from sunrise to sunset. This reoccurring fasting diet is an interesting model for studying IF. Several researches have aimed to check Ramadan effects on cognitive function (Qasrawi et al. 2017). Results are inconsistent and frequently controversial.

One of the aspects of cognitive function is alertness. Three studies reported a shift of the alertness to later hours of the day during Ramadan (Roky et al. 2000, 2003; Bahammam 2003). However, another study compared eight Muslim and eight non-

Muslim volunteers before and on the first and second weeks of Ramadan and reported no change in sleepiness or reaction time during the day (Bahammam et al. 2013a). Accordingly, another study with controlled conditions (fixed caloric intake, sleep duration and schedule, and exposure to light and dark) also reported that there was no change in drowsiness or vigilance caused by Ramadan intermittent fasting, measured by the total blink duration and mean reaction time (Bahammam et al. 2013b).

It was also reported that there is no change in cognitive function in cyclists during Ramadan (Roky et al. 2000). However, Farooq et al. (2015) showed that 4 weeks of IF during Ramadan in teenager boys resulted in improved working memory and spatial planning ability. Another study demonstrated that in tasks which demand fast responses a better cognitive performance was observed in the morning, but no change in tasks non-dependent of speed (Tian et al. 2011). In the same study, it was also reported improved vigilance and psychomotor function in the morning (09:00 h) and poorer memory and visual and verbal learning in the afternoon (16:00 h) during fasting. However, the study did not assess sleep quality and duration (Tian et al. 2011).

Changes in sleep quality and deprived or disrupted sleep cannot be excluded as a possible reason for the findings cited above since most studies did not control sleep parameters (Devoto et al. 1999). Variations between results may also be attributed to different DER intensities, protocols, and duration before data collection. In hormesis theory, the stressful stimulus should not be so intense that the organism is not able to fully recover and should last enough to elicit an adaptive hormetic response (Mattson 2008a, b). Unfortunately, studies in humans are limited, and there is still no consensus on which DER protocol is the best one to achieve cognitive benefits.

Policies and Protocols

According to the World Health Organization (WHO), many chronic diseases are consequences of unhealthy diet. Opposite to malnutrition, high caloric intake that leads to obesity is the major risk factor to illnesses such as cardiovascular diseases, diabetes, and cancer and more recently has been associated with dementias. In 2014, around 39% of adults worldwide were overweight (Waqanivalu and Nederveen 2015).

In the face of such challenge, the University of Wisconsin–Madison and the National Institute on Aging have been studying the effects of DER on aging in rodents and nonhuman primates, and preliminary results suggest that a reduction in caloric intake can delay the onset of cardiovascular diseases and diabetes and control chronic inflammatory disorders and brain atrophy (Colman et al. 2009). Other groups have already established many protocols to deeply understand the changes promoted by caloric restriction and intermittent fasting on health.

Dictionary of Terms

- **Hormesis** – is a process in which a moderate (usually intermittent) stressor elicits an adaptive beneficial response of the cell or organism.
- **Neuroplasticity**, also known as neuronal or brain plasticity, is the ability of the brain to change, adapt, reorganize itself, and form new neural connections in response to various stimulus.
- **Neurogenesis** – is the formation of new neurons from neural stem cells in the brain.
- **Hippocampus** – is a brain region that plays a key role in memory consolidation and spatial navigation.
- **Cognitive function** – is the ability to interpret, memorize, and use information from the environment and is primordial for the adaptation of an individual.
- **Morris water maze** – is a classic and widely used test in behavioral neuroscience to access spatial learning and memory in rodents (hippocampus-related cognitive function).
- **Excitotoxicity** – is a neurotoxicity process that can lead neurons to damage or death mediated by high levels of excitatory neurotransmitters being most commonly related to glutamate.
- **Apoptosis** – is a type of programmed cell death.

Summary Points

- Dietary energy restriction is a hormetic stimulus that is associated with enhanced adult hippocampal neurogenesis and cognitive function.
- The two main dietary energy restriction protocols are caloric restriction and intermittent fasting.
- Caloric restriction involves the chronic restriction of 20 to 40% of the total calorie intake.
- Intermittent fasting involves the restriction of the frequency of food consumption (for instance, every other day fasting or Ramadan intermittent fasting).
- Many animal studies have proved the beneficial effects of dietary energy restriction on cognitive function and neural plasticity.
- The brain region of the hippocampus plays a central role in learning and memory.
- The neurodegenerative diseases consist of a group of different neurological disorders that affect different subsets of neurons in specific brain areas. They are usually characterized by slow progression with no determined cause.
- In neurodegenerative diseases, some common molecular processes such as mitochondrial dysfunction, oxidative stress, and apoptosis are among the more relevant causes of neuronal degeneration.
- Intermittent fasting and caloric restriction increase the production of stress resistance response proteins and neurotrophins.

- Caloric restriction or intermittent fasting could alleviate amyloid-β peptide aggregates and microglia activation, respectively, in Alzheimer's disease, and reduce neuronal death vulnerability in substantia nigra dopaminergic neurons in Parkinson's disease.

Coordinating Evolutionarily Conserved Response of Muscle and Brain to Optimize Performance During Starvation

66

Donard S. Dwyer

Contents

Abstract

During evolution, a multitiered physiological response has emerged to deal with the repercussions of food deprivation and starvation that has been conserved across species. The main point of convergence of this system is on the Forkhead box O (FOXO) transcription factors. FOXO proteins control the expression of a wide array of genes involved in the use/disposal of oxygen, cell energetics, and proteasome/autophagy pathways. Upstream regulation is provided by insulin/IGF-1 signaling (IIS) mediated via Akt and modulated by additional kinases, including 5′-AMP-activated kinase (AMPK) and mammalian target of rapamycin (mTOR). This chapter describes the workings of this evolutionarily conserved starvation response as it relates to maintaining the performance of muscle and

brain during chronic food deprivation. This system allows tight coordination of energy usage by muscle and brain to achieve optimum function in both tissues despite changing sources of energy – from glucose and amino acids to fatty acids and ketone bodies. The IIS pathway is critical for this coordination; however, either too little or too much IIS can be detrimental during starvation. The evolution of the starvation response has conferred both assets (support for long-range foraging during famine vs. efficient storage of energy supplies in times of plenty) and liabilities (anorexia nervosa vs. obesity and diabetes) to human populations. The IIS-FOXO-AMPK-mTOR pathway may offer new therapeutic targets for the treatment of anorexia and diabetes as well as muscle wasting syndromes, including sarcopenia and cachexia.

Keywords

Anorexia · FOXO · Insulin/IGF-1 signaling · Target of rapamycin · Sarcopenia

List of Abbreviations

ACC	acetyl-CoA carboxylase
AMPK	5′-AMP-activated kinase
DMSO	dimethyl sulfoxide
FOXO	Forkhead box O
IIS	insulin/IGF-1 signaling
InsR	insulin receptor
mTOR	mammalian target of rapamycin
PI3K	phosphatidylinositol 3-kinase
SNF1	sucrose non-fermeting-1
TCA	tricarboxylic acid cycle
TNF-α	tumor necrosis factor-α
TORC1	TOR complex 1
TORC2	TOR complex 2

Introduction

Throughout most of man's history, a major question faced on a daily basis was where would the next meal come from? With advances in toolmaking, hunting, and cultivation of crops, this became a less-pressing issue, although sporadic famines and food shortages continue to occur even today. The uncertainties about the next meal have always plagued lower animal species. Consequently, mechanisms have evolved for dealing with periods of acute and even prolonged starvation. This chapter will consider the problem from a molecular and systems-based perspective with some insights into the whole organism. Other reviews (e.g., Cahill 1970; this volume) deal better with starvation at the organism and population levels.

During periods of food deprivation and starvation, two major body systems compete for the limited energy supply: the musculoskeletal system, which produces movement aimed at finding food, preparing it, and eating, and the brain, which

analyzes environmental signals to locate food and directs foraging and feeding behavior. In view of these competing demands, survival depends on the tight coordination of physiological responses aimed at preserving energy resources and using limited fuel supplies in the most efficient manner. The insulin/IGF-1 signaling (IIS) pathway has evolved as the system best suited for coordinating energy metabolism in brain, muscle, and other tissues. In this chapter, I will describe how the IIS pathway integrates functional activity of muscle and brain to promote survival during starvation. The chapter will also highlight evolutionary factors that shaped the development of this highly integrated system. A theme that will emerge from this analysis is that optimum muscle performance during starvation requires the perfect blend of IIS – either too little or too much signaling via this pathway can be harmful. Finally, I will discuss how eating disorders, diabetes, and sarcopenia may have emerged as a consequence of the biological activities produced at either extreme of IIS.

Evolutionarily Conserved Response to Starvation

Depletion of nutrients and starvation represent a constant challenge to all biological organisms. As a result, a fundamental physiological response evolved that has been conserved from yeast to man. To understand how muscle and brain adapt to starvation, it will be helpful to first explore the origins and molecular mechanisms involved in this adaptation. At the core of the starvation response is the forkhead box O (FOXO) family of transcription factors (Fig. 1). Most species typically express multiple genes belonging to the general family; yeast have four members, Fkh1, Fkh2, Fhl1, and Hcm1 (Linke et al. 2013). Notable counterparts in *C. elegans* and humans include DAF-16 and FOXO1 and FOXO3, respectively. FOXO transcription factors regulate the expression of genes that affect cell cycle progression, development, energetics (especially glucose metabolism), resistance to oxidative stress, and mitochondrial biogenesis (Calnan and Brunet 2008). The overarching theme is that FOXO governs the use/disposal of oxygen to: (1) oxidize glucose, (2) facilitate oxidation reactions (e.g., mediated by tyrosine hydroxylase), (3) minimize oxidative stress, and (4) maximize mitochondrial capacity in support of growth and development. The FOXO pathway ultimately determines the metabolic state and cell fate.

Regulation of FOXO proteins is complex and is mediated by phosphorylation, changes in the rate of protein turnover, and compartmentalization in the cell (Calnan and Brunet 2008). In yeast, the major regulator of FOXO is the serine-threonine kinase, sucrose-nonfermenting-1 (SNF1), which is an ortholog of 5′-AMP-activated kinase (AMPK) in invertebrates and mammals (Hedbacker and Carlson 2008). Sch9 is a secondary kinase that also regulates FOXO in yeast; it is the yeast version of protein kinase B/Akt (Sobko 2006), which has assumed a far greater role in the regulation of FOXO in invertebrates and vertebrates. Akt is activated downstream of different growth factor receptors, but in *C. elegans* this is mainly achieved by activation of the IIS pathway (Fig. 1). This nearly exclusive relationship suggests

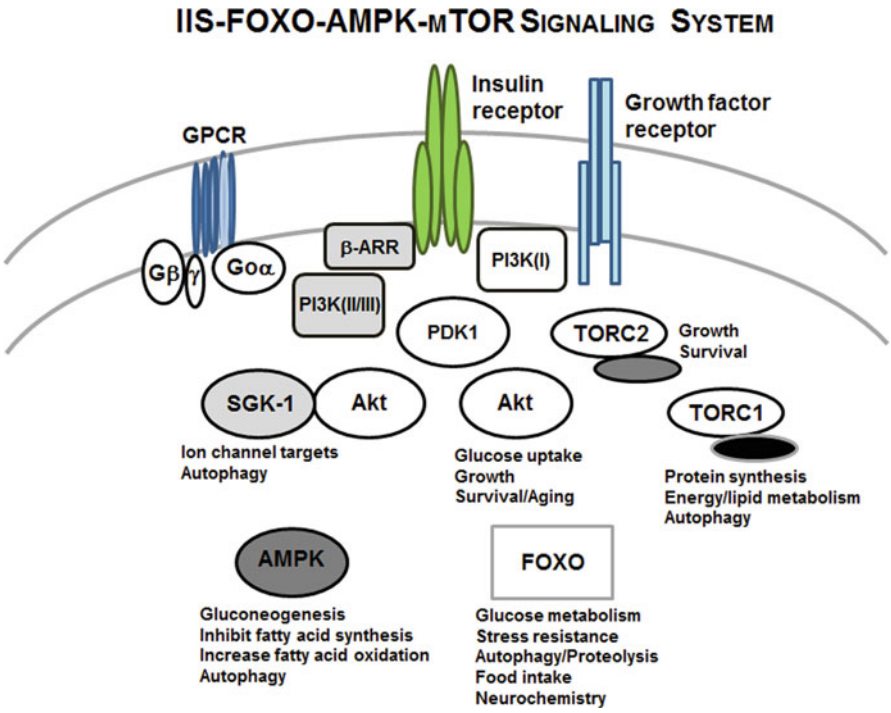

Fig. 1 The IIS-FOXO-AMPK-mTOR signaling system. The major components of these pathways are depicted here. *Arrows* showing connections were omitted for simplicity. The main responses mediated by these components are listed

that the insulin receptor may have been the original cell-surface signaling component to co-evolve with Akt.

In addition, to FOXO, AMPK, and Akt, the mammalian target of rapamycin (mTOR) pathway provides additional important feedback to the starvation response (Fig. 1). Again, this signaling mechanism has been shared from yeast to man. At the molecular level, regulation of IIS-FOXO-AMPK-mTOR signaling is very interactive and highly complex. Reviews on this topic provide the details and evidence for connections that will be discussed here in a more superficial way (Memmott and Dennis 2009; Goodman et al. 2011). There are two mTOR-containing kinase complexes: TORC1, which includes Raptor as a subunit and TORC2, which includes Rictor instead (Caron et al. 2015). TORC1 is activated in response to growth factors, amino acids, energy levels, oxygen, and stress and stimulates protein synthesis, lipid metabolism, mitochondrial biogenesis, and autophagy (Caron et al. 2015). It is broadly involved in cell growth and proliferation. TORC2 is activated by growth factors, especially insulin, and mediates changes in energy metabolism and cell survival. It targets Akt and serum and glucocorticoid-inducible kinases (SGKs) leading to their activation. There is complex interplay and feedback involving TORC1, TORC 2, Akt, and AMPK

(Memmott and Dennis 2009; Goodman et al. 2011). It is based on the type and magnitude of environmental signals, the sites on the target proteins that are phosphorylated, the momentary energy status of the cell (e.g., ATP:ADP:AMP ratios), and the cellular location where activation/deactivation takes place.

At the organismal level, there is conservation of adaptive responses to low-nutrient conditions. In *C. elegans*, the combination of low food supply and population crowding alters larval development causing young animals to enter a diapause stage also known as dauer formation (Riddle 1988). This alternate developmental trajectory is determined by IIS, including FOXO and mTOR. The dauer stage resembles seasonal hibernation observed in some mammalian species. Hibernation is also regulated by IIS, FOXO, and AMPK (Wu and Storey 2014; Lanaspa et al. 2015). The goal of dauer formation and hibernation is to diminish physical activity and therefore energy metabolism during periods of food limitation. A critical aspect of dauer/hibernation is preservation of muscle function despite a lengthy reduction in the supply of nutrients over several months. The evolution of this specialized response to fluctuations in food provides additional insights into the more general response to starvation observed on an intermittent basis.

Aside from its involvement in dauer formation and hibernation, the IIS-FOXO pathway regulates foraging and food-seeking behavior in an evolutionarily conserved fashion. Overexpression of FOXO in yeast during starvation significantly reduces a form of foraging known as pseudohyphal growth – a cell-based filament formation – aimed at dispersing yeast to nearby locations with higher nutrient value (Zhu et al. 2000). Similarly, enhanced expression of FOXO in *Drosophila* reduces food consumption (Kramer et al. 2003) and results in an anorexic phenotype (Dwyer et al. 2011). Interestingly, loss-of-function mutations in the insulin/IGF-1 receptor of *C. elegans*, along with brief food deprivation and exposure to low levels of dimethyl sulfoxide (DMSO), inhibit foraging and induce an immobile state reflecting diminished motivation (Dwyer and Aamodt 2013). Thus, insulin appears to play a role across higher species as a modulator of neural motivation circuits that govern the search for food and mates, and the avoidance of harm. Finally, the IIS-FOXO pathway has been related to the eating disorder anorexia nervosa (Dwyer et al. 2011), in further support of the evolutionary significance of this pathway.

As a logical extension of the role of IIS-FOXO in dauer/hibernation and foraging, this pathway, including mTOR and AMPK, modulates lifespan across species – from yeast to *C. elegans*, *Drosophila*, and mice (Kenyon et al. 1993; Tatar et al. 2001; Taguchi and White 2008). However, the effects on lifespan are complex and paradoxical. When IIS is partially reduced in *C. elegans* strains with temperature-sensitive *daf-2* (insulin receptor) mutations by raising the cultivation temperature from 15 °C to 20 °C, lifespan is significantly increased across the population By contrast, when the temperature is further elevated to 25 °C to produce a more complete loss of *daf-2* function, about half of the animals lives longer than normal, as expected, whereas the other half surprisingly dies prematurely (Kenyon et al. 1993). Similar observations have been made in aging studies with *Drosophila* (Tatar et al. 2001). Therefore, both too much and too little signaling via the IIS pathway can produce deleterious effects on organismal growth and development (Fig. 2). The

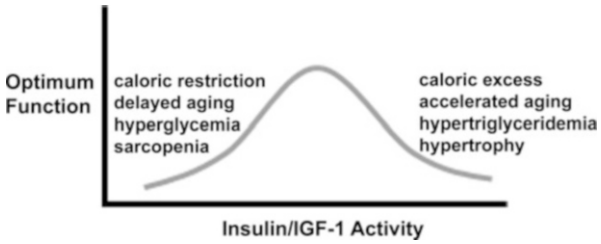

Fig. 2 The "sweet spot" between IIS and optimum physiological function. When insulin/IGF-1 signals are either too low or too high, muscle function and organism health may be adversely affected. The adverse effects and characteristics of these conditions are listed at the *left* and *right* sides of the figure

same appears to be true of IIS-FOXO effects on muscle function during starvation (Dwyer and Aamodt 2013). For example, loss of function in IIS-FOXO signaling components adversely affects recovery of pharyngeal pumping in *C. elegans* upon acute food deprivation, whereas gain-of-function mutations are associated with poorer muscle performance after 24 h, despite an initial boost in the recovery of pumping over the first 6 h of starvation. Thus, the IIS-FOXO pathway is a dual-edged sword in muscle.

Part of the reason for this duality of function can be attributed to the nature of the signals that emanate from the insulin/IGF-1 receptor upon activation. Classically, IIS is mediated via phosphatidylinositol 3-kinase (PI3K), PDK-1, and TORC2 all converging on Akt and leading to downstream phosphorylation of its targets (Manning and Cantley 2007). Evidence is emerging for a second pathway mediated via β-arrestin, class II/III PI3Ks, and Akt/SGK complexes (Fig. 1) acting at different intracellular sites and perhaps on different substrates (Dwyer and Aamodt 2013). Which of these two options is exercised will depend upon existing set points of the insulin/IGF-1 receptors (e.g., complexation with G proteins vs. β-arrestin) and coincident signals determined by nutritional state, glucose availability, etc. With this bifurcating signal, a very ancient system has been adapted and modified to cope with the increased challenges faced by complex mammals such as man during starvation.

Caloric restriction in man is accompanied by changes in appetite and behavior that may confer evolutionary advantages in certain settings. Keys et al. (1950) found that males subjected to chronic (24 week) reduction in food intake experienced loss of appetite, obsessions toward food, increased anxiety, restlessness, and early psychotic features. These psychological outcomes of caloric restriction were recognized as being the same as putative driving forces behind the development of anorexia nervosa (Guisinger 2003; Dwyer et al. 2011). A vicious cycle of self-starvation, blunted appetite, and muscle wasting ensues (Fig. 3). In addition, studies of hunger strikers revealed that this population developed denial of the adverse effects of starvation and a reduced sense of harm during a hunger strike (Fessler 2003). Guisinger (2003) proposed that anorexia nervosa may be an evolutionary adaptation to flee famine. It is informative to directly quote his reasoning for the advantages of the anorexic phenotype.

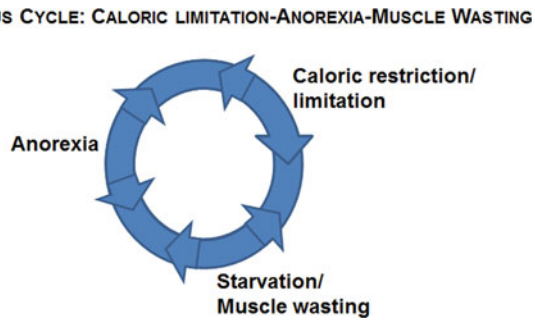

Fig. 3 Vicious cycle of caloric limitation, anorexia and starvation/muscle wasting. Any of these responses can produce the others and generally there is feed forward in the system

To migrate efficiently (during famine), individuals' bodies would have to turn off the usual adaptations to starvation. The ability to stop foraging locally, to feel restless and energetic, and optimistically to deny that one is dangerously thin could facilitate a last-ditch effort. Here it is proposed that core anorectic symptomatology includes three distinct adaptations specifically relevant for surviving past famine conditions: ignoring food, hyperactivity, and denial of starvation, including distorted body image. (Guisinger 2003, 748).

We attribute this anorexic phenotype, in part, to genetic variation in the components of the IIS-FOXO-AMPK-mTOR system (Dwyer et al. 2011). The underlying evolutionary changes that mediate this type of protective behavior must also have affected the function of tissues responsible for promoting foraging and surviving famine, namely muscle and brain.

Effects of Starvation on Muscle

Muscle has evolved efficient anabolic mechanisms to promote growth in times of plentiful food and exercise, and catabolic mechanisms to promote survival during famine and disuse. Growth is mainly regulated by growth hormone/IIS, follistatin, androgens, and β-adrenergic agonists (Schiaffino et al. 2013). Catabolic signals include TNF-α, myostatin, reduction of IIS, and starvation. Autophagy plays a paradoxical role in muscle – it is activated during atrophy and starvation (Mammucari et al. 2007), which makes sense, but it is also necessary to build and maintain muscle mass (Masiero et al. 2009). Clearly, there is a delicate balance between protein synthesis and degradation to maintain optimum muscle function that fluctuates depending on environmental conditions and endogenous signaling pathways.

The effects of starvation on muscle function need to be considered from both acute and chronic perspectives. With short-term food deprivation, glycogen stores are used first to meet the energy needs of muscle, which progressively shift to the oxidation of fatty acids, including intramyocellular triglycerides (IMTGs) (Stannard and Johnson 2003). As insulin levels fall with prolonged food deprivation, insulin-mediated suppression of proteolysis is reversed, and FOXO upregulates ubiquitin-proteasome and autophagy-lysosome protein degradation. Part of the purpose of

proteolysis is to provide glucogenic amino acids, in particular alanine and glutamine, for gluconeogenesis. Felig (1973) described the glucose-alanine cycle wherein hepatic conversion of alanine to glucose dominates the usage of glucogenic amino acid substrates from peripheral tissues. Importantly, a rise in IMTGs not only provides a substitute for glucose oxidation in muscle, but also decreases insulin sensitivity, thereby leaving more glucose in circulation for use by the brain (Stannard and Johnson 2003). If starvation continues, fatty acids are converted to ketone bodies, which become the main fuel source for the brain. Proteolysis in muscle begins to slow, but is still necessary to provide amino acids as anapleurotic substrates for the tricarboxylic acid (TCA) cycle in other tissues.

Widespread reductions in protein synthesis and other adaptations kick in at this stage to preserve muscle mass in support of last-ditch foraging efforts described by Guisinger (2003). These physical efforts and other forms of exercise feedback to inhibit autophagy and protein degradation (Zheng et al. 2015). To explain contradictory effects of exercise on autophagy (Jamart et al. 2013; Zheng et al. 2015) as well as reversal of the positive effects of gain-of-function mutations in Akt-FOXO on long-term recovery of pharyngeal pumping during starvation (Dwyer and Aamodt 2013), I propose the following sequence of events. At 6–8 h after food deprivation, autophagy is initiated at a low level. This can be enhanced by aerobic exercise, which adds to the negative energetic balance. After 24 h of food deprivation, proteolysis is in full swing. If this FOXO-mediated adaptation is blocked by gain-of-function mutations in Akt, it is detrimental for muscle function. Moreover, after 24 h of food deprivation, exercise has the opposite effect on autophagy – it is inhibited. This inhibition appears to be mediated via reactivation of the mTOR pathway and S6 kinase via PDK1 (Zheng et al. 2015). Thus, for preservation of muscle function, autophagy must be initiated 6–8 h after food restriction, but it must also be limited after prolonged starvation by exercise or adaptive signals to prevent muscle damage. This is yet another example of physiological performance being impaired by either too little or too much activity in the IIS-FOXO-AMPK-mTOR system.

The release of amino acids following protein degradation activates TORC1 in the mTOR pathway, which can directly phosphorylate FOXO (Greer et al. 2007). This leads to transcriptional regulation of atrogin-1 and enhancement of autophagy. As the ATP:AMP ratio decreases over time with starvation, AMPK activation promotes the utilization of fatty acids for energy via inhibition of acetyl-CoA carboxylase (ACC) by phosphorylation (Hopkins et al. 2003). Consequently, starving muscle undergoes a series of shifts in the main source of energy being used – from glucose derived from glycogen to glucose derived from amino acids and then to fatty acids and IMTGs derived from adipose tissue – a process known as metabolic flexibility.

Because the IIS pathway normally downregulates proteolysis and a decrease in protein degradation is needed to spare muscle during chronic starvation, how does this pathway operate when circulating levels of insulin are very low? IIS can be elicited by several mechanisms that are independent of plasma insulin concentrations: (1) transactivation via G proteins, (2) direct phosphorylation by AMPK, (3) PDK1-S6 kinase activity, (4) local IGF-1 synthesized in muscle, and (5) alternate complexes of the InsR, for example with β-arrestin. The InsR exhibits intrinsic activation that is modulated by

G proteins (O'Hare and Pilch 1990). Furthermore, drugs affecting G protein-coupled receptors can produce transactivation of the InsR (Weeks et al. 2010). The InsR is directly phosphorylated and activated by AMPK in response to low glucose (Chopra et al. 2012), so this is yet another possibility for residual IIS activity. Sustained activation of PDK1 is an additional mechanism for preserving muscle function over 24 h of starvation (Dwyer and Aamodt 2013). This kinase appears to be permissive of autophagy at early stages of food deprivation, but is protective of muscle at later stages. Low levels of PDK1 activation may occur as the result of stimulation via other growth factor receptors or by alternative kinase signaling pathways. In terms of the fourth possibility, muscle synthesizes IGF-1, and while levels normally decrease with starvation, there are reports to the contrary (Troncoso et al. 2012). Local autocrine actions of IGF-1 could limit the loss of muscle mass during starvation.

As discussed above, the InsR is activated as part of a complex with β-arrestin (Povsic et al. 2003). This pathway requires class II/III PI3Ks and the serum and glucocorticoid-inducible kinase-1, SGK-1 (Dwyer and Aamodt 2013). Glucocorticoid levels will rise as a result of the stress of starvation and act as a cosignal. This alternative IIS pathway regulates autophagy in muscle and the phosphorylation of downstream targets that may include voltage-gated and other types of calcium channels and the Na + −leak current channel. Phosphorylation of various channel substrates may maximize the function of these proteins, thereby sustaining muscle performance even while protein degradation is taking place and energy metabolism is partially compromised. Exercise achieves some of the same outcomes, although the signaling mechanisms have not been fully established. Of course, non-IIS components are likely to be involved in the maintenance of muscle performance during chronic starvation. The net effect is the preservation of muscle function for essential tasks and coordination of metabolic pathways to spare glucose for use by the brain.

Effects of Starvation on the Brain

To fully understand the effects of starvation on muscle function, it is necessary to consider the interplay between the peripheral response to food deprivation and the central response of the brain. The brain depends almost entirely on glucose or glucose-derived substrates for energy under normal circumstances. With prolonged starvation, there is a switch to the use of ketone bodies that can penetrate the blood-brain barrier (Cahill 1970). Consequently, the brain too displays a kind of metabolic flexibility. Glucose, lactate, pyruvate, and glutamine are interchangeably used in the brain for fuel in the fed state. In the early stages of starvation, muscle supplies alanine for the glucose-alanine cycle and hepatic gluconeogenesis as discussed earlier and glutamine, which can directly be used in the brain after conversion to the TCA cycle intermediate, α-ketoglutarate (see Fig. 4). In addition, a gradual reduction in glucose uptake by muscle resulting from decreased surface expression of glucose transporters means that more of the circulating glucose produced by gluconeogenesis is available for the brain.

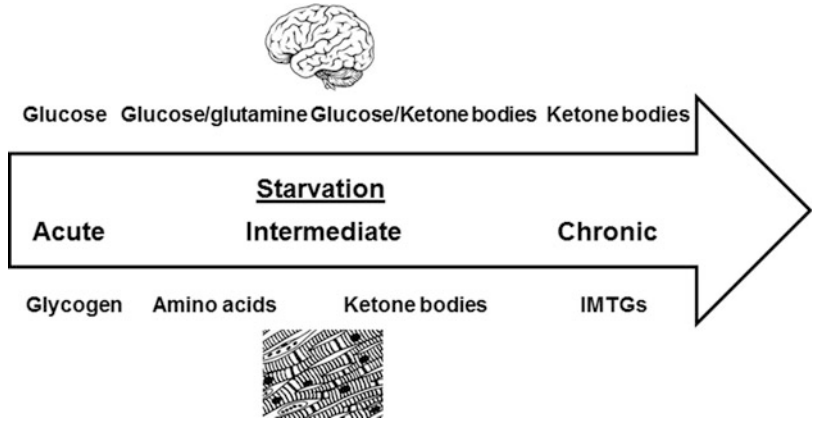

Fig. 4 Shift in energy resources as a function of starvation. Muscle (*lower diagram*) and brain (*upper diagram*) coordinate production and usage of energy substrates (*listed*) over time during food deprivation (See the text for a detailed description of this interplay)

In the next stage of starvation, ketone bodies are produced from fatty acids stored in adipose tissue. Initially, these ketone bodies provide the energy needs of both brain and muscle (Fig. 4). At this stage, the need for amino acids from muscle is reduced, which diminishes protein degradation to preserve muscle function. With prolonged starvation, muscle uses fewer ketone bodies for energy and ramps up its use of free fatty acids and IMTGs (Kelley 2005). Much like the spared use of glucose by muscle described earlier, this reduction in the use of circulating ketone bodies allows greater flux to the brain. Clearly, there is tight coordination between muscle and brain to minimize competition for the use of crucial, but limiting, energy sources such as glucose and ketone bodies.

Starvation causes neurochemical changes in the brain along with altered behavioral patterns. Here, I will focus on those changes mediated via the evolutionarily conserved IIS-FOXO pathway, which is the main focus of this chapter. As IIS is reduced in the periphery and brain as a function of the duration of food deprivation, FOXO is activated and promotes transcriptional activity in the nucleus. Among the genes whose expression is regulated are tryptophan hydroxylase and tyrosine hydroxylase (Estevez et al. 2006; Ferri et al. 2007), enzymes that catalyze rate-limiting steps in the synthesis of serotonin and dopamine, respectively. Serotonin and dopamine both regulate appetite and feeding at various levels. They stimulate feeding, control meal size and food preference, modulate reward pathways, and signal satiety. These neurotransmitters also control locomotion and foraging across species. Collectively, these findings attest to the importance of the IIS-FOXO-AMPK-mTOR system for fully integrating the behavioral response to food availability.

Insulin's direct effects in the nervous system appear to have been conserved through evolution as well. Thus, insulin regulates motivation and effort to find food (Dwyer and Aamodt 2013) and is a satiety factor in brain. Decreased insulin signaling in mice with experimentally induced diabetes is associated with increased

immobility in the forced swimming test – a measure of despair and diminished motivation (Gupta et al. 2014). Mobility is restored in these mice with exogenous insulin. Watve and Yajnik (2007) have proposed that acquired insulin resistance mediates a behavioral switch that determines whether organisms faced with environmental stress adopt a "stronger to smarter" strategy that favors brain over brawn (muscle). This fits with the picture painted above; moreover, the hyperinsulinemia that typically accompanies insulin resistance may have positive cognitive effects.

Adaptation to Starvation

Starvation causes significant adaptations at the level of both muscle and brain involving the IIS-FOXO pathway. Expression of the InsR is significantly increased along with its affinity for insulin (Kolterman et al. 1979). Therefore, the low levels of insulin that remain can more easily trigger receptor activation. In addition, insulin enhances muscle performance and efficiency by stimulating the phosphorylation of various ion channels and transporters. Therefore, excitable cells such as myocytes and neurons can maintain their capacity for generating ion fluxes with fewer channels and transporters. This adaptation preserves excitable cell function despite increased protein turnover or removal by proteolysis/autophagy. In *C. elegans*, starvation for 48 h reveals that FOXO returns from the nucleus to the cytoplasm (Weinkove et al. 2006), which is another mechanism to potentially limit excessive protein degradation. This adaptive response requires normal IIS components, in particular PI3K.

With chronic food deprivation, there is a progressive increase in the metabolism of ketone bodies and fatty acids in muscle because fat is the by far the largest storage depot for energy substrates. The IMTGs are a source of energy, but also produce insulin resistance in muscle, which shuts down protein synthesis and glycogen storage (Stannard and Johnson 2003). When fat tissue is depleted, there is an increase in protein degradation that eventually leads to atrophy and wasting. However, pushback against the loss of muscle mass occurs via several independent mechanisms. Activation of the autonomic nervous system can be directly anabolic for muscle via release of epinephrine/norepinephrine and their actions at β2-adrenergic receptors (Schiaffino et al. 2013). In addition, adrenergic receptors are reported to enhance the hepatic expression of follistatin, which counteracts induction of proteolysis by myostatin (Zhang et al. 1997). S6 kinase can be activated by amino acids (via TORC1), proteolysis, exercise, and residual PDK1 activity (Zheng et al. 2015). This would inhibit latter stages of protein degradation and reduce muscle loss. Behaviorally, feelings of anxiousness and restlessness induced by long-term food deprivation are known to cause hyperactivity (Guisinger 2003). The increase in muscle activity, like endurance exercise, would block or limit proteolysis and produce other positive effects in muscle.

The complex regulation of IIS-FOXO-AMPK-mTOR leads to a dynamic response that shifts as a function of the length of starvation. In addition, it is influenced by coincidence detection. For instance, amino acids activate TORC1 to support protein synthesis and growth (Avruch et al. 2009). However, if there is an

increase in amino acids at the same time as a decrease in the ATP:AMP ratio, AMPK is activated and TORC1 is downregulated. This dynamic regulation is also needed to promote metabolic flexibility. Specifically, there must be changes in the expression of metabolic enzymes geared for usage of the different energy substrates (e.g., glucose, lactate, glutamine, and ketone bodies) that fluctuate over the course of food deprivation. Some of this is accomplished by metabolite-mediated feedback regulation of catalytic enzymes, but multiple layers of regulation are necessary. In another twist on adaptive changes that take place, some of the molecules that inhibit the mTOR pathway are themselves degraded during ongoing proteolysis (Ghosh et al. 2008), which leads to mTOR reactivation and prevention of runaway protein degradation that would compromise muscle function.

Epigenetic changes in muscle and brain represent an important very long-term adaptation to starvation. Although this mechanism will only be briefly mentioned here, the reader is referred to informative reviews of this subject (Bocock and Aagaard-Tillery 2009; Gonzalez-Aquilera et al. 2014). Epigenetic modifications have been documented to occur as a consequence of starvation. Some of these are transgenerational and pass along to the F_2 and even F_3 offspring (Gonzalez-Aquilera et al. 2014). Epigenetic changes can be mediated by histone deacetylases that confer stress resistance during chronic food deprivation by upregulating ribosomal RNA synthesis and protein degradation pathways (Nakajima et al. 2016). In other cases, AMPK-FOXO regulation of histone arginine methyltransferases affects the expression of autophagy genes (Shin et al. 2016). A third potential regulatory strategy involves changes in ubiquitination of histone proteins that control transcription of autophagy components (Chen et al. 2017). The physiological effects of epigenetic-mediated modifications in muscle as a result of starvation have not been characterized in any detail. Nevertheless, the fact that some of these changes are transmitted to the next generation attests to the survival value of the regulatory pathways responsible and suggests additional evolutionary advantages (and disadvantages) may exist.

Unintended Outcomes of the Starvation Response: Anorexia Nervosa and Diabetes

Evolution of the starvation response has led to the emergence of both assets and liabilities for overall health. What is protective in one setting may be harmful in another. Guisinger (2003) and our group (Dwyer et al. 2011) suggested that adaptations that enhanced survival during famine may today predispose toward the eating disorder, anorexia nervosa. As local food sources were depleted, early humans faced the choice to stay and wait for a return of sustenance or to go and seek food elsewhere. Both strategies are fraught with inherent challenges: harsh weather conditions may last longer than anticipated by the "stayers" and delay the return of food, and conversely, leaving to find food elsewhere will mean exploration by the "goers" of unfamiliar territory, which may harbor new dangers and little food. Success following

the second approach required that our distant ancestors ignore feelings of hunger, get by on fewer calories, disregard harm so as to take the risks needed to find food or take on more dangerous prey, and hyperactivity to support long-range foraging. These survival advantages perfectly describe the symptoms/features of anorexia nervosa (Guisinger 2003). Depending on the gene complement specifying components of the starvation response (e.g., mutations altering expression/function of FOXO, AMPK, mTOR, etc.), certain individuals in the population (goers) may have been better suited for this approach leading to dispersal of the tribe and settlement of new areas during famine. According to this idea, behavior that is today considered pathological may be a remnant of a successful strategy that actually enabled man's survival.

Likewise, success with staying put may have depended on a set of different mutations (e.g., in IIS, Akt, and mTOR) that enhanced storage of energy substrates as fat and glycogen and the efficiency of energy metabolism to maximize accumulation of energy stores during times of plenty and limit expenditure during famines. This is a restatement of the thrifty gene hypothesis of Neel (1962), who initially proposed the idea to explain current-day prevalence of diabetes and obesity as relics of this survival strategy. In summary, goers were built to forage over great distances, but were prone to anorexia nervosa as a result. On the other hand, stayers were well suited to make the most of available food resources but tended to develop obesity, insulin resistance, and diabetes when food is plentiful. It is worth noting that the local population densities would have been very different for individuals adopting these two survival strategies. The goers would have spread out over greater areas, thus reducing local population density and competition for limiting resources, whereas the stayers would generally have higher population densities because their approach depended on the cooperative cultivation and/or acquisition of food. Interestingly, population density also affects the developmental decision of *C. elegans* to undergo dauer formation in the context of diminished IIS (Riddle 1988). Dauer larvae show distinct changes in muscle and have bouts of hyperactivity that presage the dispersal behavior of the goer contingent of human populations. Thus, adaptation to starvation during evolution has influenced the makeup of molecular signaling pathways, cellular and tissue responses aimed at preserving locomotion/foraging, and population behavior geared toward survival of the species.

Muscle Wasting in Hemodialysis, Cachexia, and Sarcopenia

In addition to starvation, various medical conditions plus aging have adverse effects on muscle mass and function. Here, I will focus on muscle wasting as a result of hemodialysis, cancer, and aging. The general unifying theme is that these conditions are associated with the induction of catabolic reactions in response to altered nutritional states and insulin resistance. Hemodialysis for kidney disease often produces muscle wasting caused by multiple factors, including uremia, negative nitrogen balance possibly secondary to metabolic acidosis, and increased proteolysis and insulin

resistance (Franch 2009). Anorexia is very common in patients undergoing hemodialysis and contributes to overall weight loss (Bossola et al. 2011). It is also a feature of cachexia and fairly common in elderly patients who develop sarcopenia (Morley 2001; Muscaritoli et al. 2010). In cachexia due to cancer, various inflammatory cytokines are released, such as TNF-α, IL-1, and IL-6, that promote catabolism in different tissues and loss of muscle mass (Keller 1993). TNF-α also counteracts IIS leading to insulin resistance. Sarcopenia associated with aging is thought to result from a combination of poorer nutritional status, oxidative stress in muscle and age-related decline in IGF-1 plasma levels and production in muscle (Sandri et al. 2013). In addition, insulin resistance frequently emerges with aging. Whereas early on IIS is needed to drive development and reproductive maturation, late in life this influence is greatly diminished to reduce the possibility that genetic liabilities of aged individuals are passed on through reproduction and to decrease competition with the young and/or fertile for food resources. Consequently, sarcopenia with aging can be considered a normal, if unfortunate, outcome of the programmed IIS trajectory. Along with muscle wasting, there is impairment in muscle function in these various conditions. Together, these maladaptive changes in muscle compromise health outcomes and quality of life. Treatment is generally focused on enhancing nutrition, including protein feeding; however, nutritional intervention alone has limited success. Exercise is more beneficial for maintaining muscle mass and performance as seen earlier in the case of starvation. In the future, the IIS-FOXO-AMPK-mTOR pathway may offer additional therapeutic targets for disorders featuring muscle wasting.

Policies and Protocols

Policies

- In starvation and muscle wasting, the goal should be to maintain muscle performance through better nutrition and exercise, as appropriate, especially in the aged population and hemodialysis patients.
  - Useful websites for nutritional information and exercise guidelines:
    https://www.nutrition.gov/life-stages/seniors
    http://www.nhs.uk/Livewell/fitness/Pages/physical-activity-guidelines-for-adults.aspx
    https://www.cdc.gov/physicalactivity/basics/older_adults/
- Because starvation for any reason is associated with emergence of anorexia, interventions should include strategies to increase appetite.
  - Helpful information for managing decreased appetite:
    https://my.pearlpoint.org/resources/loss-of-appetite-during-cancer-treatment
    https://www.cancer.org/treatment/treatments-and-side-effects/physical-side-effects/eating-problems/poor-appetite.html

Protocols

- **Detecting Akt activation**. As a measure of IIS function, the phosphorylation state of Akt and other kinases can be determined by western blotting with specific monoclonal antibodies.
- **Monitoring FOXO activation**. Activated FOXO transits from the cytoplasm to the nucleus and this can be detected by immunofluorescence staining with appropriate antibody reagents.

Dictionary of Terms

- **Anorexia nervosa** – An eating disorder characterized by failure to maintain normal body weight, excessive caloric restriction, and disturbances in the perception of body image.
- **Autophagy** – Proteolytic degradation of organelles and proteins via the lysosomal pathway in cells.
- **Epigenetics** – Nongenomic changes in DNA (e.g., cytosine methylation) that regulate expression of marked genes.
- **Phosphorylation** – A modification of proteins by addition of phosphate to serine or threonine residues that alters the function of the phosphorylated protein.
- **Sarcopenia** – Prominent loss of muscle mass and function often associated with aging.

Summary Points

- The major components and function of the IIS-FOXO-AMPK-mTOR pathway have been conserved from yeast to man.
- This system has been adapted in higher organisms to coordinate energy production and usage by muscle and brain, to reduce competition between these tissues for limited energy substrates and maintain optimum function.
- Chronic starvation causes sequential metabolism of available energy stores – from glycogen (glucose), and amino acids in muscle to adipose tissue (fatty acids and ketone bodies).
- Muscle proteolysis during starvation is both a positive factor, through contribution of glucogenic amino acids, and a negative factor, through excessive autophagy, which must be tightly regulated to prevent muscle wasting.
- Either too little or too much activity of the IIS pathway can be detrimental for muscle performance during chronic food deprivation.
- Evolution of the starvation response has entailed a downside as well, namely emergence of eating disorders (anorexia nervosa) and obesity/diabetes.

- The IIS-FOXO-AMPK-mTOR pathway offers promising targets for therapeutic intervention aimed at preserving muscle performance in syndromes associated with muscle wasting.

Defining and Assessing Skin Changes in Severe Acute Malnutrition (SAM)

67

Sofine Heilskov, Christian Vestergaard, and Mette Soendergaard Deleuran

Contents

Abstract

Specific skin changes in severe acute malnutrition have been known since the earliest publication on the subject in 1933. They vary from mild dryness or pigmentary changes to severe and widespread erosions. A common standardized way to document the skin changes observed in severe acute malnutrition is still under development. Currently five specific skin changes, characteristic to severe acute malnutrition, have been identified in African children. There is no knowledge of the global prevalence, but most reports on severe skin affections are from sub-Saharan countries.

The etiology is still unknown and the recommendations on treatment are mostly based on expert opinion. Skin changes in severe acute malnutrition have proven to be a prognostic marker for the risk of death. The mortality rate for patients treated for severe acute malnutrition is persistently high and thus the skin is a target for new treatment approaches. The skin is easily accessible for administration of treatment and assessment and is potentially a good additional target to the existing treatment protocols.

SAM	Severe acute malnutrition

Introduction

The skin is the largest organ of the body. It acts as our first-line defense against pathogens, it contributes to the regulation of body temperature and water balance, and it is an important part of the sensory system. The skin is an important clinical tool in accessing the health status of a patient and in the diagnosis of many illnesses that are reflected by dermal changes.

Patients suffering from malnutrition may develop skin changes as a sign of single nutrient deficiency. These skin changes will be referred to as *single nutrient-specific skin changes*. In the case of severe acute malnutrition (SAM) a patient may develop characteristic skin changes which have not yet been attributed to one specific dietary deficiency and these are considered unique to SAM. These characteristic skin changes will be referred to as *SAM specific skin changes*. SAM-specific skin changes can be severe and widespread, and new research has found that they have prognostic value for the patient (Heilskov et al. 2015).

Skin changes in patients suffering from malnutrition have been described in the scientific literature since the early publications on malnutrition (Williams 1933). Despite this there is still no verified explanation to the etiological background for SAM-specific skin changes, and their impact on prognosis still needs to be further elucidated. Additionally, suitable treatment directed specifically against the skin changes has yet to be explored. As skin in SAM is so poorly investigated, this is a

potential focus area for improvement of the treatment of SAM and lowering of the persistently high mortality rates. The clinical assessment of the skin is easy and there is no need to involve expensive analytic methods. It is therefore a relevant clinical tool to be used in low resource clinics.

The geographical distribution is not yet fully mapped, but reports on skin changes tend to come from the African continent. An approach to develop a common language using dermatological terminology has only recently been published (Heilskov et al. 2015). Five different skin signs were identified as specific to SAM. These results are based on Ugandan children and therefore further investigation is needed to generalize these findings on a global level.

Focus areas of this chapter are:

- Etiology and pathogenesis
- Histopathology
- Diagnosis and clinical manifestations of SAM specific skin changes
- Review clinical management options and prognosis
- Present two clinical protocols supporting proper assessment and monitoring of the skin changes

The sparse research literature on SAM and skin affection mainly focuses on preschool children. Therefore, most of the research cited in the current chapter is based on study subjects of the age of 6–59 months.

Etiology and Pathogenesis

The patho-physiological background for the skin changes in SAM is poorly understood. The clinical manifestation of the skin changes seems to be unique to SAM. Still, descriptions of skin changes in SAM tend to highlight similarities with known single nutrient deficiencies. The sparse research on the subject has focused on mechanisms in single nutrient deficiencies, but studies have not yet proven the skin changes to be connected to one nutrient alone. In patients who survive stabilization and who recover on therapeutic foods, rich in vitamins, minerals, and fatty acids, the result is healing of the skin changes without serious sequelae. A clinical example of this is shown in Figs. 1 and 2.

Etiological Focus Areas

Giving an overview, of what is known and what has yet to be explored in the search for an etiological explanation for the skin changes in SAM, is challenging. A standardized characteristic, using dermatological terminology, has only recently been published (Heilskov et al. 2015). This common language is only based on African children and thus needs to be generalized to other skin types and cultural

Fig. 1 Severe skin changes in a Ugandan patient admitted to hospital, with severe acute malnutrition and generalized edema (**a**). (**b**) The same patient after 13 days of treatment with milk-based diets (F75 and F100). (**c**) And the patient before leaving hospital, 28 days after admission to hospital. Pictures are provided by the authors

settings. Therefore, we must settle for the term "skin changes" vs. no skin changes, when considering results on the etiological research.

Edema-Specific Skin Changes

Skin changes are commonly mentioned as a clinical sign of kwashiorkor (of which edema is a diagnostic criteria), and it has been suggested that some skin changes are only seen in edematous SAM. This has not yet been systematically investigated. One study found the three stages of bullae-erosion-desquamation to be edema specific (Heilskov et al. 2015). In etiological research, some studies have concluded that measured nutrients were lower in edematous patients (Giovanni et al. 2016) and even lower in those with skin affection (Golden and Golden 1979; Vasantha 1969; Vasantha et al. 1970; Wolff et al. 1984), suggesting that the state with edema could proceed to skin changes.

Amino Acid Deficiency

It has been suggested that the skin could play a role as a protein reserve, like muscles upholding the function of other tissues, during starvation (Waterlow et al. 2006). To answer this question more research on epidermal protein turnover, compared to other tissues during starvation, must be made.

A theory on impaired maturation of collagens and cross-linking of fibers in the skin of edematous SAM patients has been suggested. This is based on the findings of an increased proportion of labile collagen in edematous patients. Supporting this theory, the same authors found lowered levels of both collagen and noncollagen

Fig. 2 Severe skin changes in a Ugandan patient admitted to hospital, with severe acute malnutrition (**a**). (**b**) The same patient, stabilized after 6 days of treatment with milk-based therapeutic diet (F75) and antibiotics. (**c**) After 23 days, the patient is shifted to F100. (**d**) Before leaving hospital, 31 days after admission to hospital. Pictures are provided by the authors

nitrogen in the skin of children with edematous SAM, compared to healthy controls, and that levels decreased with the severity of skin lesions. Furthermore, analysis of skin from SAM patients showed decreased levels of several amino acids (proline, tyrosine, and glycine) in those with skin changes compared to those without. The levels of these amino acids also decreased with the severity of the skin changes. Glycine and proline being a consistent part of the triple helical structure of collagen connect these findings to the hypothesis (Vasantha 1969; Vasantha et al. 1970).

Low availability of methionine, a sulfur-containing amino acid, has been suggested to cause the changes in skin and hair that is seen in SAM by impairing the creation of sulfur bonds in keratin (Roediger 1995). The connection to the sulfur amino acid has been mentioned in other studies (Jahoor et al. 2008; Jahoor 2012; Amadi et al. 2009), but the theory has not yet been properly investigated. Plasma levels of methionine have been found to be lower in SAM patients compared to stunted controls and the lowest levels were found among those with edema (Giovanni et al. 2016).

As methionine is essential in the initiation of protein synthesis, it would be surprising if the effect of methionine depletion was restricted only to affect keratin synthesis. Inadequate amounts of methionine should theoretically affect stability of

secondary and tertiary protein structures in general. Furthermore, as part of the coenzyme s-adenosyl methionine, methionine depletion would have effect on the regulation of several metabolic processes.

Skin changes did play a central role in a study on dogs fed a diet devoid of methionine. Apart from weight loss and anorexia, the study subjects showed evidence of a marked dermatitis (Milner 1979).

Fatty Acids

Essential fatty acid deficiency (EFAD) is accompanied by dry and scaly skin (Collins et al. 1971). Severe cases show weeping erosions in the flexural folds (Braun-Falco et al. 2009). A study of whole blood samples from children with SAM showed a different fatty acid balance compared to healthy controls. This included a lower n-6: n-3 ratio in the SAM patients. Arachidonic acid levels have been found to be lower in edematous SAM compared to nonedematous patients (Leichsenring et al. 1995; Wolff et al. 1984) and to be highly correlated with the presence of skin changes (Wolff et al. 1984). Animal models studying EFAD have shown that an impaired cutaneous permeability barrier due to EFAD causes a 50% increase in DNA synthesis of the skin, reflecting epidermal hyper proliferation (Proksch et al. 1991). This is in contrast to findings of lowered total protein and DNA content of the hair, in malnourished patients (Bradfield 1972).

Niacin Deficiency (B3)

Skin changes in SAM have been suggested to be a variant of pellagra caused by niacin deficiency (Stannus 1935). The skin changes in pellagra forms a symmetrical, sharply bordered erythema developing into exudative eruptions restricted to sun exposed areas such as hands and neck (Casal's neckless) (Hegyi et al. 2004). Other clinical features of pellagra such as diarrhea are common clinical features in fulminant SAM. The mood changes seen in children with SAM could also be a clinical expression of the dementia seen in pellagra. This thesis has not yet been confirmed in a clinical setting where the skin changes are successfully treated with nicotinic acid (Ground 1957; Trowell 1954). One study found decreased urinary excretion of N1-methylnicotinamide, compatible with pellagra, in seven out of nine adults with various degrees of malnutrition and additional skin changes of lower extremities (Maltos et al. 2015).

In a recent publication serum, tryptophan levels were found to be decreased in patients with edematous SAM (kwashiorkor) compared to those with nonedematous SAM (marasmus). This difference was one of the ten most distinguishing features when comparing the two patient groups (Giovanni et al. 2016).

Deficiency of other vitamins in the B group has not yet been investigated.

Zinc Deficiency

In acrodermatitis enteropathica, where the intestinal absorption of zinc is impaired, the isolated consequences of zinc deficiency can be seen. Dermatological features are dermatitis, xerosis, and alopecia evolving into crusty and sharply demarcated erosions. Other symptoms are stunting, diarrhea, anorexia, and impaired cognitive

function. All of which are features observed in SAM. Low plasma levels of zinc have been described in edematous SAM. In this study, an insignificant tendency for lower levels among patients with skin changes was noted (Golden and Golden 1979).

Histopathology

There are only few studies on the histo-pathological changes of SAM, but they consistently describe an epidermis with changes of parakeratosis and acanthosis indicating a rapid cell turn-over. The dermis show changes characteristic of inflammation with papillary edema and a tendency to lymphocytic inflammation. Table 1 gives an overview of the histological cohort studies in SAM (Rangam et al. 1962; Sims 1968; Thavaraj and Sesikeran 1989).

Diagnosis and Clinical Manifestation of SAM Specific Skin Changes

Skin assessment is performed on admission to hospital. When a patient with SAM presents with skin changes, it is to be considered as SAM with medical complications (see treatment).

The patient must be naked to estimate the body surface area (BSA) affected. A photo protocol can be used to monitor the skin status during treatment and as a tool for registration of data in research setups (Protocol, Fig. 10).

Setting:

- Ensure warm room temperature to avoid hypothermia
- Ensure privacy
- Ensure involvement of the caretaker when assessing a child
- Involve a local healthcare staff as assistant, if you cannot speak the local language

SAM Specific Skin Changes

Five specific skin changes in SAM have been identified, in a recent dermatological publication on skin changes in Ugandan preschool children (Heilskov et al. 2015):

- Telogenic effluvium
- Pigmentary changes (hyper- and hypopigmentation)
- Ichthyosiform skin changes (grade 1–3)
- Lichenoid skin changes (grade 1–3)
- Various stages of bullae, erosions, and desquamation (grade 1–3)

Table 1 Overview of histological findings in biopsy material from skin in severe acute malnutrition. First published in JEADV 2014 (Heilskov et al. 2014) (With permission from publisher. Licence number 3933660523976)

Study	Epidermal findings	Dermal findings	Study subjects and material
(Rangam et al. 1962**) cohort study**	In areas of athrophy, the entire thickness exist of *stratum granulosum* and -*lucida* and there are no kerato-hyaline granula	*Papillary layer* shows oedematous thickening, separation of fibrils and fragmentation	31 African children
			Oedematous malnutrition
	Increase in alkaline phosphatase. Placed in a band-like appearence in *stratum basale* and -*spinosum*	Generalized infiltration of histocytes, especially in the *papillary layer*	Biopsy from crus and lateral abdomen
	Displacement of cells and loss of cohesion in the basal layer	Elastic fibres show fragmentation and clumping	Light microscopy
		Few sweat and sebaceous glands	
(Sims 1968**) cohort study**	Reduced overall thickness	No observations	15 Zulu children, Durban
	Reduced thickness of *stratum corneum*		Oedematous malnutrition
	Reduced thickness of *rete Malpighi* (*basale, spinosum, granulosum*)		Biopsy from medial side of the axilla. Area with no visible skin affection
	Reduced length of desmosomes		Electron- and light microscopy
(Thavaraj and Sesikeran 1989**) cohort study**	Exaggeration of *stratum corneum*	Atrophy of hair bulbs	20 African children
	Atrophy of *stratum granulosum* and -*spinosum*		Mixed oedematous and non-oedematous malnutrition
	In subjects with dermal oedema collagen was reduced and there was crowding of elastic fibres		Biopsy from less affected areas
			Light microscopy

The clinical manifestation can be a mixture of the five skin changes (Fig. 3). Therefore, the systematic clinical score for SAM specific skin changes, SCORDoK (Protocol, Fig. 9), can be used to standardize the registration of the skin changes.

The presence of lichenoid skin changes has shown to be an independent predictor of death and the hazard ratio (HR) increases with severity of the lesions (Heilskov et al. 2015).

Fig. 3 Features in skin changes, related to severe acute malnutrition, on admission to hospital. Severe acute malnourished Ugandan child, complicated by oedema and severe skin involvement with mixed skin changes: Lichenoid skin changes grade 3 and bullae, erosions and desquamation grade 2. Hyperpigmentation is seen in relation to lichen and erosions. Scalp hair has been razed of. Pictures are provided by the authors

Telogenic Effluvium

Telogenic effluvium is loss of telogen hair caused by a disturbed hair cycle (Fig. 4). This can vary from mild thinning to total hair loss. Telogen hairs are in a preserved state of rest opposite to growing hairs in the anagen phase. During research on hair, it was noted that the hair was easier pulled out in malnourished patients. The hair bulbs had a smaller diameter and this was directly related to a lower weight for age. A higher proportion of hair bulbs were in the resting state (telogen phase) in the case of

Fig. 4 Telogenic effluvium. Various manifestations of increased telogenic effluvium, also showing depigmentation and straightening of the hair (**a**, **b**, **c**). First published in JEADV 2015 (Heilskov et al. 2015) (With permission from publisher. Licence number: 3,933,580,522,015)

malnutrition (Bradfield et al. 1968). Telogenic effluvium is known to be secondary to changes in several physiological mechanisms that are expected to be compromised in SAM and related to co-morbidities such as infections (Braun-Falco et al. 2009).

SAM-related telogenic effluvium is often combined with depigmentation and/or straightening of curly hair. The *flag sign*, where light bands in the hair reflect the nutritional status of a child over time, can be observed. Changes in hair status are connected to hair cycle and thus are slow. It takes 2–5 months before a telogen hair is shed, after the shift from the anagen phase. Telogenic effluvium is therefore expected to be a sign of more chronic malnutrition. It has also been noticed that changes in the status of the hair are not seen during the short time of recovery from SAM in a hospital (Heilskov et al. 2015).

Pigmentary Changes

Pigmentary changes (Fig. 5) are hyper- and hypopigmentation. The change in pigmentation can be general, as seen in systemic disease, or well-defined areas. In SAM, pigmentary changes often follow the other SAM-specific skin changes but can be the only skin change in a SAM patient.

Ichthyosiform Skin Changes

Ichthyosis is generalized scaling of the skin and is histologically characterized by hyperkeratosis. Ichthyosis can be coupled to the protein synthesis of the keratinocytes, as in ichthyosis vulgaris, or the lipid components of the extra-cellular matrix, as in X-linked recessive ichthyosis, both resulting in retention hyperkeratosis, which is abnormal shedding of the corneal layer (Braun-Falco et al. 2009; Williams 1992). Grades of affection in ichthyosiform skin changes in SAM are shown in Fig. 6.

Grade 1 is characterized by dry skin, hyperpigmentation, and accentuation of the lines of the skin. Mild shedding of fine grey scales is observed in few areas. In **grade 2**, the dark skin turns greyish and the dusty scales loosen easily. Areas with

Fig. 5 Pigmentary changes. Pigmentary changes in SAM. Hypopigmentation caused by desquamation (**a**, **b**) and erosion (**b**, **c**) and hyperpigmentation in lichenoid skin changes (**c**). First published in JEADV 2015 (Heilskov et al. 2015) (With permission from publisher. Licence number: 3,933,580,522,015)

Fig. 6 Ichthyosiform skin changes. Grades of affection in ichthyosiform skin changes on extremities. Grade 1 (**a**), grade 2 (**b**), grade 3 (**c**). First published in JEADV 2015 (Heilskov et al. 2015) (With permission from publisher. Licence number: 3,933,580,522,015)

hyperkeratosis appear. In these areas, the scales are more infiltrated and bigger. In **grade 3** scales are hard, shiny, and slightly hyperpigmented. Erosions appear where the scales are shed.

Lichenoid Skin Changes

Lichenoid skin change is a term for skin changes that clinically resemble the prototype lichen planus. Lichen is noninfectious and is histologically characterized by lymphocytic infiltrate at the epidermal function forming a band-like pattern.

Fig. 7 Lichenoid skin changes. Grades of affection in lichenoid skin changes. Grade 1 (**a**), grade 2 (**b**), grade 3 (**c**). First published in JEADV 2015 (Heilskov et al. 2015) (With permission from publisher. Licence number: 3,933,580,522,015)

Papules tend to fuse into flat-topped patches bordered by the skin lines. There are many clinically variants of lichen.

In research on SAM, no authors have commented on pruritus, but a distribution of the skin changes to areas of mechanical stress rather than sun-exposed areas has been noted (Heilskov et al. 2014). Grades of affection in lichenoid skin changes in SAM are shown in Fig. 7.

Grade 1 is characterized by small ($\leq$0.5 cm) papules. These are hyperpigmented and irregular on the surface but not hyperkeratotic. The smallest (1–2 mm) are purple-brown. In **grade 2**, the areas affected are bigger and coalesce to highly hyperpigmented plaques of various sizes. These can be hyperkeratotic and the lines of the skin are accentuated. The border is irregular, but well defined and in these areas, the original papules can be identified. Plaques can loosen and peel off. In **grade 3,** the plaques are more infiltrated and rigid and the surface can be shiny. Plaques peel off leaving thin epidermis or erosions. The whole body can be affected, but palms and soles are spared.

Bullae, Erosions, and Desquamation

A bulla is a raised circumscribed lesion containing serous fluid and measuring $>$5 mm. The involved layers of the epidermis can vary and no histological research has yet been made concerning the bullae in SAM. A bulla tends to rupture and the outer layer desquamates from the skin, leaving the epidermis exposed as an erosion. An example of bullae, erosions, and desquamation in SAM is shown in Fig. 8. As the erosions affect primarily the epidermis, it tends to heal without scarring.

Severity grade of this SAM-specific skin change is defined by the affected BSA. Bullae, erosions, and/or desquamation is observed on the body, affecting $<$5% of the body in **grade 1**, from 5 to 30% in **grade 2** and more than 30% in a **grade 3**.

Fig. 8 Bulla, erosion and desquamation. Bullae, erosions and desquamation on lower extremities (**a**, **b**, **c**). First published in JEADV 2015 (Heilskov et al. 2015) (With permission from publisher. Licence number: 3,933,580,522,015)

The cut-off values for grade of affection are not based on experience on outcome or investigation on prognosis.

Differential Diagnosis

Burns, diaper dermatitis, atopic eczema, staphylococcal scalded skin syndrome (SSSS), and skin changes due to a single nutrient deficiency.

Skin Changes in Single Nutrient Deficiencies

A malnourished patient is most likely to be lacking several vitamins that are important for maintenance of healthy skin. Still the clinical skin manifestation can be dominated by the signs of a single nutrient deficiency of which niacin (B_3), zinc, some amino acids, and essential fatty acids have been described. The fat-soluble vitamin A, water-soluble riboflavin (B_2), pyridoxine (B_6), and vitamin C and biotin are also connected to skin and mucosal changes. The diagnosis of the single nutrient deficiencies, based on clinical findings, is difficult as the clinical appearance is often less characteristic.

Clinical Management Options

Skin changes in SAM account for one criterion of complicated SAM and these patients are preferably referred to hospital care. There are currently few well-documented recommendations on treatment of skin changes in SAM.

Table 2 Focus areas in the hospital treatment of skin changes, complicating severe acute malnutrition

Milk based therapeutic food (Ashworth et al. 2003; WHO and UNICEF 2009).	Admission and stabilisation: F75, containing 75 kcal/100 ml and 0.9 g protein/100 ml.
	After stabilisation: F100, containing100 kcal and 2.9 g protein/100 ml.
	Give the food orally ore use nasogastric tube. Never parenteral substitutes.
	Encourage continued breastfeeding.
Possible regimes for topical treatment (Ashworth 2005; Ashworth et al. 2003).	Zinc (Golden et al. 1980) and castor oil ointment, or petroleum jelly or paraffin gauze) to raw areas.
	Soak the affected areas for 10 min/day in 0.01% potassium permanganate solution. Disadvantages of this regime has been discussed (Golden and Grellety 2012).
	Application of oils rich in essential fatty acids, like sunflower seed oil (linoleic acids) has proven to approve skin barrier function, enhance weight gain and lower the risk of skin infection in preterm infants (Salam et al. 2013). This regime is for ulcer-free skin affections and is, for now, to be considered as a low-cost alternative to the above mentioned.
Antibiotics (Ashworth 2005; WHO 2013; WHO and UNICEF 2009).	Gentamicin IV or IM (7.5 mg/kg), once daily for 7 days, plus ampicillin IV or IM (50 mg/kg), every 6 h for 2 days.
	Followed by amoxicillin oral (15 mg/kg), every 8 h for 5 days.

Recommendations on treatment of SAM complicated by skin changes are summarized in Table 2 (Ashworth 2005; Ashworth et al. 2003; Golden and Grellety 2012; Golden et al. 1980; Salam et al. 2013; WHO 2013; WHO and UNICEF 2009).

Prognosis and Complications

Complicated SAM has a high mortality rate even when being managed in hospital. Known complications in SAM that theoretically can be related to a broken skin barrier are hypothermia, dehydration, electrolyte imbalance, and infection/sepsis.

Three studies have confirmed skin changes to be a predictor of death (Becker et al. 2005; Heilskov et al. 2015; McLaren et al. 1969). In a characteristic of specific skin changes in SAM, it was found that lichenoid skin changes significantly lowered the chance of survival and that the HR increased with the grade of severity (Table 3) (Heilskov et al. 2015). It was also revealed that lichenoid skin changes could be used in a logistic regression model, to forecast death when admitting SAM patients to hospital. The misclassification error of the model, constructed of known risk factors, was improved when adding lichenoid skin changes as a variable.

Table 3 P-values from Cox-regression for correlation between six skin predictors and risk of death (hazard). From the table, it is seen that lichenoid skin changes significantly lower the chance of survival and that the risk of death relative to healthy controls, increase with the grade of severity (hazard rate, HR) Data are from JEADV 2015 (Heilskov et al. 2015) (With permission from publisher. Licence number: 3,933,580,522,015)

Predictor	Hazard ratio	Unadjusted model (0/1)	Adjusted model (0/1)[a]	Unadjusted model (grade 0–3)	Adjusted model (grade 0–3)[a]
	[HR]	[P]	[P]	[P]	[P]
Telogenic effluvium[b]	0,65	0,64	0,58	–	–
Pigmentary changes[b]	1,26	0,42	0,73	–	–
Ichthyosiform skin changes^		–	–	–	–
Lichenoid skin changes		0,34	0,23	**0,03**	**0,02**
Grade 1	^				
Grade 2	6,00				
Grade 3	13,79				
Bullae – erosions – desquamation		0,30	0,38	0,09	0,35
Grade 1	^				
Grade 2	2,65				
Grade 3	3,22				
Body surface area[c]	–	–	–	0,30	0,42

[a]Adjusted for age, sex and oedema
[b]Telogenic effluvium and pigmentary changes are both dichotomous (1/0) variables and there are therefore no p-value for these as graded predictors
[c]Body surface area is a continuous predictor (0–100%) and therefore there is no p-value for a stratified analysis.

Policies and Protocols

Protocol-Assessing Skin Status

Standardized Clinical Score of Skin manifestations in SAM-SCORDoK

Comparability of results and objectivity in registration are important factors when reporting research results. This protocol is a tool for registration of the characteristic skin changes in SAM, with an estimate of severity and affected BSA.

Setting:

- It is important to have sufficient light in order to evaluate the skin changes.
- Ensure warm room temperature to avoid hypothermia.

- Ensure privacy.
- Ensure involvement of the caretaker when assessing a child.
- Involve a local healthcare staff as assistant, if you cannot speak the local language.

Figure 9 below is a guide to register the SAM-specific skin changes and to estimate affected BSA in preschool children. Be aware that the BSA distribution is different in adults, children, and babies.

Protocol-Standardized Photo Protocol

Photography is traditionally used in the dermatological field for reporting and registering skin changes.

This photo protocol is a practical tool to monitor the development of the skin changes during treatment and when monitoring intervention.

A good picture protocol is also an advisable supplementation to a study setup, to ensure objectivity and when later assessing intra- and interobserver variability. Dermatologists are often not available in developing countries and the use of photos in telemedicine requires standardized picture of good quality.

Setting:

- Assure informed consent before taking pictures
- Use a camera of good quality
- Establish good light and a matt colored background
- Ensure warm room temperature to avoid hypothermia
- Ensure privacy
- Ensure involvement of the caretaker when assessing a child
- Use the assistance of a local healthcare staff, if you cannot speak the local language

A guide to a systematic photo protocol, using the preschool child as an example, is shown below (Fig. 10).

Dictionary of Terms

- **Severe acute malnutrition** – It is the acute form of malnutrition usually affecting children and is characterized by low weight for height (wasting) or bilateral pitting edema. The diagnosis is supported by anthropometric measures and a history of insufficient food intake.
- **Body surface area** – It is widely used in the dermatology to reflect the grade of affection in skin disease. Best known is the “Rule of Nines” chart, used in the assessment of skin damage from burns.

SCORDoK

- **Mortality rate** – It is a measure of deaths per unit time, in a given population.
- **Hazard ratio** – It is used in survival analysis to reflect the risk of death in a study cohort relative to a control group. If the treated cohort has a mortality rate twice as high than the control group, the hazard ratio equals 2. A hazard ratio > 1 indicates increased risk of death in the cohort.
- **Logistic regression model** – It estimates a probability of an outcome, for example death. It is based on binary variables and gives the opportunity to conclude whether the presence of a variable increases the risk of the current outcome.

Summary Points

- This chapter focuses on characteristic skin changes in severe acute malnutrition.
- The sparse research on the subject has focused on mechanisms in single nutrient deficiencies, but studies have not yet proven the skin changes to be connected to one nutrient alone.
- Focus areas in the etiological research have been amino acid deficiency, essential fatty acid deficiency, niacin deficiency (B_3), and zinc deficiency.
- Five skin changes have been identified as specific to severe acute malnutrition (telogenic effluvium, pigmentary changes, ichthyosiform skin changes, lichenoid skin changes and stages of bullae, erosions, and desquamation).
- Skin changes in severe acute malnutrition can be severe and comprehensive and research has found that they increased risk of death if present.
- Lichenoid skin changes significantly lower the chance of survival and the hazard ratio increases with the grade of severity.
- Skin changes in severe acute malnutrition are one criterion of complicated severe acute malnutrition, and these patients are preferably referred to hospital care for intravenous therapy with antibiotics, in addition to therapeutic feeding.
- The standardized clinical score of skin manifestations in severe acute malnutrition, SCORDoK, ensures a standardized system to monitor the skin during treatment and secure comparability of results when reporting research observations.
- A photo protocol is a practical tool to monitor the development of the skin changes during treatment, when monitoring intervention, and is essential in tele-medical communication.
- The etiology of the skin changes is unknown and suitable treatment, based on research results, has yet to be developed.
- The epidermis has changes of parakeratosis and acanthosis indicating a rapid cell turn-over.
- The dermis show changes characteristic of inflammation with papillary edema and a tendency to lymphocytic inflammation.
- The geographical distribution is not yet mapped out but reports on skin changes tend to come from the African continent.

risk or already qualify as being malnourished, with 30–40% of hospitalized patients experiencing further nutritional decline during their hospital course. When left unnoticed, malnourishment, especially in the hospitalized patient, is associated with several negative sequelae, including immunosuppression, higher infection rates, increased muscle loss with delayed functional recovery, impaired wound healing, increased risk of treatment complications, fewer ventilator-free days, longer hospital stays, higher overall treatment costs, and increased mortality rates. Several nutritional risk scoring systems exist to help clinicians risk-stratify these patients upon admission, with the goal of starting early nutritional therapy when deemed necessary.

Objectives

- Overview of malnutrition and its effects on hospitalized and critically ill patients
- Review of nutritional assessment
- Recognize the importance of early nutritional support in patients
- How and when to initiate nutritional therapy
- Review nutritional goals in various clinical conditions
- Postdischarge nutritional maintenance

Malnutrition is a broad term used to describe any imbalance in nutrition that can develop as a result of dietary intake, increase in basal requirements, poor absorption, excessive nutrient losses due to an underlying disease state, or any combination of such factors. In 2012, the Academy of Nutrition and Dietetics and the American Society for Parenteral and Enteral Nutrition released a consensus statement recommending an etiology-based approach for the detection of malnutrition in adults. Three etiology-based definitions fall

under this guideline: starvation-related malnutrition without inflammation, chronic disease-related malnutrition with mild to moderate inflammation, and acute disease- or injury-related malnutrition with marked inflammation. These definitions reflect that inflammation, whether chronic or acute, acts as an underlying factor in the pathogenesis of malnutrition associated metabolic alterations, further stressing the importance of early nutritional therapy in critically ill.

While traditionally thought of as adjuvant care, nutritional goals have become more focused to prevent cellular injury from oxidative stress and improve overall immune response, abating the metabolic response to bodily stresses endured in critical illness. In this chapter, we will discuss several methods clinicians can implement to achieve these goals.

Effects of Energy Deficiency

Upon admission, 15–60% of hospitalized patients are at risk or already qualify as being malnourished, with 30–40% of hospitalized patients experiencing further nutritional decline during their hospital course (Mauldin and O'Leary-Kelly 2015). More often than not, patients had poor nutritional intake in the days leading up to admission and often continue to receive poor nutritional support while admitted. This cycle leads to weight loss and further nutritional decline, making it difficult for patients to ultimately recover from illness Naber et al. 1997; Norman et al. 2008).

Over recent years, it has become increasingly apparent that proper nutritional balance plays a vital role in aiding the recovery of hospitalized patients and the critically ill. Several prospective observational studies have shown that malnutrition is frequently associated with several negative outcomes in hospitalized patients, including immunosuppression, higher infection rates, increased muscle loss with delayed functional recovery, impaired wound healing, increased risk of treatment complications, fewer ventilator-free days, longer hospital stays, higher overall treatment costs, and increased mortality rates (Norman et al. 2008; Hiesmayr et al. 2009).

Critical illness is a catabolic stress state characterized by a systemic inflammatory response that increases the body's nutritional needs from baseline requirements. When present, critical illness can lead to multi-organ dysfunction, exacerbating many of the negative outcomes already associated with underlying malnutrition, thus resulting in a higher likelihood of adverse outcomes. Nutritional therapy is vital to abate the inflammatory catabolism of lean body mass and the associated poor prognostic and economic outcomes.

Assessment of Nutritional Risk

Integral to the care of the critically ill patient is an initial assessment of malnutrition or risk thereof. A simple evaluation can be done with history and physical, however, several nutritional risk scores can be used for a more robust assessment. While

(i) Score of Disease Severity	
Score 1	General malignancy, hip fracture, long-term hemodialysis, diabetes, chronic disease (COPD, cirrhosis, etc)
Score 2	Hematologic malignancy, severe pneumonia, major abdominal surgery, stroke
Score 3	Head/brain injury, bone marrow transplant, intensive care patients with an APACHE score higher than 10
(ii) Score of the Impaired Nutrition Status	
Score 1	Weight loss > 5% over 3 months Food intake below 50-75% of normal requirement in preceding week
Score 2	Weight loss > 5% over 2 months Food intake below 25-50% of normal requirement in preceding week, BMI < 20.5 with poor general condition
Score 3	Weight loss > 5% over preceding month Food intake below 25% of normal requirement in preceding week BMI < 18.5 with poor general condition
Score of the Age	
Score 1	> 70 years old

Fig. 1 Nutritional Risk Score (NRS-2002); Risk screening score = Score of severity of disease + Score of impaired nutrition status + Score of age

nutritional assessment scales such as the Mini Nutritional Assessment, Malnutrition Universal Screening Tool, Short Nutritional Assessment Questionnaire, Malnutrition Screening Tool, and the Subjective Global Assessment may suffice for initial admission screening for hospitalized patients, they do not take disease severity into account. Due to this, the Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (ASPEN) recommend the use of the Nutritional Risk Score (NRS-2002) or NUTRIC score for all critically ill patients thought to be high risk for or whom are admitted with malnutrition (Taylor et al. 2016).

The NRS-2002 (Fig. 1) is a validated scoring system supported by several randomized controlled studies in predicting postoperative complications. Patients are considered "at risk" with a score > 3 based on components such as severity of disease, recent weight loss, baseline body mass index, general food intake, and age (Taylor et al. 2016).

The NUTRIC score (Fig. 2) is a nutritional risk assessment tool designed to quantify critically ill patients' risk of malnutrition related morbidity and mortality that may be preventable with aggressive, early nutritional therapy. Notably, it was developed and validated specifically for ICU patients, taking six main factors into account: age, APACHE II score, baseline sequential organ failure assessment score (SOFA), existing comorbidities, length of hospital stay prior to ICU admission, and

Variable	Range	Points
Age	< 50 years old 50-75 years old >75 years old	0 1 2
APACHE II	< 15 15-20 20-28 >28	0 1 2 3
SOFA	< 6 6-10 > 10	0 1 2
Number of Co-Morbidities	0-1 ≥ 2	0 1
Days from hospital to ICU admission	0-1 > 1	0 1
IL-6	0-400 ≥ 400	0 1

Fig. 2 NUTRIC Score; Scores associated with worse clinical outcome vary depending on availability of IL-6 level. When IL-6 level is available, a score of 6–10 is considered high; a score of 5–9 is considered high when IL-6 is not available. These patients are most likely to benefit from early, aggressive nutritional therapy

interleukin-6 level (if available). Patients are considered high risk if scored ≥6 (≥ 5 if interleukin-6 not available). In a prospective, observational study of 597 patients, Heyland et al. showed an association between high NUTRIC scores and prolonged time on mechanical ventilation as well as mortality rate. While there may be some limitations to this scale, it does serve as a good initial assessment to classify ICU patients that may benefit from early nutritional therapy (Heyland et al. 2011; Taylor et al. 2016).

While outpatient nutritional evaluations may benefit from the use of traditional serum protein markers such as albumin, prealbumin, transferrin, and retinol-binding protein, these markers are not validated in the critically ill patient. Because albumin has a long half life, 2–3 weeks, acute protein deficiency due to critical illness will only gradually affect serum levels. Prealbumin and retinol-binding protein, with half lives of 2–3 days and 11 hours respectively, may show variations related to malnutrition sooner; however, several disease states and the acute inflammatory response can alter these levels irrespective of nutritional status. These proteins may be falsely decreased due to increased vascular permeability in the setting of an acute inflammatory response, thus they may not accurately reflect nutritional status. Similarly, anthroprometrics such as body mass index (BMI), adjusted body weight (ABW), and arm muscle circumference (AMC) are not reliable in this population either, as they do not account for the edema that typically accumulates in the critically ill (Raguso et al. 2003; Whitson and Barrera 2014; Martindale et al. 2009).

Nutritional Therapy

When to Start Nutritional Therapy

As previously discussed, hospitalized and critically ill patients are at nutritional risk, and as such, nutritional therapy should be considered once the patient is deemed hemodynamically stable. For patients with baseline malnutrition or those in a high catabolic state such as that seen in critical illness, nutritional therapy should be initiated within the first 24–48 hours of admission when it is expected that the patient will be unable to voluntarily maintain caloric intake or meet their nutritional needs (Martindale et al. 2009). Several observational studies have shown improved clinical outcomes when nutritional therapy is given during this time period. These studies found that early nutritional therapy was associated with improved maintenance of functional and structural intestinal integrity, thus decreasing the risk of translocation of gut flora, modulation of systemic immunity via GALT within intestinal walls, minimized effects of oxidative stresses leading to decreased activation and release of inflammatory cytokines, and an overall decrease in length of stay, morbidity, and mortality (Kudsk 2002; Jabbar et al. 2003; Kang and Kudsk 2007).

Enteral Versus Parental Nutrition

When nutritional therapy is required, the preferred route is enteral over parenteral infusion. Enteral nutrition presents a significantly decreased rate of infectious complications, and it does not require central line access, further reducing complication risk. Parenteral nutrition may, however, be required in certain circumstances. Patients at high nutritional risk that are unable to tolerate oral diet or enteral nutrition within 5 days of admission and are not expected to be able to do so within the next 7 days may require parental nutrition. However, unless already at high risk of malnourishment, parenteral nutrition has not been shown to provide much benefit in well-nourished patients within the first 5–7 days of hospitalization. Parenteral dependent patients, such as those with short-gut syndrome, should continue with parenteral nutrition upon admission, with the exception of when bacteremia is suspected (Martindale et al. 2009; Taylor et al. 2016).

Supplemental parenteral nutrition may be required in patients of both low and high nutritional risk that are receiving enteral nutrition, yet are unable to meet at least 60% of their energy and protein requirements. However, there is no evidence in the literature that has clearly shown the optimal time to start supplemental parenteral nutrition in such patients. Once initiated, tolerance of enteral nutrition should continually be monitored, with down-titration of supplemental parenteral nutrition until discontinuation as enteral tolerance allows (Martindale et al. 2009; Taylor et al. 2016).

Meeting Energy Needs

The primary goal of any nutritional regimen is to provide sufficient caloric support without overfeeding. When available, indirect calorimetry (IC) is recommended to

determine energy needs. However, elements of ICU care, like mechanical ventilation, renal replacement therapy, and sedation with certain anesthetic agents, may affect it's accuracy. IC also requires invasive monitoring, resulting in a point estimate that may not give an accurate depiction of the patient's overall nutritional requirements (Bartlett et al. 1982; Whitson and Barrera 2014). Thus, when not available or feasible, published, simplistic weight-based equations (25–30 kcal/kg/day) should be used to determine energy needs, as other anthropometric equations have not been validated in the critically ill patient. Regardless of initial method used, energy requirements should be reassessed, at the minimum, on a weekly basis to ensure energy provision is fully optimized. Providers must also be cognizant of any additional caloric intake that may be provided through other treatments, such as dextrose-containing solutions and lipid-based medications like propofol which are commonly used in the ICU setting and contribute to the calculation of any nutritional regimen used to meet nutritional goals (Villet et al. 2005; Alberta et al. 2009; Whitson and Barrera 2014).

Equally as important as adequate overall energy provision is adequate protein delivery. While no evidence exists for the accurate determination of protein needs in the critically ill, many clinicians tend toward the use of simplistic weight-based equations. One could also use nitrogen balance as an estimate of protein turnover, however, this has limited value in the critically ill patient, as several conditions common to this population, including renal failure, burns, and fluid shifts, could alter these levels outside of the expected values one may see in an otherwise healthy patient. For non-critically ill patients, the protein goal is typically to provide 0.8 g/kg actual body weight/day. However, several studies found that despite meeting overall energy requirements, critically ill patients that were given this protein range did not exhibit the same improvement in mortality as those that had higher protein goals, typically in the range of 1.2–2 g/kg/day (Weijs et al. 2012; Plank 2013).

Monitoring Tolerance

Once nutritional therapy has been initiated, the next step is to ensure that patients are tolerating what is being provided. When continuous infusion is initiated, it is typically started at a rate below goal to allow for assessment of tolerance, usually starting at 20–30 ml/hr and increased by 10–20 ml/hr every 4–8hr as tolerated until the goal rate is reached. Multiple studies show that the greatest benefit of nutritional therapy is seen when started within 48 hours of presentation. Treatments common to the critically ill, including mechanical ventilation and use of vasoactive agents, should not be thought to be contraindications to the initiation or continuation of nutritional therapy. Clinical evidence of gastrointestinal function (bowel sounds, flatus, passage of stool, etc) are also not required prior to initiation; on the contrary, the initiation of enteral feeds is likely to promote gut motility (Martindale et al. 2009; Taylor et al. 2016).

Enteral feeds may be held for several reasons, including pausing for planned diagnostic tests and procedures or concern for patient tolerance. Thus, patients will commonly only receive approximately 80% of their prescribed nutritional therapy. Presumed patient intolerance accounts for about 30% of cessations for an average of

8–20% of prescribed infusion time, yet only half of these episodes are true intolerance. Several physical exam findings can be suggestive of patient intolerance of enteral nutrition, including vomiting, diarrhea, abdominal distention, decreased flatus/stool output, high naso/oropharyngeal output, and high gastric residual volumes (Martindale et al. 2009; Taylor et al. 2016).

While several feeding protocols exist, a broad distinction can be made based on methods of achieving goal rate and dealing with intolerance. In the volume-based approach, a target 24 hour rate is determined, and the hourly rate of feeds can then be adjusted, taking into account periods during which feeds were held, in order to meet the established 24 hour goal. The top-down approach, while similar to the volume based approached, also includes methods to enhance tolerance, such as the addition of prokinetic agents, adjustments in feed formulation, and feeding tube placement. Both of these approaches allow providers to correct for nutrition-free periods when feeds had been held, optimizing enteral nutritional delivery and ultimately aiding in meeting daily nutritional goals (Taylor et al. 2016).

A common method used to monitor patient tolerance is the periodic evaluation of gastric residuals, typically performed every 4 hours. The goal should be to minimize pauses in nutritional delivery whenever possible. As such, enteral nutrition should only be held if residuals are greater than 500ml or when lesser volumes are associated with clinical evidence of a change in tolerance. When these criteria are met, feeds should be discontinued until symptoms or residual volumes improve. Studies suggest no correlation between residual volumes less than 500cc and adverse outcomes, however, these patients may benefit from pro-kinetic agents, such as metoclopramide or erythromycin (Taylor et al. 2016).

In additional to high residuals, patients on enteral feeds also commonly develop diarrhea. If this occurs, the first step should be to assess the formulation provided. The common causes include the amount of fiber in the formulas, formula osmolality, mode of delivery (continuous vs bolus), other medications received, and infectious causes (e.g., C.dif). In the absence of infectious processes, an initial step to address persistent diarrhea could be the addition of a mixed soluble and insoluble fiber solution, but this should be avoided if there is thought to be a high risk of bowel ischemia or severe dysmotility. If diarrhea still persists, a small peptide formula can be substituted in the setting of a possible malabsorption process not responsive to the addition of fiber. It is also imperative to remember to monitor the sequelae of persistent diarrhea, such as electrolyte disturbances, dehydration, perianal skin breakdown, and wound contamination, while attempting to correct the underlying cause (Taylor et al. 2016).

Effect of Different Disease States on Caloric Requirements

For the majority of hospitalized and critically ill patients, basic polymeric formulations should be sufficient when initiating enteral nutrition, as the routine use of specialty formulas has not been found to provide any clear benefit in morbidity or mortality. Below we will discuss specific nuances to nutritional therapy for several commonly encountered medical and surgical conditions.

1. Medical
   (a) Sepsis

   Specific studies addressing nutrition in severe sepsis/septic shock are lacking, thus much data has been extrapolated from general data pertaining to all critically ill patients. However, compared to other critically ill patients, this subset is at a higher nutritional risk due to the hypermetabolic state that results from the exaggerated inflammatory response that occurs in sepsis. As such, nutritional therapy should be initiated once fluid resuscitation is complete and the patient is hemodynamically stable. The Surviving Sepsis Campaign published in 2012 recommended giving trophic feeds (10–20 kcal/kg/day) in the initial phase of sepsis, advancing as tolerated within 24–48 hours, with the aim to achieve >80% of determined energy goal within the first 7 days of admission. Protein goals are difficult to determine in septic patients, but current recommendations are to provide 1.2–2 g/kg/day as extrapolated from other critical illness criteria. Energy expenditure varies greatly in states of severe sepsis, thus follow-up nutritional assessments should be performed every 4–5 days to assure adequate nutrition is being provided. Immune modulating formulas supplemented with arginine, eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), glutamine, nucleic acid, and the like are not recommended in sepsis, as no improvement in overall outcomes has been documented. The results of several observational studies would also suggest avoidance of exclusive or supplemental parenteral nutrition, as it seems to be associated with worsening clinical outcomes, including increased infectious rate, longer ICU and hospital length of stay, and longer duration of organ support (renal replacement therapy, mechanical ventilation, etc) (Taylor et al. 2016).

   (b) Diabetes Mellitis

   Given recent multicenter trials comparing tight and moderate glucose control, it is recommended that goals for glycemic control should aim for a range of 140–180 mg/dL in critically ill patients, as discussed in both SCCM and ASPEN guidelines. The Normoglycemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation (NICE SUGAR) study found that tighter glycemic control was found to be associated with increased hypoglycemic episodes and increased overall mortality. Glycemic control can be achieved with a short-acting insulin intermittent sliding scale given in 6 hour intervals, or by regular insulin given as a continuous infusion and titrated hourly based on point of care glucose testing. If hyperglycemia remains difficult to control despite these means, formulas with a lower proportion of calories from carbohydrate may be substituted until glycemic control is achieved (Whitson and Barrera 2014; Taylor et al. 2016).

(c) Respiratory Failure

Patients with existing chronic lung disease may tend toward baseline carbon dioxide retention depending on the degree of alveolar ventilation limitation. It was thus postulated that high carbohydrate diets, associated with a higher respiratory quotient, could raise the V_{co2} which varies in proportion to the fat:carbohydrate caloric load. While providing a higher proportion of calories from fat should theoretically lead to a lower CO_2, it is now likely of little consequence given current recommendations for caloric requirement goals. High-fat/low-carbohydrate enteral formulations had previously been thought to be associated with decreased duration of mechanical ventilation, however, these findings could not be reproduced and were only found clinically significant in instances of overfeeding. Providers should, however, carefully monitor phosphate levels, as phosphate is essential for synthesis of ATP and 2,3 DPG which are vital for normal diaphragmatic contractility and thus optimal respiratory functioning (Whitson and Barrera 2014; Taylor et al. 2016).

(d) Renal Insufficiency/Failure

Patients with poor renal function and subsequent decreased glomerular filtration rate are susceptible to multiple electrolyte abnormalities – hyperkalemia, hyperphosphatemia, hypermagnesemia, and, when oliguric or anuric – are also at risk of fluid overload. Thus, close monitoring and careful consideration is needed when selecting the appropriate nutritional therapy for these patients. Patients with acute kidney injury (AKI) or acute renal failure (ARF) should receive standard formulation, energy requirements, and protein requirements. If significant electrolyte abnormalities do develop, specialty formulations with lower potassium and phosphate may be used. For patients requiring renal replacement therapy, there is a baseline tendency toward lean body mass metabolism, as well as significant amino acid loss during hemodialysis. As such, protein should not be restricted in these patients; on the contrary they may have higher protein requirements, upwards of 2.5 g/kg/day. Nitrogen intake above this has not been shown to give any added benefit and may only serve to increase the rate of urea production in such patients. Similarly, hemodialysis patients also require higher doses of water-soluble vitamins, as these too are removed during hemodialysis (Whitson and Barrera 2014; Taylor et al. 2016).

(e) Hepatic Failure

Nutritional risk in these patients is directly correlated to the severity of liver disease, and they usually tolerate general nutritional recommendations. Calculating energy and protein requirements can, however, be difficult in this population, as they commonly have edema and ascites that can render weight-based formulations inaccurate. While dry weight may be difficult to obtain, it is recommended that ideal or dry weight be used in any predictive equations to determine nutritional needs, though IC should be used whenever available. Although patients with portal hypertension are prone to the

development of hepatic encephalopathy, protein should not be restricted. With appropriate lactulose therapy, patients can usually tolerate typical protein recommendations. There is also no current evidence to suggest that branched-chain amino acids lead to improved outcomes compared to standard protein formulations (Whitson and Barrera 2014; Taylor et al. 2016).

(f) Acute Pancreatitis

The delivery of nutritional therapy in acute pancreatitis is directly based on disease severity. No specialized nutrition is required for patients with mild pancreatitis. Instead, these patients should be advanced to an oral diet as tolerated. However, if any complications occur or the patient remains unable to tolerate oral intake for >7 days, enteral nutrition should be initiated. In moderate to severe disease, enteral nutrition should be initiated at a trophic rate and advanced to goal in conjunction with volume resuscitation, with the goal to reach target energy delivery within 24–48 hours of admission. Enteric nutrition is preferred over parenteral because of the better risk/benefit ratio, and there have been no differences in outcome based on gastric or jejunal enteral tube placement. Standard polymeric formula may be used, as current data pertaining to use of immune-modulating formulas is insufficient. If not tolerated, the formula may be changed to a polymeric formula with small peptides or a nearly fat free elemental formulation. If still not tolerating well, the infusion level may also be diverted more distally within the GI tract, and feeds should be given via continuous infusion rather than bolus. Patients that have inadequate nutrition for ≥7 days or have developed complications (fistula, abscess, pseudocyst, ascites, pain exacerbated by feeds) may require parenteral nutrition to meet their energy requirements (Windsor et al. 1998; Whitson and Barrera 2014; Taylor et al. 2016).

2. Surgical

(a) Severe Burn

Patients that have suffered severe burn injury have notably higher caloric requirements due to the hypermetabolic state that ensues post-injury. These patients should have enteral nutrition started early in their hospital course, within 4–6 hours of injury if feasible. Predictive equations are notoriously inaccurate in burn patients, thus IC should be used whenever available. Despite these high requirements, many burn patients do meet their energy needs when provided 25–30 kcal/kg/day. Both the 2001 American Burn Association and the 2013 SPEN guidelines recommend protein in the range of 1.5–2 g/kg/day, as patients that had received daily protein amounts upward of these were found to have increased rates of protein catabolism. Fluid status should also be closely monitored, as these patients have extensive evaporative loses dependent on the percentage of body surface area affected (Rousseau et al. 2013; Whitson and Barrera 2014; Taylor et al. 2016).

Although these patients will likely have frequent trips to the operating room interrupting delivery of enteral feeds, enteral nutrition has still been shown to be more beneficial, as patients that received parenteral nutrition alone or in combination with enteral nutrition were found to have higher infectious rates. Use of a volume-based approach would be advantageous in this patient population, so as to better deliver daily goal energy requirements. These patients may also benefit from immune-modulating formulas containing glutamine, arginine, and omega-3 fatty acids, with studies showing such formulations had a positive effect on indices of morbidity and may reduce the degree and duration of the associated systemic inflammatory response (Martindale et al. 2009; Drover 2011; Taylor et al. 2016).

(b) Trauma

The 2008 Trauma Nutrition Guidelines recommend that a high protein polymeric enteral formula similar to that recommended for other critically ill patients should be initiated within 24–48 hours of injury. Gastric enteral feeding has been found to be safe in this patient population once hemodynamically stable. Because trauma patients typically have frequent pauses in feeds for return trips to the operating room, these patients would likely benefit from a volume-based protocol (Taylor et al. 2016).

Unlike the basic starvation response, the metabolic response to trauma drastically changes metabolism, promoting skeletal muscle breakdown in order to generate the substrates needed to support the immune response and recovery. This, combined with muscle breakdown from prolonged bedrest and subsequent decreased muscle protein synthesis, lead to a rapid deterioration of lean body mass if adequate nutrition is not provided early on in the clinical course. The body's response to traumatic injury is also a dynamic process, with resting energy expenditure peaking 4–5 days post-injury, but remaining elevated for the up to 2–3 weeks. Energy goals should aim for the 20–35 kcal/kg/day range, starting toward the lower end of this range early on with liberalization as the patient clinically improves. Protein goals are similar to that of other critically ill patients, but trauma patients would likely benefit from the higher end of the 1.2 to 2 g/kg/day range due to the increased skeletal muscle breakdown previously discussed. Little data is available suggesting benefit from the use of immune-modulating formulas in this population (Taylor et al. 2016).

(c) Traumatic Brain Injury

Recommendations for traumatic brain injury (TBI) patients regarding energy goals are similar to those of other critically ill patients with a trend toward better outcomes when nutritional therapy is initiated within 24–72 hours of presentation. Protein requirements are, however, slightly higher (1.5–2.5 g/kg/day). While further studies are required, immune-modulating formulations containing arginine or EPA/DHA supplements have recently gained popularity in this population due to the potential for hastened recovery (Taylor et al. 2016).

(d) Open Abdomen

In the absence of bowel injury, patients with an open abdomen are still recommended to receive early enteral nutrition with standard energy and protein requirements. Retrospective studies have found these patients to be safely fed within 24–48 hours of injury, and the use of early nutritional therapy was associated with earlier abdominal fascial closure, less fistula formulation and intra-abdominal complications, and decreased mortality compared to delayed nutritional provision. An additional 15–30g of protein per liter lost is also required in excess of baseline protein requirements to correct for the significant protein loss that occurs as a consequence of the high protein exudate produced from the exposed peritoneum (Taylor et al. 2016).

(e) Post-operative Critically Ill (Surgical Intensive Care Unit – SICU)

As previously discussed, nutritional risk scores, such as the NRS-2002 and NUTRIC score should be used upon admission to SICU in order to determine nutritional risk. When feasible, nutritional therapy should begin within 24 hours of surgery, and enteral nutrition remains the preferred route over parenteral nutrition. While bowel discontinuity or high concern for bowel ischemia would preclude a patient from receiving enteral nutrition, instances such as high output fistulas, bowel anastomoses, open abdomen, use of vasopressors, and mechanical ventilation should not be considered contraindications to its initiation. Meta-analyses have shown that early initiation of enteral feeding has decreased post-operative infectious rates, noninfectious complications, and hospital length of stay. While energy requirements are calculated similarly to medical patients, surgical patients may benefit from high protein formulas, upward of 1.5–2 g/kg/day of protein, to aid in wound healing and recovery. Immune-modulating formulas are recommended over standard polymeric formulas for the post-operative SICU patient. Major surgery can lead to a depletion of arginine levels, which can adversely affect T-cell function, leading to immunosuppression, and EPA and DHA help to reduce systemic inflammation (Drover 2011; Marimuthu et al. 2012; Taylor et al. 2016).

While enteral nutrition is preferred, some procedures may preclude patients from receiving enteral feeds (i.e., upper GI procedure). For such patients, parenteral nutrition should be initiated 7–10 days before the scheduled procedure, as it has not been found to provide the same beneficial effects if only given in the post-operatively period. For patients at high nutritional risk that underwent an emergent procedure and thus were not able to receive pre-operative parenteral nutrition, the post-operative period prior to initiation should be shortened from the usual 5–7 days (Taylor et al. 2016).

For patients that will be receiving an oral diet post-operatively, literature does not suggest any physiologic advantage to advancing from a clear to solid diet. While clears may transit more quickly through the GI tract,

they are also more easily aspirated. Studies showed no increased morbidity or mortality by initiating a solid diet, with some data suggesting quicker return of bowel function in patients that were started with a regular diet rather than slowly advanced from clears (Pearl et al. 2002; Lassen et al. 2008).

3. Obese

Obese patients pose a challenge to clinicians in providing proper nutritional therapy, as clinicians frequently misinterpret high BMI as evidence for adequate nutritional reserves. As such, nutritional assessments may be overlooked in these patients. These patients are at greater risk of insulin resistance and are prone to having difficulty with fuel utilization compared to their lean counterparts. A baseline nutritional assessment should be performed like that of any other hospitalized patient, with special attention paid to determining actual, usual, and ideal body weight, as well as waist circumference. Biomarkers (glucose, lipid panel, etc.) can be used to assess for metabolic syndrome and emerging comorbidities that may make nutritional management more difficult. The presence of central adiposity, metabolic syndrome, BMI $>$ 40, and SIRS places these patients at higher risk of nutritional associated morbidity and mortality, and recommendations are thus based on nutritional optimization (Mauldin and O'Leary-Kelly 2015; Taylor et al. 2016).

Target energy goals should not exceed 65–70% of that predicted by IC. This permissive underfeeding promotes steady weight loss while still providing adequate nutrition. If IC is not available, weight-based equations can be used based on body weight. For a BMI 30–50, 11–14 kcal/kg *actual* body weight/day should be given. For a BMI $>$ 50, 22–25 kcal/kg *ideal* body weight should be provided. Protein requirements are calculated using ideal body weight, with recommendations of 2 g/kg/day for patients with BMI 30–40 and 2.5 g/kg/day for patients whose BMI is $>$40. Subsequent protein requirements can be adjusted throughout the hospital course using nitrogen balance studies to achieve equilibrium whenever possible. A high protein, hypocaloric formula with a low nonprotein calorie to nitrogen ratio is recommended to achieve these goals, as hypocaloric formulations have been associated with shorter length of stay, lower infectious rate, and more vent-free days compared to eucaloric formulas (Dickerson et al. 2002; Taylor et al. 2016).

Complications

A variety of complications can be associated with nutritional therapy, whether enteral or parenteral. The nutritional therapy provided by clinicians is now responsible for meeting the patient's needs for macronutrients, water, vitamins, and minerals, and as such, several metabolic complications can ensue. These complications can range from simple electrolyte imbalances requiring repletion, poor glycemic control and fluid disturbances, or life-threatening conditions like refeeding syndrome.

Energy intake in the form of glucose in excess of the patient's needs can cause various complications. Excessive glucose intake can lead to poor glucose control and hyperglycemia that can, in turn, lead to increased infectious risks. Breakdown of this glucose for utilization via glycolysis generates carbon dioxide, which when present in excess can lead to hypercapnia. Similarly, overfeeding can lead to other metabolic derangements, including hyper- or hypo-osmolarity, acid-base derangements, hypertriglyceridemia, and weight gain. Thus, close monitoring of electrolytes and blood glucose is required to enable detection of electrolyte deficiencies, disturbances in water balance, and glycemic instability. Careful consideration of both formulation and rate must occur in order to ensure patients are getting optimal nutrition while prudently avoiding these complications (Whitson and Barrera 2014; Taylor et al. 2016).

Refeeding syndrome occurs when nutritional support provides a carbohydrate source to a patient that was previously dependent on fatty acid metabolism for energy in starvation state. Patients with prolonged malnutrition are at highest risk, however, anyone with little or no nutritional intake for >5 days can develop this condition, typically within the first 3–4 days of nutritional supplementation. This occurs because the starvation state depletes the body's stores of intracellular cations (magnesium, potassium, phosphorous), as well as ATP and thiamine which serve as substrates for bodily processes that serve in the breakdown of macronutrients to their usable forms. Rapid reintroduction of carbohydrates increases insulin secretion while decreasing glucagon production and stimulates the synthesis of protein, fat, and glycogen, further depleting the body's already limited stores. This in turn leads to cardiac, neurologic, pulmonary, renal, and hepatic dysfunction and failure. Refeeding syndrome can be avoided with early recognition, notably aggressive electrolyte repletion and avoidance of rapid provision of high carbohydrate feeds (Whitson and Barrera 2014).

In addition to complications caused by the formulation of the selected nutritional therapy, there are also mechanical complications that may occur. Aspiration of enteral feeds is a common complication that occurs in patients receiving enteral nutrition. Careful attention should be paid to identifiable risk factors, such as nasogastric feeding tube, mechanical ventilation, poor oral hygiene/care, age $\geq$ 70 years old, frequent transport, bolus feeds, neurological deficits, and existing acid reflux disease. Once recognized, efforts can be made aimed at prevention. These patients should have the head of the bed elevated to 30–45 degrees unless there is a valid reason to do otherwise. Other protective methods include continuous infusion in place of intermittent bolus feeds, use of prokinetic agents and avoidance of unnecessary opioid use and neuromuscular blockade, correction of electrolyte abnormalities, and the use of small bore feeding tubes placed within the small bowel instead of the stomach. Such measures can help to reduce the risk of aspiration in patients known to be prone to this occurrence (Whitson and Barrera 2014; Taylor et al. 2016).

An uncommon but serious complication seen in less than 1% critically ill patients receiving enteral nutrition is bowel necrosis, with patients receiving vasopressor drugs at highest risk. An imbalance between the metabolic oxygen demand required

for digestion and the availability of splanchnic oxygen supply is thought to be the mechanism. While enteral nutrition has generally been proven to be safe, a high index of suspicion is required for patients showing clinical signs concerning for ischemic bowel (Whitson and Barrera 2014).

Post-Discharge Nutritional Maintenance

Recovery from critical illness does not end at discharge, and appropriate nutritional care should be continued after hospitalization in order to improve patient outcomes and prevent hospital readmission. It is imperative that patients have outpatient follow-up arranged to ensure that their nutritional needs continue to be met after leaving the hospital.

Policies and Protocols

In this chapter, we describe at risk populations for malnutrition and its adverse effects on hospitalized patients. Though difficult to fully define malnutrition, we provide two validating scoring systems, NUTRIC and NRS-2002, to help identify at risk patients. Once such patients are identified, we also provide methods to assist in decisions involving mode of nutrient delivery, monitoring tolerance, and disease-specific caveats to nutritional provision.

Dictionary of Terms

- **Anthroprometric** – Any means of measuring body dimensions
- $\mathbf{V_{co2}}$ – Rate of elimination carbon dioxide
- **Enteral Feeds** – Nutritionally complete food (carbohydrates, fat, and protein) delivered to the gastrum or jejunum
- **Parenteral Feeds** – Nutrition delivered through a vein, bypassing the gastrointestinal system
- **Trophic Feeds** – Use of low-volume enteral feeds to stimulate gastrointestinal function
- **Respiratory Quotient** – Ratio of the volume of carbon dioxide delivered to oxygen consumed

Summary Points

- Malnourishment is predominant in the outpatient community, and further nutritional decline is typically seen during patients' hospital course.
- Malnourishment in hospitalized patients is associated with immunosuppression, higher infection rates, increased muscle loss with delayed functional recovery,

impaired wound healing, increased risk of treatment complications, fewer ventilator-free days, longer hospital stays, higher overall treatment costs, and increased mortality rates.

- A nutritional assessment should be performed on all patients presumed to be at risk for malnutrition, utilizing various existing nutritional scores. NRS-2002 and NUTRIC are recommended for use in critically ill patients, as both scores address disease severity.
- Adequate and appropriate nutrition should be initiated within 24–48 hours (earlier in burn and some surgical patients) and is associated with decreased morbidity and mortality.
- Enteral nutrition is the preferred route over parenteral whenever possible.
- Nutritional recommendations may vary slightly based on the underlying medical/surgical condition.
- Outpatient follow-up should be arranged to ensure patients' nutritional needs continue to be met in the community after discharge.

Abstract

The effects of caloric restriction on tumor growth and progression are known for over a century. Indeed, fasting has been practiced for millennia, but just recently

has emerged the protective role that it may exert toward cells. Fasting cycles are able to reprogram the cellular metabolism, by inducing protection against oxidative stress and prolonging cellular longevity. The reduction of calorie intake as well as short- or long-term fasting has been shown to protect against chronic and degenerative diseases, such as diabetes, cardiovascular pathologies, and cancer. In vitro and in vivo preclinical models showed that different restriction dietary regimens may be effective against cancer onset and progression, by enhancing therapy response and reducing its toxic side effects. Fasting-mediated beneficial effects seem to be due to the reduction of inflammatory response and down-regulation of nutrient-related signaling pathways able to modulate cell proliferation and apoptosis. In this chapter, we will discuss the most significant studies present in literature regarding the molecular mechanisms by which dietary restriction may contribute to prevent cancer onset, reduce its progression, and positively affect the response to the treatments.

Keywords

Caloric restriction · Cancer · Cell proliferation · Diet · Dietary restriction · Fasting · Feeding · IGF-1 · Inflammatory response · Long-term starvation · Molecular pathways · Oxidative stress · Short-term starvation · Therapy response

List of Abbreviations

AKT	Serine/threonine kinase
AMPK	AMP-activated protein kinase
APN	Aminopeptidase N
ATM	Ataxia telangiectasia mutated
BER	Base excision repair
Bm1	B Lymphoma Mo-MLV insertion region 1 homolog
C/EBPβ	CCAAT/enhancer-binding protein β
CAAs	Cancer-associated adipocytes
ChK2	Checkpoint kinase 2
CR	Caloric restriction
DEN	Diethylnitrosamine
DR	Dietary restriction
DSBs	Double-strand breaks
DSR	Differential stress resistance
EGFR	Epidermal growth factor receptor
ERK	Extracellular signal-regulated kinase
FGF21	Fibroblast growth factor 21
FOS	FBJ murine osteosarcoma viral oncogene homolog
FOXO	Forkhead box subgroup O
GCN2	General control nonderepressible 2
H2AX	H2A histone family member X
HCC	Hepatocellular carcinoma
HDAC1	Histone deacetylase 1
HER2	Human epidermal growth factor receptor 2
HopX	HOP homeobox

HSL	Hormone-sensitive lipase
IGF-1	Insulin-like growth factor 1
IGFBP-1	IGF-binding protein 1
IL-6	Interleukin 6
KD	Ketogenic diet
Lgr5	Leucine-rich repeat containing G-protein-coupled receptor 5
LTS	Long-term starvation
MAPK	Mitogen-activated protein kinase.
Msn2/4	Moesin 2/4
mTOR	Mammalian target of rapamycin
mTORC1	mTOR complex 1
NF-KB	Nuclear factor kappa-light-chain-enhancer of activated B cells
NSCLC	Nonsmall cell lung cancer
OGG1	8-Oxoguanine DNA glycosylase 1
PARP-1	Poly (ADP-ribose) polymerase 1
PI3K	Phosphoinositide 3-kinase
PKA	Protein kinase A
PSA	Prostate-specific antigen
RAF	V-Raf-1 murine leukemia viral oncogene homolog
Ras	Rat sarcoma viral oncogene homolog
REV1	DNA-directed polymerase
ROS	Reactive oxygen species
SIRT1	Sirtuin 1
SOD2	Superoxide dismutase 2
SSBs	Single-strand breaks
STS	Short-term starvation
TKIs	Tyrosine-kinase inhibitors
VEGF	Vascular endothelial growth factor

Introduction

In recent years, increasing evidences showed that several types of intermittent, chronic, or periodic dietary approaches, including short-term starvation (STS), long-term starvation (LTS or fasting), caloric restriction (CR), may exert a protective role against aging and other age-related pathologies as well as cancer in humans and numerous animal models (Lee and Longo 2016; Brandhorst and Longo 2016; Longo et al. 2015; Trepanowski et al. 2011). Interestingly, these dietary restriction (DR) regimens showed significant anticancer effects mostly in preclinical models, suggesting the possibility of using these methods to increase lifespan and improve therapy response in cancer patients. However, prolonged fasting periods could impair the patient health conditions already unfavorable due to physiological weight loss (Cleary and Grossmann 2011; Lluch et al. 2014). For this reason, STS (or intermittent fasting), consisting of the lack of food intake for a short time, appears to be the most suitable approach for cancer patients, although there are conflicting

opinions about it. STS aims to slow down growth of tumor, by restricting temporarily its exposure to different nutrients, including glucose, and generating protective effects against cancer (Robertson and Mitchell 2013; Anton and Leeuwenburgh 2013). Conversely, LTS consists of a prolonged food deprivation, resulting in adaptive cellular responses able to decrease inflammatory processes and oxidative stress, enhance energy metabolism, and strengthen cell protection (Longo and Mattson 2014). For example, a serum starvation able to bring down basal cellular activity was applied to several in vitro models, in order to study molecular mechanisms underlying apoptosis, cellular stress response, and autophagy (Pirkmajer and Chibalin 2011). Finally, CR is defined as the reduction in calorie intake aimed to inhibit tumorigenesis and prevent other diseases, including diabetes and cardiovascular pathologies, by inducing an improved insulin sensitivity and reducing the oxidative damage and metabolic rate (Lv et al. 2014; Lefevre et al. 2009).

This chapter aims to provide an overview of the most recent studies present in literature concerning the molecular mechanisms by which dietary restriction may contribute to prevent cancer onset, slow down its progression, and positively affect the response to anticancer therapies, also suggesting a close correlation between diet and reduction of treatment-induced side effects.

Molecular Pathways Involved in Dietary Restriction and Cancer-Related Events

Molecular Changes Induced by Dietary Restriction

Nowadays, the link between cancer and metabolism is becoming increasingly evident (Longo and Mattson 2014; Brandhorst et al. 2017). It is clear that beneficial effects mediated by fasting, in particular by CR, do not involve a single gene, a pathway or a unique molecular mechanism. The benefits are due to the negative regulation of nutrient-signaling pathways, including insulin-like growth factor 1 (IGF-1) pathway and its effector extracellular signal-regulated kinase (ERK), mitogen-activated protein kinase (MAPK), and phosphoinositide 3-kinase (PI3K), which are known to modulate important proliferation pathways (Cangemi et al. 2016). Furthermore, it is well known that genomic instability is a distinctive feature of cancer, and CR tumor response seems to play a key role for the maintenance of genomic integrity (Robertson and Mitchell 2013; Duan et al. 2017). Due to these evidences, new metabolic approaches are being sought today for anticancer treatment. CR, also used in combination with the conventional chemotherapies, has allowed to obtain good results in animal models (Klement and Fink 2016).

CR-Induced Changes in Tumor Microenvironment

The most recent data in literature showed a correlation between aging and neoplastic diseases. It has been observed that aging promotes neoplastic cell growth and

proliferation through surrounding microenvironment alterations. This process, named "adaptive oncogenesis," is determined by tissue decline caused by age and oncogenic cell alterations (Cadoni et al. 2017). Changes in age-associated tissue microenvironment seem to play an important role in cancer and cancer-related diseases. Although the mechanisms responsible for delays in aging and carcinogenesis have not been fully identified, CR is today the only known nongenetic approach able to extend organism life. Nutrient-sensing pathways play a pivotal role in cellular response to CR probably because these regulatory processes are responsible for maintaining a microenvironment that promotes aging and carcinogenicity (Cadoni et al. 2017).

The deacetylase SIRT1 is a protein implicated in regulation effects downstream of CR, in both human and murine models (Cohen et al. 2004). The SIRT1 levels are low in senescent cells probably due to the formation of the C/EBPβ complex and HDAC1, which bind and inhibit SIRT1 promoter. Several studies showed that long-term CR is able to block the formation of the C/EBPβ and HDAC1 inhibitory complex, restoring the functionality of SIRT1 promoter in murine liver cells (Jin et al. 2011).

The SIRT1-activated pathway is also involved in the regulation of forkhead box subgroup O (FOXO) protein, which is deacetylated by SIRT1 in response to oxidative stress. The FOXO1 levels seem to be increased in rat liver cells during long-term CR. This suggests that both SIRT1 and FOXO1 have a modulating role in long-term CR and are responsible for creating a microenvironment that delays aging and prevent cancer (Yamaza et al. 2010).

DR and Inflammatory Response

Several studies showed that DR also plays a role in modulating inflammatory response. Liver cells of diethylnitrosamine (DEN)-induced HCC mice models submitted to DR showed a reduction in levels of NF-kB, a mediator of inflammation associated with cell proliferation and cancer (Duan et al. 2017). A decrease in levels of cytokines and inflammatory chemokines was observed in murine liver, kidney, and spleen tissues (Chiba and Ezaki 2010). Also, mice under 4 weeks DR condition display a reduction of proinflammatory gene expression and an increase in anti-inflammatory gene expression (Robertson and Mitchell 2013; Fig. 1).

DR and Chemotherapy Protection

Proliferation pathways regulated by Ras and AKT are almost always constitutively activated in cancer cells. Cells dramatically reduce the cell division number and become more resistant to stress in response to poor nutrition conditions, such as fasting or DR. This occurs because DR inactivates nutrient-sensing signaling pathways (Brandhorst et al. 2017). The link between cell proliferation, which depends on the nutrient-sensing pathways, and stress resistance is the basis of the protective effect that DR exerts on normal cells compared to tumor cells. This resistance is

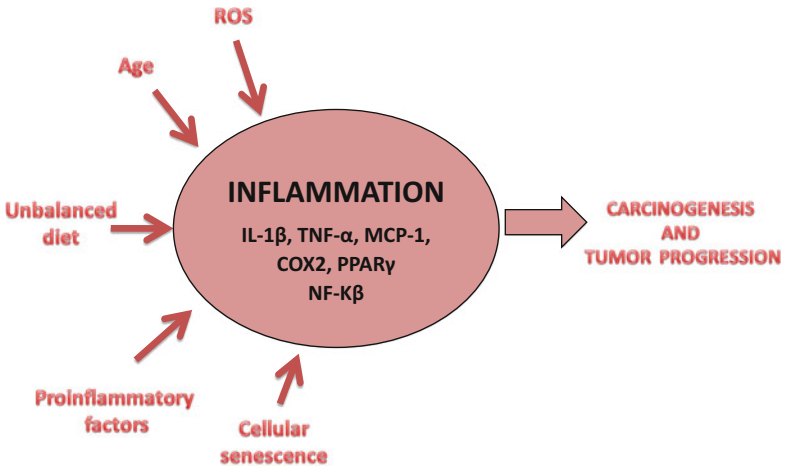

Fig. 1 Association between inflammation and cancer. Unbalance diet, age, cellular senescence, and accumulation of proinflammatory factors and ROS cause cell inflammation

called differential stress resistance (DSR). In fact, tumor cells are unable to protect themselves from stress, because oncogenes negatively regulate resistance genes (Brandhorst et al. 2017; Raffaghello et al. 2008). Moreover, several mutations accumulated in cancer cells make them less able to adapt to extreme environmental conditions created by fasting (Longo and Fontana 2010). Several studies showed that DR-induced DSR may be used to protect healthy cells from the toxic effects of chemotherapy (Brandhorst et al. 2017).

The fasting-induced protection has been shown also in in vivo experiments. CR protects mice from high dose etopoxide toxicity 4, nausea and vomiting induced by doxorubicin, and irinotecan-induced weight loss (Raffaghello et al. 2008; Tinkum et al. 2015). It has also been found that IGF-1 gene deletion protects against chemotherapeutic toxicity of doxorubicin and cyclophosphamide (Brandhorst et al. 2017). Probably, the protective effect induced by DR and starvation is due to a change in microenvironment of the intestinal cryptic stem cells. Indeed, fasting before chemotherapy preserves the correct architecture and functioning of intestinal cells by maintaining the expression of genes such as Lgr5, Bm1, and HopX (Tinkum et al. 2015).

In other studies, it was observed that DR makes cancer cells susceptible to cisplatin-based chemotherapy effects through activation of the ATM/ChK2/p53 signaling pathway, which causes temporary loss of coordination between cell proliferation and growth stimulated by nutrients (Shi et al. 2012).

Correlations Between DR and IGF-1, Insulin, and Cancer

One of the nutrition-related pathways involved in carcinogenesis is the IGF-1 signaling, which affects both sensitivity to oxidative stress and DR. Insulin and

IGF-1 play a pivotal role in controlling metabolism and growth in response to nutritional signals and nutritional state of cells (Shi et al. 2012). IGF-1 pathway regulates cell proliferation and differentiation, showing a tumorigenic effect through apoptosis inhibition (Ramsey et al. 2002; Prisco et al. 1999). Epidemiological studies highlighted the role that IGF-1 pathway plays in cancer pathology. Indeed, high serum IGF-1 concentration is associated with an increased risk of prostate, breast, and colon cancers (Renehan et al. 2004).

A study performed on murine xenograft models showed that deregulation of IGF-1 and PI3K/AKT pathways results in DR resistance. IGF-1 recruits PI3K on cell membrane via binding to tyrosine kinase receptor, resulting in AKT activation. AKT, in turn, phosphorylates and activates downstream effectors that induce cell proliferation (Kalaany and Sabatini 2009).

FOXO1 protein is an effector downstream of IGF-1/AKT pathway, negatively regulated by AKT. This protein is able to modulate the expression of genes involved in oxidative metabolism, stress resistance, and longevity (Cangemi et al. 2016). It has been observed that DR-sensitive cells show a decrease in AKT cytoplasmic levels. This results in FOXO1 nuclear relocation and induction of the proapoptotic and antiproliferative gene transcription. In addition, in vivo studies on xenograft models demonstrated that DR-induced apoptosis increases in tumor cells that overexpress FOXO1. These results are consistent with the antitumorigenic effect of FOXO1 in DR conditions (Kalaany and Sabatini 2009).

A significant role is played by downstream effectors of the PI3K pathway, such as mTOR, AMPK, and SIRT1, which are probably related to cellular sensitivity to DR. Moreover, it has been observed that mutations constitutively activating PI3K protein are important for tumor sensitivity to DR. In fact, an increased sensitivity to DR is observed when PI3K levels decrease. This suggests that molecular analysis of PI3K mutational state could represent an interesting tool to identify DR resistance markers (Lee et al. 2012b; Fig. 2).

Several epidemiological studies showed that there is a strong correlation between increased adiposity and tumor risk (Lee et al. 2012b; Fanale et al. 2017; Wang et al. 2012; Toren et al. 2013; La Paglia et al. 2017). Adiposity is associated with an increase in insulin serum levels. Insulin, an anabolic hormone produced by pancreatic β-cells, exhibits mitogenic effects on many cell types, especially on preneoplastic cells. Furthermore, insulin increases IGF-1 activity, reducing synthesis and secretion of IGF-binding protein 1 (IGFBP-1) (Esposito et al. 2003). Hyperinsulinemia increases concentration of circulating sex hormones, in particular stimulating the production of androgens involved in the growth of different tumors. Several studies showed that DR counteracts metabolic anomalies associated with excessive adiposity, by reducing insulin levels, sex hormones, IGF-1, inflammatory cytokines, prostaglandins, and other various markers of oxidative stress and DNA damage (Esposito et al. 2003, Heilbronn et al. 2006; Fig. 3). According to the data of epidemiological studies carried out on dietary style of Western countries, DR associated with low protein intake has been shown to decrease serum IGF-1 levels in humans (Fontana et al. 2008; Giovannucci et al. 2003).

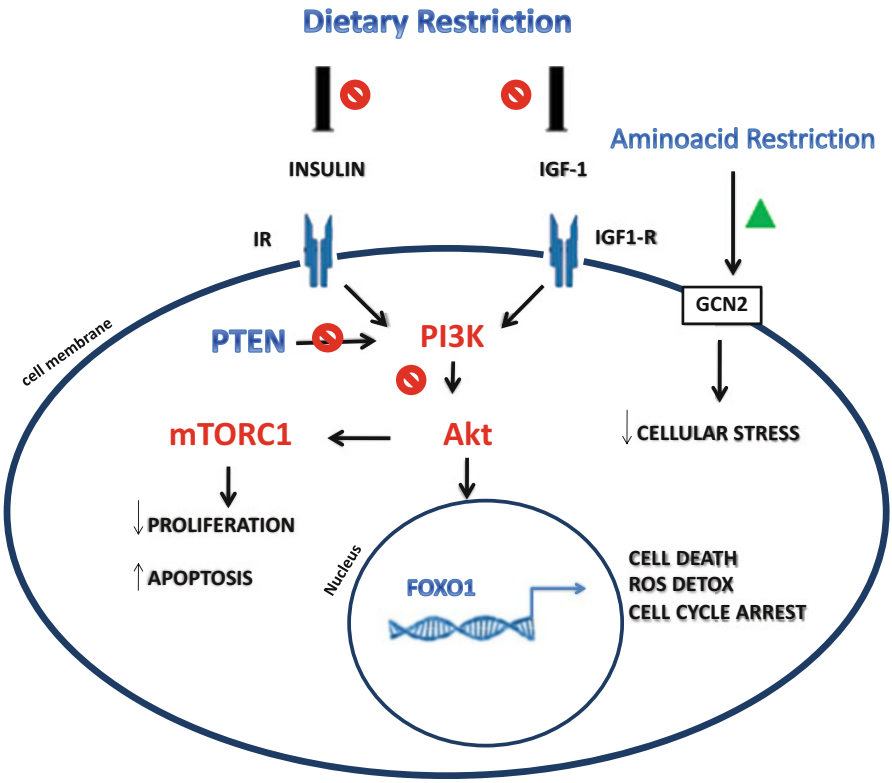

Fig. 2 Molecular pathways modulated by dietary restriction. Dietary restriction decreases the circulating levels of insulin and IGF-1, resulting in inhibition of PI3K/AKT pathway, and leading to increased apoptosis and decreased proliferation

DR in combination with deprivation of essential amino acids triggers protective events for cells, by inducing a decrease in mTORC1 cellular levels and a concomitant increase in amino acid deprivation sensor (GCN2) (Brandhorst et al. 2017).

Although there is still no data regarding the effect of fasting in preventing cancer in humans, the most likely hypothesis is that the effect of DR on IGF-1 levels could generate a protective environment for healthy cells and an adverse environment for tumor cell growth (Longo and Mattson 2014). Another protein restriction marker is FGF21, the fibroblast growth factor, regulated by PPARα whose plasma levels increase during DR associated with protein restriction. In summary, DR has effects on FGF21, IGF-1, and mTOR activity, which are probably linked to carcinogenesis (Klement and Fink 2016).

DR and Oxidative Stress Response

Many studies indicated that the increase of antioxidant factors in tumor cells is mediated by threonine tyrosine kinase Rim15 and transcription factors Msn2/4 and

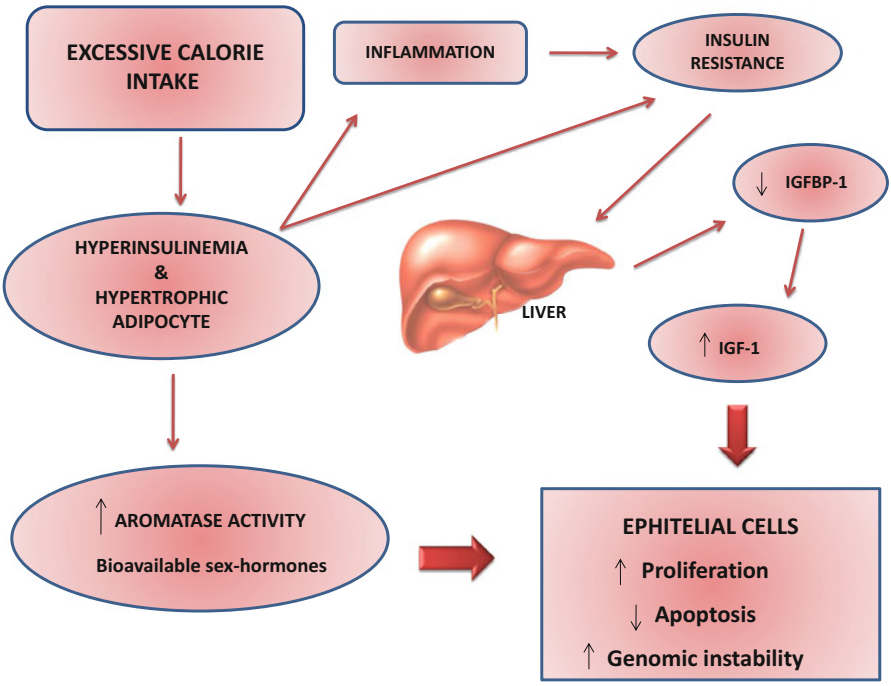

Fig. 3 Correlation between calorie intake and adiposity. Excessive calorie intake causes hyperinsulinemia, hypertrophy of adipose tissue, and increased inflammation

Gis1, which regulate several genes, including mitochondrial SOD2, implicated in oxidative stress resistance (Madia et al. 2009; Hlavata et al. 2003). Additionally, Tor/Sch9 and Ras/AC/PKA pathways regulate the expression of several DNA repair genes, including REV1 gene (Madia et al. 2009).

According to this evidence, Mn-superoxide dismutase (MnSOD) heterozygous knockout mice showed an increased DNA oxidative damage and tumor incidence. This suggests a complex interaction between oxidative stress and cancer (Van Remmen et al. 2003).

Another mechanism induced by DR is the autophagy response to oxidative stress. Autophagy is a process by which cells under DR conditions convey nutrients to essential metabolic processes. DR-induced autophagy is activated by poly (ADP-ribose) polymerase 1 (PARP-1), a nuclear enzyme induced by DNA damage. ROS (reactive oxygen species) production under DR conditions causes DNA damage, which determines PARP-1 activation and fasting-induced autophagy (Cangemi et al. 2016). ROS induce different types of DNA damage, including single-strand breaks (SSBs), double-strand breaks (DSBs), and ionized DNA nucleotides. The repair of latter damage requires the intervention of the base excision repair (BER) system, in particular the OGG1 (8-oxoguanine DNA glycosylase) enzyme 1. Both in vitro and in vivo experiments showed that BER activity is influenced by the availability of nutrients. Indeed, autophagy has no effects on OGG1 expression in the absence of fasting (Siggens et al. 2012).

DEN-induced mice HCC cells exhibit high levels of Caspasi 3, PARP, and Citocromo C, which are proteins involved in mitochondria-mediated autophagy, suggesting that DR suppresses proliferation and promotes apoptosis (Lu et al. 2008; Duan et al. 2017).

According to previous studies (Xie et al. 2007; Standard et al. 2014), gene expression analysis of DEN-induced mice HCC cells revealed that DR restores functioning of many MAPK genes. MAPK pathway regulated by RAS promotes tumor growth and is one of the most important molecular targets for treatment of several types of cancers (Duan et al. 2017).

The Implication of Dietary Restriction in Cancer

The different molecular signature that distinguishes a normal cell from a tumor cell is the main reason that could explain the different susceptibility to growth stimuli. In fact, tumor cells undergo a series of genetic and epigenetic modifications that make their growth independent of the presence of growth factors (Hanahan and Weinberg 2011; Fig. 4). The accumulation of these genetic alterations constitutively activates key components of intracellular pathways. Among these, the most common deregulated signal pathways are Ras/Raf/MAPK and PTEN/PI3K/AKT, responsible for an uncontrolled cell proliferation (Massihnia et al. 2016). The deprivation of nutrients both in vitro and in vivo results in a decrease of growth factor levels in normal cells, forcing thus the cell to enter a proliferative quiescent status (Flemstrom

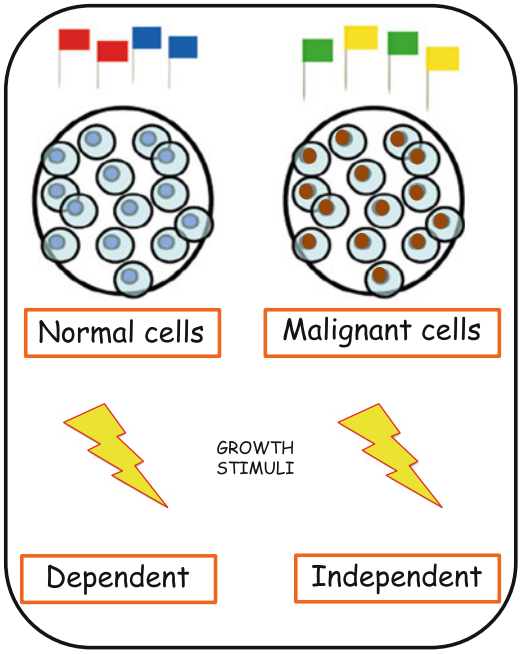

Fig. 4 Growth stimuli of normal and malignant cells. The different molecular profile between normal and malignant cells is responsible for the differences in behavior toward growth stimuli

et al. 2010; Pirkmajer and Chibalin 2011). Unlike normal cells, tumor cells overcome this block by reprogramming their metabolic state and thus maintaining high proliferative abilities (Hanahan and Weinberg 2011). The discovery that different types of dietary restrictions can protect normal cells from the most common side effects of chemotherapy has recently raised interest in its possible clinical application. Moreover, STS seems to protect not only healthy cells but also increase the sensitivity of various types of cancer to the therapy (Lee and Longo 2011). Indeed, fasting in combination with chemotherapy determines increased cytotoxic effects in malignant cells from different types of cancers (Russo and Rizzo 2008). The validity of STS has been evaluated in immunosuppressed nude mice xenograft models in which human neuroblastoma cells were subcutaneously injected. Surprisingly, after 34 days of fasting combined with cyclophosphamide treatment the tumor mass was reduced (Lee et al. 2012a). The usefulness of STS has also been demonstrated for its attenuating properties on chemotherapy side effects. Indeed, its cardioprotective properties have been recently demonstrated during doxorubicin-based treatments (Dirks-Naylor et al. 2014). In addition, a recent work on murine models revealed that following a prolonged fasting of 48–60 h prior to the administration of a high dose of etoposide, the side effects, generally resulting from the treatment, were attenuated (Raffaghello et al. 2008). The synergy between refeeding and DNA damage caused by pharmacological treatment may favor the growth of new foci in various organs including liver, colon, and rectum (Laconi et al. 1995; Premoselli et al. 1998). Interestingly, in a tumor mass, malignant cells are strictly connected with the so-called "cancer-associated adipocytes" (CAAs) and interact with them (Calle and Kaaks 2004). In particular, CAAs show the reduction of peculiar markers including HSL, APN, and resistin, and increased proinflammatory cytokine expression such as IL-6 and IL-1β and TNF-α (Berstein et al. 2007; Ribeiro et al. 2012; Dirat et al. 2011). This altered expression, associated with the production of adipokines, results in a tumor microenvironment variation that favors uncontrolled growth. Therefore, fasting, having a massive effect on the size of adipocytes, can consequently decrease the secretion of tumor-favorable factors (Hermsdorff et al. 2009). Recently, CR efficacy has also been demonstrated in relation to radiotherapy, leading to an increase in the sensitivity to radiation-induced cytotoxicity (Champ et al. 2013). As alternative to standard chemo−/radiotherapy, another type of metabolic therapy has been proposed (ketogenic diet) whose beneficial effects have been demonstrated in the multiform glioblastoma and brain cancer for its antiangiogenic, anti-inflammatory, and antiapoptotic abilities (Seyfried et al. 2015). Below we will discuss deeper the association of chemotherapy and dietary restriction in some of the most spread cancers worldwide looking at the benefits deriving from their combination (Fig. 5).

Breast Cancer

Breast cancer is one of the main causes of cancer deaths in the female population (Fanale et al. 2013). Various clinical studies have shown the efficacy of fasting in the

Fig. 5 Association between dietary restriction and chemotherapy. The figure shows the relevant benefits arising from the association between different types of dietary restriction and drug administration

favorable outcome of the chemotherapy treatment to which some patients affected by breast cancer have undergone. In particular, it seems that a short period of fasting pre- and posttreatment will have a better outcome in terms of patient's tolerability by reducing the side effects. Indeed, the case report of three different patients treated with different therapies and subjected to different times of fasting is below described. A first woman of 51 years with a breast cancer at stage 2A did not show any side effect once subjected to fasting 140 h before and 40 h after treatment with docetaxel and cyclophosphamide. The validity of the association was confirmed in a second 53-year-old patient, also suffering of a tumor in stage 2A and HER2+. In particular, chemotherapy cycles associated with fasting 64 h before and 24 h after were not accompanied by high toxicity effects or in any case with negligible and/or reversible transient effects. The third case saw a 78-year-old patient with a HER2+ tumor, after mastectomy and subjected to variable fasting periods in the course of carboplatin-based, docetaxel and trastuzumab-based chemotherapy cycles. Significant levels of pharmacological toxicity have not been reported (Safdie et al. 2009; Table 1).

Ovarian Cancer

Among gynecological tumors, ovarian cancer is one of the most common and the fifth cause of death in the female population (Reid et al. 2017). Al-Wahab et al. (2014) published a study showing the effects of energy balance in mouse models

Table 1 Case reports of different tumors. The table summarizes the cases described in the text and related fasting schedules adopted in pre- and posttreatment

Breast cancer	Case I (51yo)	140 h before 40 h after treatment
	Case II (53yo)	64 h before 24 h after Treatment
	Case III (78yo)	Not shown
Ovarian cancer	Case I (44yo)	62 h before 24 h after treatment
Lung cancer	Case I (61yo)	48 h before 24 h after treatment
Prostate cancer	Case I (74yo)	60 h before 24 h after treatment

subjected to high energy diet or CR conditions. Mice group under high-energy diet showed the most extensive tumor formation accompanied by the highest tumor score at multiple sites. Moreover, they showed increased levels of insulin, leptin, IGF-1, VEGF, and proinflammatory factors (IL-6). Instead, the mice group under CR showed a lower tumor burden as well as a great reduction in insulin, IGF-1, leptin, MCP-1, VEGF, and IL-6 levels (Al-Wahab et al. 2014). Also, clinical trials demonstrated the effectiveness of the association chemotherapy/DR. The case of a 44-year-old woman suffering from ovarian cancer has been emblematic, because she has benefited from the antineoplastic treatment in combination with STS carried out 62 h before and extended 24 h after drug treatment (Safdie et al. 2009; Table 1).

Lung Cancer

Lung cancer is one of the major causes of cancer-related morbidity and death in men and women population worldwide. Depending on EGFR mutational status, therapy may vary in favor of tyrosine-kinase inhibitors (TKIs). Among them, erlotinib is one of the most commonly used TKIs in I and II line of treatment (Passiglia et al. 2017). Currently, the recommended dose is 150 mg under complete fasting conditions or 2 h after the meal consumption. Two modalities of administration are resulted able to determine a different drug absorption and consequent increase in therapeutic efficacy. In particular, drug seems to have greater effect when the administration takes place 2 h after the meal (Katsuya et al. 2015). An interesting clinical case is that of a 61-year-old NSCLC patient who has seen mitigating the side effects of drug therapy after STS 48 h before and 24 h after therapy (Safdie et al. 2009; Table 1).

Prostate Cancer

Prostate cancer is considered as the second cause of cancer-related death in male population (Vanacore et al. 2017). Interesting is the case of a 74-year-old man

diagnosed with stage 2 prostate adenocarcinoma. The patient has undergone several cycles of chemotherapy during which he faced many side effects such as fatigue, weakness, short-term memory impairment, and peripheral neuropathy. Moreover, PSA levels raised with an unstoppable trend. After many failed attempts, patients were enrolled in a rigorous fasting schedule consisting of restrictions 60 h prior to and 24 h post drug administration. After treatment, PSA levels dropped dramatically and a marked reduction of side effects was reported (Safdie et al. 2009; Table 1).

Conclusion

Recently, accumulating evidence showed that starvation condition seems to play a pivotal role in preventing cancer development and progression as well as improving the response to different therapeutic treatments. The above presented studies and considerations seem to confirm the protective role exerted by fasting against cancer. However, a potential limitation is represented by time required for each cancer patient to obtain an optimal fasting condition, since a severe nutrient deprivation for several months may be needed, as showed by in vivo preclinical analyses. Furthermore, not all patients are fit to undergo such dietary regimens, because many of them are subject to weight loss due to the chemotherapy toxicity and tumor itself. For this reason, since CR and ketogenic diet (KD) have been shown to be approaches particularly effective unlike intermittent fasting whose role is still controversial, further clinical studies are yet necessary in order to assess the safety and efficacy of these methods.

Policies and Protocols

Protocol for Maintaining Cancer Cells Under Short-Term Starvation Conditions

In this chapter, we have discussed the most significant studies present in literature concerning the molecular mechanisms by which dietary restriction may contribute to prevent cancer development, slow down its progression, and positively influence therapy response. Since most of the current experimental evidences concerning the correlation between dietary restriction and cancer arise from studies mainly performed on in vitro preclinical models, here we discuss a rapid and convenient method for maintaining the healthy and malignant breast cells under short-term starvation conditions restricting the supply of glucose. Glucose metabolism represents a primary source of energy able to support cell proliferation and regulate cell death-related signaling pathways. The impaired balance between excessively high glucose consumption and its poor supply determines glucose deprivation in the tumor microenvironment, activating a positive feedback mechanism that involves ROS production by NADPH oxidase and mitochondria, inhibition of tyrosine

phosphatases by oxidation, and amplification of tyrosine kinase signaling in cells dependent on glucose for their survival.

Both cell lines are grown at 37 °C, 5% CO2, and 80% confluence, in a culture medium DMEM (Dulbecco's Modified Eagle Medium) containing high glucose concentration (4.5 g/l D-glucose, 110 mM pyruvate) and enriched with fetal bovine serum (10% FBS), nonessential amino acids (NEAA-1%), and streptomycin-penicillin (1% Strepto/Pen). For short-term starvation experiments aimed at establishing a glucose deprivation, cells are washed twice with PBS (phosphate-buffered saline) and then incubated in glucose-free DMEM without pyruvate and supplemented with 10% FBS, 1% NEAA, 1% Strepto/Pen.

Dictionary of Terms

- **Caloric restriction** – Reduction of calorie intake that implicates feeding once daily or thrice weekly. It can be distinguished in two forms: intermittent caloric restriction and chronic caloric restriction.
- **Dietary restriction** – Condition of short- or long-term fasting which can involve the lack of food consumption for short or prolonged periods. It includes the caloric restriction, short- and long-term starvation, and ketogenic diet.
- **Hyperinsulinemia** – The increase in circulating insulin levels that lead to a greater IGF-1 activity, by reducing synthesis and secretion of IGF binding protein 1, and elevated concentration of circulating sex hormones.
- **Inflammatory response** – Set of actions exerted by the immune system to fight an inflammation through release of several factors that mediate this response, including chemokines and cytokines.
- **Therapy response** – Assessment of the extent of sensitivity or resistance of a tumor to a specific anticancer treatment.

Summary Points

- This chapter focuses on molecular mechanisms by which dietary restriction may contribute to prevent cancer onset and improve therapy response.
- Dietary restriction involves food deprivation for short or prolonged periods.
- Dietary restriction includes short-term starvation, long-term starvation, caloric restriction, and ketogenic diet.
- Numerous experimental evidences showed that fasting may exert a protective role against aging and other age-related pathologies as well as cancer.
- Preclinical models suggested the potential use of fasting to induce anticancer effects and improve patient life's quality.
- However, prolonged fasting periods could impair the patient health conditions already unfavorable due to physiological weight loss induced by tumor itself.

- Fasting-mediated benefits seem to be mediated by the reduction of inflammatory response and down-regulation of nutrient-related signaling pathways able to modulate cell proliferation and apoptosis.
- Good results were obtained in animal models by associating caloric restriction with conventional chemotherapies.
- Deregulation of IGF-1 and PI3K/AKT pathways causes dietary restriction resistance.
- This chapter describes some case reports for different types of cancer.

Maternal Undernutrition and Developmental Programming: Implications for Offspring Reproductive Potential

70

Stella Chadio and Basiliki Kotsampasi

Contents

Abstract

A growing body of evidence suggests that the concept of developmental programming can also be applied to reproductive system development and function. Variation in the nutrient supply during fetal life and particularly maternal undernutrition has been proposed as a dominant cause of programming. This chapter reviews the existed data from animal and human studies on the impact of maternal undernutrition on later reproductive health and competence. Specific outcomes depend on the severity, duration, and stage of development when nutritional perturbations are imposed, while sex-specific effects are also manifested.

Human cohort studies linking maternal undernutrition, reflected by weight at birth, to a number of reproductive health outcomes and fertility measures are also presented and critically evaluated. Maternal undernutrtion affects offspring gamete quality and reproductive parameters, while effects on fertility are still questionable. Evidence exists for an effect of maternal undernutrition on ovarian reserve, indicating an impact on the time of menopause and reproductive ageing. Mechanisms underlying reproductive programming are still poorly understood. They might include altered cell proliferation/apoptosis, changes in hormone levels or receptor abundance. The periconceptional period, during which major epigenetic changes take place, is of critical importance. Maternal malnutrition can disturb the apposition of epigenetic marks throughout this period, leading to detrimental reproductive outcomes in later life. Evidence also exists that adverse outcomes extend beyond first generation to induce transgenerational effects, through epigenetic mechanisms.

Delineating the mechanisms responsible for long-lasting effects of early nutritional programming will help in developing useful interventions during periconceptional and fetal life to ensure reproductive health in later life.

Adopting policy strategies to prevent and improve maternal nutritional status is a long-term investment that will benefit the present as well as the future generation.

Keywords

Maternal undernutrition · Fetus · Programming · Periconceptional · Offspring · Reproduction · Fertility · Ovarian reserve · Epigenetics · Transgenerational

List of Abbreviations

AGA	Appropriate for gestational age
AMH	Anti-Müllerian hormone
BW	Body weight
DOHaD	Developmental origin of health and disease hypothesis
HPG	Hypothalamic–pituitary–gonadal
IGF-1	Insulin-like growth factor-1
IVF	In vitro fertilization
SGA	Small for gestational age
TTP	Time to pregnancy: The time it takes to become pregnant when planning pregnancy

Introduction

Maternal nutrition is of critical importance for fetal growth and development. A compromised nutrient supply will result in low-birth-weight neonates which suffer an increased risk of perinatal mortality. Apart from short-term outcomes, accumulating evidence from animal and human studies indicate that maternal nutritional status can also affect offspring future health and well-being. This has given rise to the "developmental origins of health and disease"(DOHaD) or developmental

programming hypothesis, which implies that adverse environmental factors acting in utero program the development of fetal tissues, resulting in permanent changes to the structure, physiology, and metabolism in offspring, leading to detrimental consequences and diseases in later life (Wadhwa et al. 2009).

Variation in the nutrient supply during fetal life in terms of both quantity and quality and especially maternal undernutrition has been highlighted as a dominant cause of programming. To date such nutritional programming effects have been largely characterized in terms of susceptibility to cardiovascular and metabolic diseases (McMillen and Robinson 2005). However, in the last years, the DOHaD approach has been extended to encompass programming of reproductive function and health, as reproductive axis and its hormonal control systems are largely established in fetal life, thus being particularly vulnerable to nutritional programming (Chadio and Kotsampasi 2014).

The way through which early nutrition contributes to the onset of later detrimental outcomes likely involves a complex interaction between the maternal environment, placental changes, and epigenetic programming of the embryo. The mechanisms underlying programming effects may include tissue remodeling by alterations in cell proliferation or differentiation, resulting to altered organ structure and function (Hoppe et al. 2007). Endocrine programming is also considered a possible mechanism, since hormones influenced by maternal undernutrition can directly or through changes in placenta phenotype act on the fetal tissues to alter cell growth and differentiation, consequently affecting their function later in life (Harding et al. 2010). Particularly, glucocorticoid exposure has been implicated as a mediator of developmental programming effects (Seckl 2004) and in this respect maternal undernutrition has been shown to alter HPA axis function in young and adult offspring (Chadio et al. 2007).

Finally, epigenetic modulation of gene transcription provides the most plausible mechanism through which fetal nutrient supply can alter gene expression in the developing fetus, leading to later permanent effects. Epigenetic regulation of gene expression include DNA methylation, chromatin and histone modifications, and noncoding RNAs, which can initiate and regulate epigenetic changes in both DNA and histones (Sabin et al. 2013). Effects on reproductive potential and fertility could possibly be mediated by altered expression of genes involved in gonadal development and function and/or in the regulation of the HPG axis. Moreover, alteration in gene expression, if present in germline, may also result in transgenerational effects (Fig. 1).

Nutritional Programming and Gonadal Development

Animal models most widely used in developmental programming studies have been rodents and sheep. Rodents offer significant advantages due to their short gestation period, while studies in sheep provide power for translation to human pregnancy, as sheep have a long gestation period enabling targeting of specific developmental windows during pregnancy and produces a fetus comparable in size to humans.

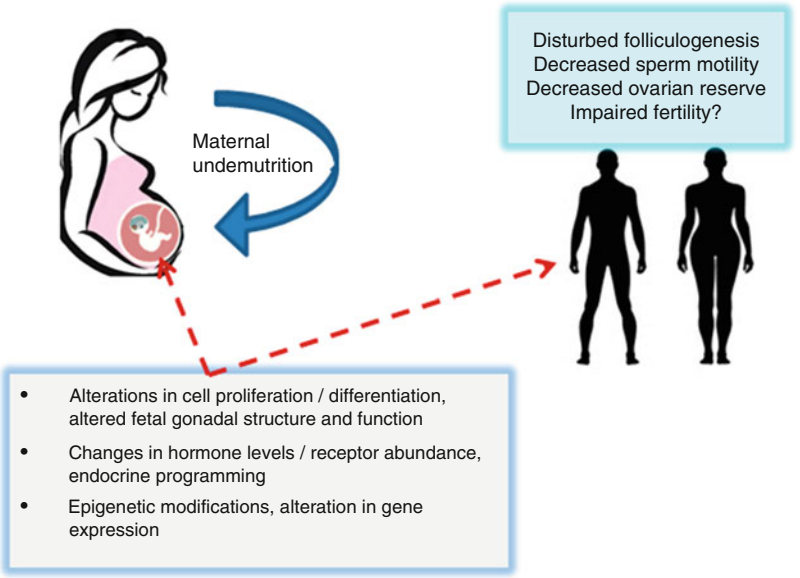

Fig. 1 Nutritional programming of reproductive function

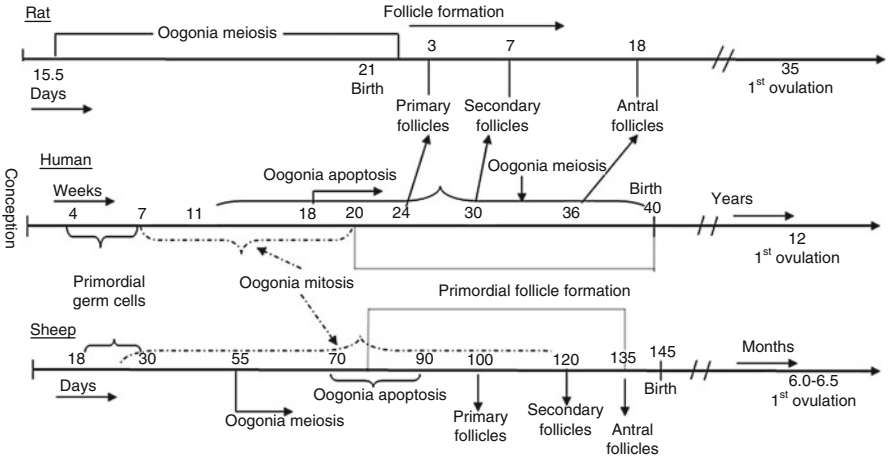

Fig. 2 Milestones of ovarian development in rat, sheep, and human

In females, normal ovarian development during embryogenesis determines the fertility and reproductive capacity later in life (Sarraj and Drummond 2012), while in males, spermatogenesis relies on the establishment of a normal adult Sertoli cells number which are the primary determinant of sperm production and testes size in adulthood and proliferate during fetal, neonatal, and peripubertal period (Sharpe et al. 2003) (Figs. 2 and 3).

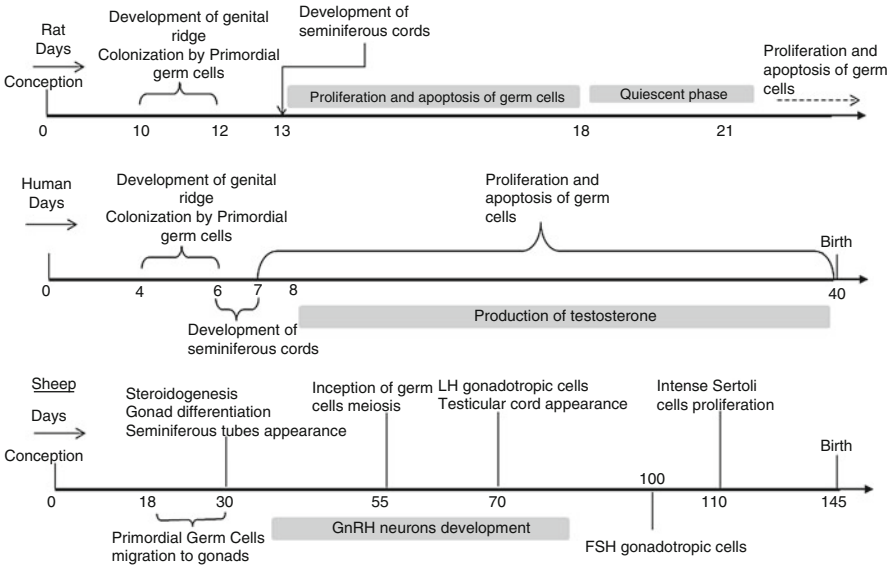

Fig. 3 Milestones of testis development in rat, sheep, and human

A number of animal studies examining the effects of in utero undernutrition on fetal gonadal development indicate a detrimental effect on follicular number and development. In female rats, maternal food restriction imposed during late gestation and/or lactation resulted in a decrease in uterine and ovarian weight, along with disturbed folliculogenesis, reflected by a greater number of antral follicles of small size and a reduced number of graafian follicles of large size (Leonhardt et al. 2003).

In sheep fetuses undernourished during the first month of gestation, a delay in oogonial meiosis and follicular development has been reported (Rae et al. 2001), probably due to alterations in the apoptosis-proliferation balance, leading to reduced follicle number postnatal (Lea et al. 2006). In the same animal model, maternal undernutrition increased the incidence of DNA damage in fetal oogonia (Murdoch et al. 2003), while from early to mid-gestation, it decreased fetal ovarian vascular development, possibly affecting follicular quality (Grazul-Bilska et al. 2009).

On the other hand, it should be emphasized that early perturbations could be of significance only if long-lasting effects are considered. In this regard, rat adult offspring of nutritionally restricted dams showed reduced numbers of primordial and antral follicles, along with changes in key ovarian gene expression and elevated levels of ovarian oxidative stress, which has been associated with ovarian ageing (Bernal et al. 2010). Furthermore, data from sheep showed a sex and window of exposure effect of undernutrition in utero on subsequent gonadal development and function in adult animals. In particular, increased accumulation of antral follicles of small size or reduced number of corpora lutea, consistent with anovulation, were found in 10-months-old female offspring born to mothers undernourished from day 1–30 or day 30–90 of gestation, respectively (Kotsampasi et al. 2009a). In males,

Table 1 Impact of maternal undernutrition on gonadal development and function in offspring

Species	Duration of gestational undernutrition	End points	Effects	Reference
Rats	Late gestation/ lactation	At birth	Disturbed follicullogenesis	Leonhardt et al. 2003
Rats	Whole gestation and/ or lactation	Adult offspring	Reduced number of primordial follicles, increase in oxidative stress, accelerated ovarian ageing	Bernal et al. 2010
Rats	Low protein diet during gestation	12/ 24 week of age	Reduced number of primordial follicles	Aiken et al. 2013
Sheep	0–30 day	Fetal day 50	Delayed ovarian follicular development	Rae et al. 2001
Sheep	65–110 day; 0–110 day	Fetal day 110	Increased rate of apoptosis	Lea et al. 2006
Sheep	28–78 day	Fetal day 78	Increased oxidative damage in oogonia	Murdoch et al. 2003
Sheep	50–135 day	Fetal day 135	Decrease in ovarian vascular development, follicular quality	Grazul-Bilska et al. 2009
Sheep	0–30/31–100	10 months of age	Reduced Sertoli cell number	Kotsampasi et al. 2007a
Sheep	0–30/31–100	10 months of age	Increased number of small antral follicles, decreased number of corpora lutea	Kotsampasi et al. 2007b
Cows	−11 to 110 day	Adult	Diminished ovarian reserve, lower AMH levels, reduction of antral follicle count	Mossa et al. 2013

maternal undernutrition during early to mid-gestation resulted in a reduction in the number of Sertoli cells, accompanied by an increased apoptotic rate, indicating a direct gonadal effect (Kotsampasi et al. 2009b).

These findings in sheep were more recently confirmed in cows, in which maternal nutrient restriction during the first third of pregnancy resulted in diminished ovarian reserve, as measured by AMH and FSH levels and antral counts up to 86 weeks of age (Mossa et al. 2013) (Table 1).

In human studies, given the difficulty to retrospectively assess nutrition in utero, birth weight is usually used as a proxy for fetal nutritional status. In particular, small weight at birth may be the result of either maternal undernutrition or reduced nutrient delivery to the fetus due to different placental insufficiency.

Prospective studies with SGA girls, followed by catch-up growth, showed reduced uterine and ovarian volume and a marked low ovulation rate during their

adolescence (Ibáñez et al. 2002a), suggesting poor ovarian reserve. Furthermore, prenatal growth restraint was found to be followed by elevated serum FSH concentrations in infant girls and boys (Ibáñez et al. 2002b), probably reflecting reduced fractions of granulosa and Sertoli cells within the gonads.

In SGA males, a number of studies have shown reduced gonadal function, as compared with those born of AGA weight (Vanbillemont et al. 2010), while others failed to detect any significant relationship between BW and gonadal function (Olsen et al. 2000; Jensen et al. 2007).

Taking together, the above data point out to sex-specific effects of developmental programming and further emphasize the significant influence of timing and duration of maternal undernutrition on programming gonadal development and function. However, to date there is no direct link between maternal undernutrition and epigenetic modifications that relate to a fertility phenotype, mainly because these mechanisms have not been widely investigated so far.

Does Nutritional Programming Compromise Future Fertility?

A common finding among studies in rodents, sheep, and humans is the disruption of follicular development that follows undernutrition in utero. Therefore, it is of significant importance to determine if this prenatal compromise translates into any significant functional deficit in subsequent fertility, the main outcome of reproductive function.

Data from human studies regarding nutritional programming of reproductive function are very limited. Apart from the well-recognized general limitations of epidemiological studies due to various methodologies, definitions, follow-up periods, and inclusion criteria involved, there are some added parameters related to the study of reproductive function in human populations, such as social or cultural differences which could potentially complicate the interpretation of the observed outcomes. The Dutch famine paradigm (the consequence of a German-imposed food embargo in the western part of the Netherlands toward the end of World War II in the winter of 1944–1945) provided a unique opportunity to address the impact of maternal undernutrition during different gestational windows on later health parameters, including reproductive competence. Follow-up studies of this historical women cohort, examining a number of fertility markers (age at first pregnancy, completed family size, and interpregnancy interval) do not support a detrimental effect on fertility of those exposed to famine as embryos (Lumey and Stein 1997; Lumey 1998). In contrast, a substantial increase in the risk for sterility among rural, but not urban, Chinese women was detected for those conceived and born during the 1959–1961 Chinese famine, indicating that exposure to acute malnutrition in utero may lead to a long-term negative impact and impaired fecundity (Song 2013). No consistent results have also been reported when birth weight was taken as a surrogate for intrauterine nutritional status. A French cohort study reported no evidence of any

relation between BW and fertility of both men and women (Meas et al. 2010), in agreement with recently reported findings from a large longitudinal study based on the Aberdeen Maternity and Neonatal Databank (AMND) records (Shayeb et al. 2014). On the contrary, reports from a case control study in Swedish women seeking infertility treatment revealed that those with low birth weight or SGA had an increased risk for infertility due to female factor (Vikstrom et al. 2014). In support of this, reports from the Danish National North Cohort study revealed an association between low maternal birth weight and a TPP of more than 1 year, indicating effects on fecundity (Nohr et al. 2009).

However, given the well-recognized impact of the catch-up growth that follows in utero growth restriction in mediating many of the adverse metabolic outcomes in adulthood (Gluckman et al. 2005), it is likely that a mismatch between the predicted and actual environment may also underlies some of the effects on reproductive function, a hypothesis that needs further elucidation. Furthermore, it should be not ignored that birth weight cannot be considered an accurate measure, since the critical windows during which the fetus is vulnerable to maternal nutrient disruptions occurs before measurable effects on fetal weight are expressed, and more importantly programming effects may well be expressed in the absence of any changes in birth weight (Chadio et al. 2007; Kotsampasi et al. 2009a, b). Evidence for epigenetic differences among individuals who were exposed to famine early in gestation, but exhibiting a normal birth weight, strengthens this aspect further (Heijmans et al. 2008).

In males, data on the relationship between birth weight and gonadal function are still conflicting, ranging from no effect of birth weight on semen quality (Ramlau-Hansen et al. 2010; Olsen et al. 2000; Ozturk et al. 2001) to a significant association between birth weight and testosterone levels, independent from adult weight (Vanbillemont et al. 2010). Previous studies reported lower BW in subfertile men of unknown etiology (Francois et al. 1997), while birth weight was found to be associated with sperm DNA fragmentation and inversely correlated with total sperm count in primary infertile men (Faure et al. 2015).

Interestingly, very recent data support an association between birth weight and male reproductive function, as men with low birth weight were presented with reduced sperm motility, but normal sperm morphology compared to normal or high birth weight (Boeri et al. 2016).

Overall, despite the methodological inadequacies of individual study results, accumulating evidence from animal and human studies points toward an impairment of gonadal function caused by perinatal growth restriction, probably associated with increased risk of reproductive health.

Nutritional Programming and Reproductive Life Span

Accumulating evidence support a relationship between early life events and increased risk of premature adrenarche, early puberty and associated fertility problems. In this respect birth weight, taken as a surrogate for in utero nutrition has been

reported to affect sexual maturation (Hernández and Mericq 2008), although data on the relationship between birth weight and age at menarche are controversial, mainly due to heterogeneity in the study designs. An association between low birth weight and earlier onset of puberty or menarche has been reported in a number of Cohort studies (Cooper et al. 1996; Ibáñez et al. 2000), suggesting an effect of birth weight per se. On the other hand, different lines of evidence clearly indicate that SGA children gaining body weight rapidly develop central adiposity, accompanied by elevated IGF-1 and leptin concentrations and insulin resistance, factors that contribute to precocious pubarche and earlier menarche (Ong et al. 2000). The normalizing effect of treatment with an insulin sensitizer confirms that insulin resistance is the key mechanism linking a post-SGA state to early menarche (Ibáñez et al. 2006). These findings clearly support a central role for an interplay between low birth weight and accelerated weight gain in determining age at menarche and further support the suggestion the timing and intensity of the catch-up growth that follows prenatal growth restraint may have consequences on the endocrine, metabolic, and reproductive systems that persist over time (Ibáñez et al. 2011).

On the other hand, evidence for an association between maternal nutrition and age at menopause is more straightforward. It is well accepted that in females the follicular reserve is set up during the fetal life and serves as the source of developing follicles and oocytes for life time supply (McNatty et al. 1995). Therefore, a key end point to evaluate the possible effects of nutrition in utero on ovarian reserve is offered by examining the age at natural menopause. Data on the relation between maternal nutrition and age at menopause are very limited, while more frequently reported are studies on the association between birth weight, taken as a proxy for intrauterine nutritional status and age at menopause. In this regard, although earlier reports from the Dutch Hunger paradigm found no such an association, more recent data from the same cohort reported an increased likelihood of menopause at any given age for those women exposed to Dutch famine in utero (Yarde et al. 2013). Furthermore, data from a British birth cohort study using birth weight standardized for gestational age revealed that both extremes of birth weight (<2.5 kg or >4 kg) were indeed associated with an earlier age at menopause (Tom et al. 2010), suggesting that prenatal nutrition can probably influence reproductive lifespan in adult life. Evidence for such an association has also been shown in SGA girls that are thought to be at an increased risk of experiencing premature infertility (Vikstrom et al. 2014), although these results are still contentious (Meas et al. 2010).

It is interesting to note that a reduction in the age at menopause was also detected for women exposed to Dutch winter famine during their childhood (Elias et al. 2003). These observations along with data from poorer, rural communities (Kapur et al. 2009) points out to an effect of nutrition on age at menopause. However, there is still need to clarify the relative contributions of early versus later life nutrition, especially in the light of the well-known effects of catch up growth in developmental programming paradigm (Gluckman et al. 2005).

It is well accepted that ageing of the reproductive system occurs more rapidly than somatic ageing (Li et al. 2012), making the reproductive tract particularly sensitive to the ageing aspects of developmental programming exposures, such as maternal

Table 2 Impact of low birth weight or undernutrition in utero on fertility parameters in humans

Females/ males	Birth weight/ nutrition in utero	End point	Effect	Reference
Females	SGA	Adolescence	Reduced ovulation rate	Ibáñez et al.
Females	Low BW	Adult	Reduced fecundity	Nohr et al. 2009
Females	Low birth weight/ SGA	Adult	Increased risk for infertility	Vikstrom et al. 2014
Females	BW <2.5 kg or >4 kg	Adult	Early age at menopause	Tom et al. 2010
Females	Undernutrition in utero	Adult	No effects on fertility	Lumey 1998
Females	Undernutrition in utero	Adult	Earlier menopause	Yarde et al. 2013
Males	SGA	Adult	Reduced gonadal function	Vanbillemont et al. 2010
Males	Low birth weight	Adult	No effects on semen quality	Ramlau-Hansen et al. 2010; Olsen et al. 2000; Ozturk et al. 2001
Males	Low birth weight	Adult	Reduced sperm motility	Boeri et al. 2016
Males-females	Low birth weight	Adult	No impact on fertility	Meas et al. 2010; Shayeb et al. 2014

undernutrition. A number of elegant studies in the rat model of low-protein maternal nutrition showed an increased oxidative stress in offspring ovaries and oviducts along with increased mitochondrial DNA copy number and telomere shortening, all indicative of accelerated ageing. Most importantly, this accelerated cellular ageing was accompanied by a decline in the ovarian reserve in programmed animals (Aiken et al. 2013). This kind of insights from animal studies shed more light on the molecular mechanisms that underlay reproductive senescence and might have significant implications in light of the current trend toward later childbearing in many populations. However, there is need to be further explored in longitudinal human studies, before any safe conclusion can be drawn (Table 2).

The Importance of Periconceptional Nutrition and the Role of Micronutrients

Maternal nutrition can influence the development of the fetal reproductive system at all stages of development. However, recently the periconceptional period has attracted more attention in the context of DOHaD concept, as being the potentially more critical period in which developmental plasticity is vulnerable to environmental challenge, including maternal malnutrition. This period

encompasses gametogenesis, fertilization, conceptus formation, implantation, and placentation, which represent particular time windows during which epigenetic changes can have long-lasting consequences on the development and function of the tissues and therefore long-term effects on phenotype and diseases (Attig et al. 2010). The gametes and the embryo represent particularly sensitive stages, during which the epigenome can be altered. Changes to the immediate environment surrounding oocytes, probably resulting from nutritionally induced changes in hormone and metabolite levels, can alter the pattern of genes expressed by ovarian follicles, impacting immediate and longer-term development (Ashworth et al. 2009). Moreover, preimplantation embryo has been shown to be sensitive to environmental perturbations with long-term consequences (Fleming et al. 2004).

The vital role of periconceptional nutrition has been highlighted in studies involved in diet manipulation of donor animals. In particular, a reduced number of cleaved oocytes following IVF has been reported for ewes undernourished from 8 weeks prior to conception (Grazul-Bilska et al. 2012), while maternal global undernutrition has been shown to reduce blastocyst and trophectoderm cell number in the same species (Borowczyk et al. 2006).

Accumulating evidence also suggest that apart from macronutrients, micronutrient imbalance can adversely affect fertility, embryogenesis, and placentation (Cetin et al. 2010). In particular, gametogenesis and early embryogenesis are critical developmental windows for erasure, acquisition, and maintenance of genomic imprints (Ashworth et al. 2009). Malnutrition is well known to disturb a number of metabolic pathways and among these the 1-carbon metabolism, which determines the flux of methyl groups via the linked folate–methionine cycle toward synthesis or methylation of DNA (Thuesen et al. 2010). The excellent review by Steegers-Theunissen et al. (2013) considering different lines of evidence, including human and animal studies, support a link between 1-C derangements and reproductive outcomes. Elevated homocysteine levels, a sensitive biomarker of deranged maternal 1-C metabolism, have been negatively associated with the number of oocytes recovered, embryo quality, and pregnancy outcome (Boxmeer et al. 2008).

In humans, in which periconceptional period is thought to start around 14 weeks prior up to 10 weeks after fertilization in women and about 10 weeks for the spermatogenic cycle in men, data on the effects of periconceptional nutrition on later reproductive outcomes are very scarce. However, it is worth noting that a Dutch study demonstrated that women adhered to a Mediterranean (rich in 1-C metabolites, such as folate and B12 derived from vegetables, fruits, etc.) diet in the weeks before IVF were 65% more likely to achieve an ongoing pregnancy (Twigt et al. 2012).

Apart for the well-established role of micronutrients in short-term pregnancy outcomes, accumulating evidence support also a role in developmental programming leading to later onset risk of noncommunicable diseases (Christian and Stewart 2010). Further studies are required to establish links with fertility as well.

Policies and Protocols

Despite the well-recognized improvement in maternal nutrition during the last decades, disparities still exist among populations not only in developing, but in developed countries as well, particularly in adolescent girls (Mouratidou et al. 2006; Black et al. 2008). In the context of long-term consequences of poor maternal nutrition for the fertility and reproductive performance of next generations, a life time approach with respect to intervention strategies should be considered. The periconceptional period, because of its paramount significance, is crucial for the implementation of measures to provide within an integrated preconceptional care approach nutritional advice to women planning pregnancy. Central to the preventive strategies will also be efforts to improve the nutrition of adolescent girls and women of reproductive age, especially those in lower socioeconomic groups.

The fact that maternal undernutrition may impact on the ovarian reserve should be taken into account considering fertility and assisted reproduction counseling. Moreover, the consequences of diminished ovarian reserve may impact not only fertility, but also general health due to a number of early menopause-related commodities. These latter effects are of particular interest nowadays, in light of current trend toward late motherhood.

Evidence that maternal undernutrition may lead to transgenerational effects creates new policy challenges about protecting and promoting reproductive competence and health through maternal nutrition, to ensure reproductive health across the generations that follow.

Regarding future research, although historical cohort studies provided useful results, there is a need for more randomized controlled trials to assess the impact of maternal nutrition on later reproductive health. Apart from macronutrients, specific attention should also be paid to ascertain which micronutrients are important and therefore should be supplemented before conception and during pregnancy. The results from contemporary cohort studies, which are more descriptive and provide more material for biological analysis, particularly for epigenetic studies will help in elucidating the underlying mechanisms.

There is an emerging need for a fruitful collaboration between the scientific community and policymakers. The participation of scientist in the decision-making process is of crucial significance to provide an evidence-based perspective and effective implementation.

A recent report from the WHO Regional Office for Europe, in the context of HEALTH 2020, highlights the need for development and updating of national guidelines to protect and promote public health through the improved nutrition of women of reproductive age, especially during the preconception and pregnancy periods (WHO 2016).

The prevention of maternal undernutrition is a long-term investment that will benefit the present as well as the future generation.

Dictionary of Terms

- **DOHaD** – The developmental origin of health and disease hypothesis implies that a stimulus or insult acting during critical periods of growth and development may result in developmental adaptations that permanently affect structure and metabolism, leading to increased risk of diseases in later life.
- **Nutritional programming** – The process through which variations in the nutrient supply during fetal life, in terms of both quantity and quality, exerts permanent effects upon the developing fetus.
- **Epigenetics** – The study of heritable changes in gene expression that occur without alterations in genomic sequence.
- **Periconceptional period** – The period before and immediately after the time of conception. It encompasses gametogenesis, fertilization, implantation, and early embryogenesis stage.
- **Transgenerational effects** – The ability of environmental insults during development to promote a phenotype state not only in the individual exposed but also in successive generations.

Summary Points

- Evidence from human epidemiological and animal studies clearly indicate that maternal undernutrition affects offspring gamete quality and reproductive parameters, but effects on fertility are not yet well documented.
- Data from human famine paradigms are not consistent, reporting either no detrimental effects of maternal undernutrition on fertility or a decrease in the ovulation rate in women undernourished as fetuses.
- Outcomes depend on the timing and duration of maternal undernutrition, while sex-specific effects are also evident.
- A substantial body of evidence, both from animal and human studies, indicates that maternal undernutrition may impact on ovarian reserve, probably affecting the time of menopause and thus reproductive longevity. These findings represent an issue of translational interest, especially in light of global population trends toward late childbearing.
- The periconceptional period, during which major epigenetic changes take place, is of critical importance. Maternal malnutrition can disturb the apposition of epigenetic marks throughout gametogenesis, fertilization, and the first steps of embryonic development, leading to detrimental outcomes in later life.
- Recent evidence indicates that parental nutrition during the periconceptional period can affect reproductive performance via 1-C metabolic pathways.
- Evidence also exists that adverse outcomes extend beyond first generation to induce transgenerational effects through epigenetic mechanisms.

- Delineating the mechanisms responsible for long-lasting effects of early nutritional programming may lead to develop useful interventions during periconceptional and fetal life to ensure reproductive health in later life.

Contents

Abstract

Low birth weight is increasing worldwide. In poor societies, this is linked to maternal undernutrition and in high-income countries it is mainly due to

David Ramiro-Cortijo and Pilar Rodríguez-Rodríguez contributed equally to this work.

gestational complications associated with the delay in first pregnancy. In both situations, the consequence is fetal undernutrition and deficient growth. In addition to the high risk of perinatal mortality and morbidity, low birth weight has long-term health consequences, increasing the risk of cardiometabolic disease development. The process that associates a deficient fetal growth with a higher risk of adult disease is known as fetal programming. In addition to undernutrition, other stress factors during intrauterine life – such as exposure to toxic substances – also contribute to programming. All of them are known to disrupt the physiological systems responsible for cardiovascular and metabolic control, being oxidative stress a common denominator. Fetal responses to stress factors seem to be modulated by sex. Under adverse intrauterine conditions, females exhibit a better placental adaptation and fetal growth. Later on, during fertile life, estrogens also represent a biological advantage for females, due to their cardiovascular protective actions. However, gender-related factors, such as social or cultural inequities, are likely to counteract the better biological adaptation of females. Sex and gender are often difficult to separate and their relative influence in fetal programming is still far from being understood. Additional research is needed to design-specific interventions and policies in order to reduce the impact of fetal programing on cardiometabolic health in future generations.

Antioxidants · Cardiometabolic diseases · Fetal programming · Gender · Malnutrition · Oxidative stress · Placenta · Sex

List of Abbreviations

BMI	Body Mass Index
CMD	Cardiometabolic disease
CVD	Cardiovascular disease
GPX	Glutathione peroxidase
GR	Glutathione reductase
GSH	Reduced Glutathione
HPA	Hypothalamic-Pituitary-Adrenal axis
IUGR	Intrauterine growth restriction
LBW	Low birth weight
MDA	Malondialdehyde
NO	Nitric oxide
RAAS	Renin-Angiotensin-Aldosterone system
RNS	Reactive nitrogen species
ROS	Reactive oxygen species
SNS	Sympathetic nervous system
SOD	Superoxide dismutase
T2DM	Type 2 Diabetes Mellitus

Introduction

Over 20 million low birth weight (LBW) babies are born every year, related to intrauterine growth retardation (IUGR), prematurity, and other causes, and the rate is growing worldwide (World Health Organization 2014). The incidence of LBW is much higher in poor societies, but is also increasing in high-income countries. LBW not only contributes to neonatal morbidity and mortality, but also predisposes to long-term noncommunicable diseases, a process known as fetal programming. In particular, LBW associates with cardiovascular diseases and their risk factors – hypertension, obesity, and type II Diabetes Mellitus (T2DM) – referred in this chapter as cardiometabolic diseases (CMD).

LBW is mainly the result of fetal undernutrition related either to a poor maternal diet or to placental complications. However, factors such as exposure to toxic substances or psychological stress may also contribute. All these fetal stressors seem to converge on the same organic alterations – oxidative stress being a common underlying mechanism. In addition, the sex of the individual seems to modulate the responses to fetal stressor and may exert an influence on CMD development. Furthermore, gender aspects, including social and educational factors, might also modulated fetal programming.

The aim of this chapter is to summarize current knowledge on the role of oxidative stress in fetal programming with a focus on the influence of sex and gender.

Fetal Programming: Stress Factors and Mechanisms Implicated

Intrauterine life is a period of high plasticity, the individual being highly vulnerable to stress factors – particularly nutritional limitations. Over four decades of study have provided sufficient evidence of the relationship between fetal stress, LBW, and CMD. This association was postulated by Barker, based on epidemiological studies in populations that suffered starvation in early twentieth century (Forsdahl 1977; Barker and Osmond 1986).

Barker's hypothesis has been extensively confirmed in populations of different ethnic origin and geographical location exposed to malnutrition in fetal life, which exhibited an increased risk of hypertension, T2DM, and obesity in adult life (Alexander et al. 2015; Liu et al. 2016). Postnatal growth acceleration following inadequate fetal growth has an additional negative impact, further contributing to CMD programming (Singhal and Lucas 2004).

The main stress factors interfering with fetal growth are maternal malnutrition, obstetric complications, exposure to toxic substances, and psychological stress.

Although the term "malnutrition" is often used as synonym of undernutrition, it can also be used to indicate a dietary imbalance or excess. Maternal undernutrition was the first recognized stress factor responsible for LBW and CMD programming, and continues to be the most important contributor. More than 4.5% of pregnant women worldwide suffer undernutrition, mainly in low- and middle-income countries

(Yasmin 2016). Furthermore, micronutrient-deficient diets are also common and also contribute to LBW and prematurity (Black et al. 2013). Pregnant women from high-income countries might also have micronutrient deficiency due to unbalanced diets related to lifestyle factors. Another form of malnutrition is obesity, which is a worldwide growing problem. It has been estimated that around 57% of pregnant women are overweight, which is also a risk factor for LBW (Tarrade et al. 2015).

Fetal undernutrition might also be a consequence of obstetric complications, such as gestational diabetes mellitus (GDM) and preeclampsia, unrelated to the maternal nutritional status. These complications contribute to LBW by restricting nutrient and oxygen availability to the fetus and are associated with CMD programming (Boney et al. 2005).

Some toxic substances related to lifestyle habits, like tobacco and alcohol intake, interfere with fetal growth, increase the risk of LBW (Ko et al. 2014; Nykjaer et al. 2014), and program hypertension (Simonetti et al. 2011). It is remarkable that alcohol intake has negative effects on fetal growth not only when consumed during pregnancy, but also during the period prior to conception and women should be advised when planning to conceive (Nykjaer et al. 2014). Similarly, some environmental contaminants, which are difficult to evade due to their ubiquitous presence, interfere with fetal development and might program CMD (Al-Gubory 2016).

Other substances known to interfere with fetal growth are glucocorticoids and, in particular, cortisol, which might be elevated in the mother as a consequence of pharmacological treatment or psychological stress (Alexander et al. 2015). The passage of cortisol from the mother to the fetus is limited by the placental enzyme 11-β-hydroxysteroid dehydrogenase-2 (11-β-HSD-2). In situations of undernutrition, placental insufficiency, or maternal exposure to toxic substances, this enzyme is inhibited, allowing cortisol to reach the fetus in excess and, therefore, contributing to LBW. Epidemiological studies provide evidence that cortisol elevation might contribute to LBW and cardiovascular disease in adult life (Van Montfoort et al. 2005). A schematic diagram summarizing the main fetal stress factors is shown in Fig. 1.

Studies in animals mimicking gestational complications, exposure to malnutrition, toxic substances, or excess cortisol during intrauterine life, confirm that these stressors lead to LBW and subsequent CMD. These studies have also investigated the mechanisms through which an adverse fetal environment translates into physiological alterations, demonstrating that different fetal stressors converge onto similar alterations in the systems responsible for cardiometabolic control (Nuyt 2008; Alexander et al. 2015). Thus, studies in animal models of fetal programming reveal a deficient kidney, heart, and vascular development, evidenced as low organ weight and cell number at birth. These initial alterations are associated with later insufficient renal function, cardiac hypertrophy, and arterial stiffening – factors contributing to hypertension development in adult life (Alexander et al. 2015; Rodríguez-Rodríguez et al. 2017). Fetal programming of hypertension has also been associated with alterations in the renin-angiotensin-aldosterone and the sympathetic nervous systems (RAAS; SNS), which are key for blood pressure regulation (Alexander et al. 2015).

Regarding the organs responsible for metabolic control, alterations in fetal pancreatic β-cells, adipocytes, skeletal muscle, and liver have been found in animals

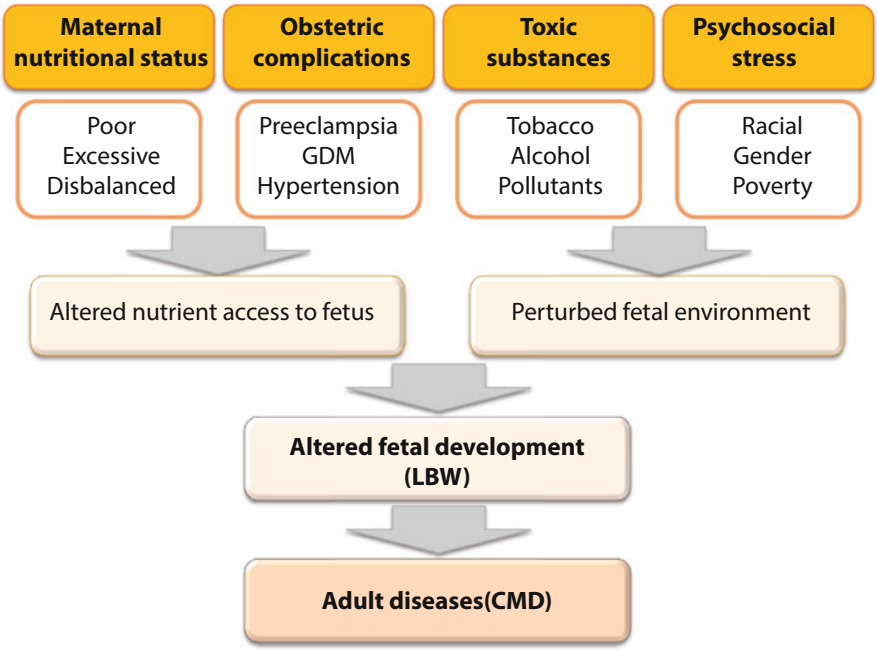

Fig. 1 Main stress factors implicated in fetal programming of cardiometabolic disease. Adverse factors known to interfere with fetal growth contributing to low birth (*LBW*), and subsequent development of cardiometabolic diseases (*CMD*) in adult life. *GDM* Gestational Diabetes Mellitus

exposed to fetal stress factors. These initial alterations have been associated with abnormal control of glucose and fat metabolism and the subsequent development of T2DM and obesity in adult life.

Some of the aforementioned alterations might be mediated by epigenetic processes, i.e., the modification in gene function and expression without changes in the DNA sequence. Several fetal stress factors seem to alter the expression of important genes for cardiometabolic control, including 11β-HSD2, several RAAS components, and some glucose transporters – through epigenetic modulation (Ingelfinger and Nuyt 2012; Alexander et al. 2015). Epigenetic changes are inheritable, and thus, CMD programming can be transmitted from one generation to the other. Figure 2 summarizes the main alterations induced by fetal stressors in organ growth and physiological systems responsible for cardiometabolic control.

Oxidative Stress as Mechanism Implicated in Fetal Programming

Oxidative stress can be defined as an imbalance between pro-oxidative substances (reactive species) and antioxidants, favoring the former.

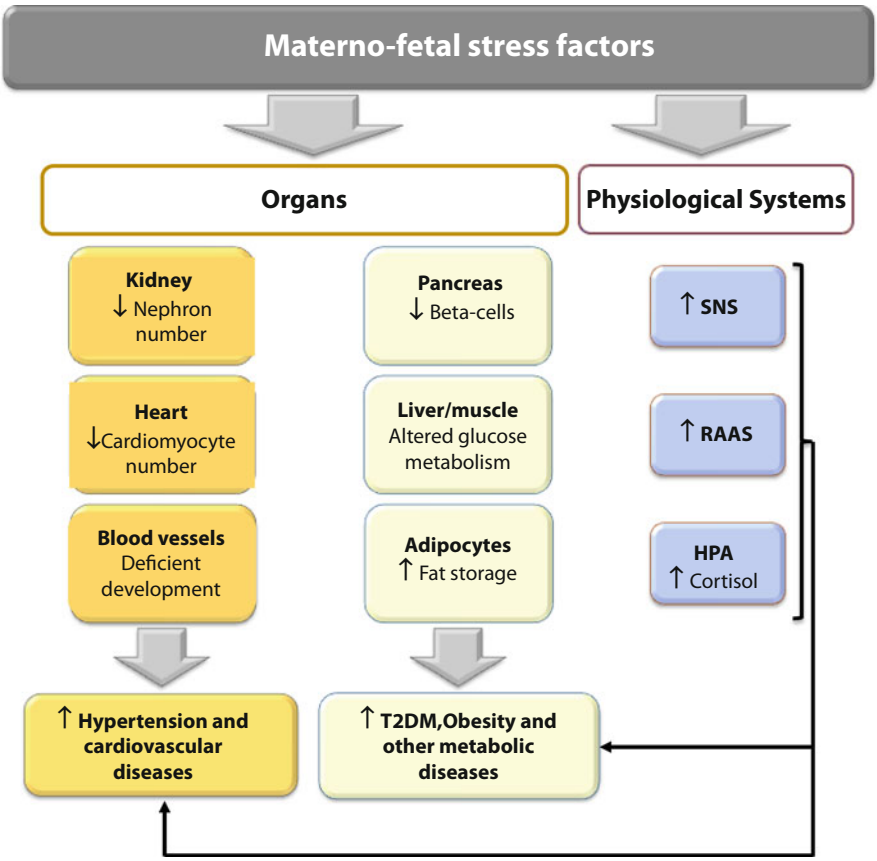

Fig. 2 Alterations implicated in fetal programming of cardiometabolic diseases. Stress factors during fetal life lead to cardiometabolic diseases, such as hypertension, type 2 diabetes mellitus (*T2DM*), and obesity, through modifications in several organs and physiological systems such as the sympathetic nervous system (*SNS*), the renin-angiotensin-aldosterone system (*RAAS*), and the hypothalamic-pituitary-adrenal axis (*HPA*)

Oxidative stress is well known to contribute to kidney, heart, and vascular pathophysiological alterations associated with CMD diseases through oxidative damage to macromolecules. Therefore, it is plausible that oxidative stress may be the underlying common link between adverse fetal environment and increased risk of CMD (Thompson and Al-Hasan 2012; Alexander et al. 2015).

Reactive Species and Antioxidants

Biologically relevant reactive species includes reactive oxygen species (ROS) – generated as a consequence of aerobic metabolism – and reactive nitrogen species (RNS) which can be either free radicals or nonradical species. Their common

characteristic is their high instability. Thus, reactive species have a tendency to react with surrounding molecules, thereby oxidizing them. ROS and RNS have important physiological functions as cell signaling molecules and in the immune defense, among others. However, in excess, they produce oxidative damage to lipids, proteins, and DNA, resulting in functional loss (Halliwell and Gutteridge 2015; Nikolaidis et al. 2015).

The main cellular ROS are superoxide anion ($O_2\bullet^-$) and derived molecules, such as hydrogen peroxide (H_2O_2) and hydroxyl radical (OH•). Biologically relevant RNS include nitric oxide (NO) and peroxynitrite ($ONOO^-$).

To counteract the high oxidative capacity of reactive species, the organisms display a well-organized endogenous antioxidant system. From a wide point of view, an antioxidant can be defined as a substance that delays, prevents, or removes oxidative damage to target molecules. Endogenous antioxidants can be enzymatic systems, low molecular weight molecules, and the hormone melatonin (Reiter et al. 2016).

Figure 3 shows a schematic diagram of biologically relevant reactive species and antioxidants contributing to redox balance.

Biomarkers to Assess Oxidative Stress in Biological Samples

Oxidative stress is considered an important mechanism in diseases and its assessment, through biomarkers present in accessible biological samples, provides important information for disease diagnosis and progression. However, this is not an easy target and the question on which biomarker is most suitable remains under debate. To evaluate oxidative stress, it would desirable to have information on the levels of both reactive species and antioxidants, which represent the two sides of the balance. While the majority of endogenous antioxidants can be easily measured, reactive species are difficult to assess due to their short half-life.

Oxidative stress is frequently determined by the products of the oxidative damage to lipids, proteins and DNA. Lipids are the first target of oxidation by reactive species, altering cell membrane function, and lipid peroxidation products are frequently used to assess their damage. Protein oxidation by reactive species alters the function of key physiological molecules such as antibodies, enzymes, or receptors. Carbonyl groups in proteins are highly susceptible for oxidation and they are frequently used to assess the degree of protein damage. DNA oxidation occurs continuously in cells, but it is usually followed by repair. However, if the repair process is overwhelmed, cell mutation or death might occur. DNA oxidative damage can be assessed in plasma and urine by several biomarkers (Nikolaidis et al. 2015).

An elevation in these biomarkers over normal levels is indicative of oxidative stress. However, it does not identify the origin, i.e., an increase in reactive species, a decrease in antioxidants, or both. Further information can be obtained by evaluating antioxidants, which can be assessed in biological fluids. There are many endogenous antioxidants with different chemical characteristics and the assessment of a particular one does not provide sufficient information about the global antioxidant status.

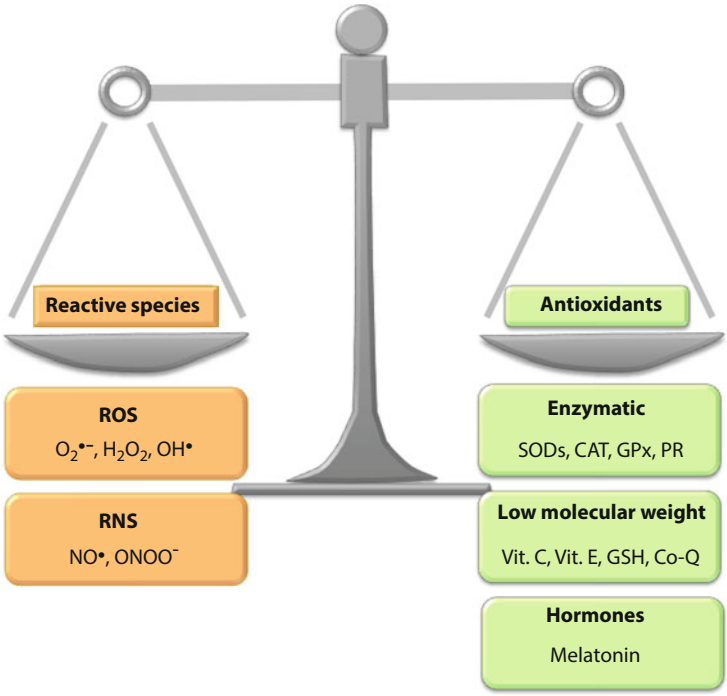

Fig. 3 Pro-oxidant/antioxidant balance in biological systems. Main biological pro-oxidant (reactive species) and antioxidant substances that are balanced in physiological situations. A pro-oxidant excess or an antioxidant deficiency induces a disbalance known as oxidative stress. Reactive species include Reactive Oxygen Species (*ROS*) and Reactive Nitrogen Species (*RNS*). The main biological ROS are superoxide anion ($O_2^{\bullet-}$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($OH^{\bullet}$). The main RNS are nitric oxide ($NO^{\bullet}$) and peroxynitrite ($ONOO^-$). Endogenous antioxidants include the enzymatic systems superoxide dismutases (SODs), catalase (CAT), glutathione peroxidase (*GPx*) and peroxiredoxins (*PR*), several vitamins (*Vit.*), reduced glutathione (*GSH*) and coenzyme Q (*Co-Q*), and the hormone Melatonin

Therefore, it would be desirable to quantify as many antioxidants as possible. A better approach is to combine all antioxidants measured into an index, a parameter representative of the global antioxidant status of the individual. The use of an antioxidant index might be useful to predict obstetric and fetal complications (Ramiro-Cortijo et al. 2016).

Oxidative Stress and Fetal Programming

There is wide evidence supporting the implication of oxidative stress in fetal programming. Different stress factors, including malnutrition (Gupta et al. 2004), nicotine (Stone et al. 2014), environmental pollutants (Al-Gubory 2016), or glucocorticoids (Stark et al. 2011), have been shown to associate with increased oxidative

damage, measured both in pregnant women and in the offspring. The implication of oxidative stress in fetal programming is reinforced by the demonstration in animals that maternal exposure to fetal stress factors during gestation together with an antioxidant treatment avoids hypertension development in the offspring (Alexander et al. 2015).

Oxidative damage may be related to poor antioxidant levels during gestation, as found in neonates with growth deficiency and their mothers (Saker et al. 2008). Antioxidant deficiency can be a consequence of deficient passage of antioxidants through the placenta, particularly important during the last weeks of pregnancy (Davis and Auten 2010). However, oxidative disbalance may also occur in the first trimester of pregnancy and has been associated with higher risk of obstetric complications and deficient fetal growth (Potdar et al. 2009; Ramiro-Cortijo et al. 2016). The finding that low antioxidant levels in maternal plasma during gestation associate with diets poor in fruits and vegetables suggests the importance of maternal nutrition and micronutrients in particular for oxidative balance (Ramiro-Cortijo et al. 2016).

Influence of Sex and Gender in Fetal Programming

Sex and gender are terms which are often exchanged, but have specific meanings. Sex refers to the classification according to biological genetic differences and can be considered as fixed. Gender is used to distinguish the socio-cultural differences assigned to women and men, which vary with time and among societies. Sex influences can be easily determined from studies in experimental animals using males and females. However, in humans, sex and gender are closely interrelated and their relative influence is difficult to separate.

Despite growing evidence that human diseases present a sexual dimorphism in the prevalence, symptoms, and severity, sex and gender-based considerations are still not sufficiently taken into account in biomedical research or in clinical practice. In particular, their role in fetal programming is still not completely understood.

Sex Influences

There is evidence that fetal programming of CMD exhibits a sexual dimorphism. Among the biological factors which contribute, the best characterized are the placenta and sex hormones. The majority of experimental animal studies conclude that males exposed to fetal stress exhibit a higher susceptibility to hypertension and cardiovascular diseases development than females (Dasinger and Alexander 2016). However, in humans, sexual dimorphism is not evident and women and men who suffered starvation in utero exhibit similar CMD risk (Smith et al. 2016; Liu et al. 2016). The apparent discrepancy might be related to age influences, menopause being a possible confounding factor. This is supported by longitudinal studies using animals exposed to undernutrition during intrauterine life, which show that young females exhibit a better cardiovascular response compared to males. However, at old

age females and males exhibit similar cardiovascular alterations (Rodríguez-Rodríguez et al. 2017). Interestingly, females seem to exhibit similar or even higher vulnerability than males in the development of CMD when the fetal stressor is overnutrition or nutritional disbalance (Alexander et al. 2015). Despite these findings, there is insufficient information on the long-term responses of females to fetal stress factors and an effort should be made to increase the number of studies to clarify the role of sex and age in fetal programming.

Role of the Placenta

The placenta has endocrine, metabolic, and barrier functions and also participates in the suppression of maternal immunity against the fetus. When exposed to an insult, failure or inadequate placental response may contribute to alterations in fetal growth and subsequent disease programming.

The placenta is generated by the fetus and, therefore, has the same biological sex. Male and female placentas exhibit structural and molecular differences and respond differently to adverse stimuli. Female placenta seems to have a better buffering capacity against suboptimal nutrition (Eriksson et al. 2010; Tarrade et al. 2015; Rosenfeld 2015). However, in a situation of overnutrition, females seem to be at disadvantage and more prone to programming. This may explain why there is a larger prevalence of T2DM and strokes in women from obese mothers (Eriksson et al. 2014). Differences in genetic regulation between male and female placenta might also account for the better adaptation of females to fetal stress factors. Thus, female placenta are able to upregulate the enzymatic barrier 11β-HSD2 in response to excess glucocorticoid exposure, leading to a better adaptation than males against alterations in HPA axis (Rosenfeld 2015).

Sex differences in placental function may be related to oxidative stress. During gestation, there is an elevation of ROS, which play important physiological roles. Incapacity of the placenta to counteract this ROS elevation through a concomitant increase in antioxidants is a predisposing factor for maternal and fetal complications (Wu et al. 2015). Male and female placentas also respond differently to stressors which modify oxidative status. In male placentas glucocorticoids induce a pro-oxidant state, with a detrimental impact on placental function and fetal growth (Rosenfeld 2015). Among endogenous antioxidant systems, melatonin – which may be synthesized by the placenta – has been suggested to play a protective role in obstetric and fetal complications, reducing oxidative stress (Marseglia et al. 2016). Whether melatonin levels in the placenta are influenced by sex remains to be determined.

Role of Sex Hormones

The abovementioned sexual dimorphism in the placenta may be related to the effect of sex hormones. In males, testicular development and synthesis of the sex hormone testosterone starts around week 6–8 of gestation. This period marks the difference with females, which will be mainly exposed to maternal female sex hormones, estrogen, and progesterone, during the gestational period. Male and female sex hormones have opposing influences on placental vasculature. While estrogens stimulate production of NO (a well-known vasodilator) and stimulate vascular

development, testosterone has the opposite effects (Chinnathambi et al. 2013; Gopalakrishnan et al. 2016; Maliqueo et al. 2016). A deficient placental vasculature and inadequate vasodilatation would compromise feto-placental blood flow leading to fetal undernutrition. This might explain why excess in maternal testosterone levels (which occur in some pathological situations) are associated with inadequate fetal growth (Palomba et al. 2013; Gopalakrishnan et al. 2016).

In adult life, estrogens and testosterone also exert opposing influences and it is well recognized that female sex hormones exhibit cardiovascular protective effects (Maric-Bilkan et al. 2014). Therefore, sex hormones could modulate the effects of fetal programming. The favorable effects of estrogens are supported by the fact that female animals exposed to a fetal stress usually do not exhibit high blood pressure, while males develop hypertension. Furthermore, ovariectomy induces blood pressure elevation, together with alterations in cardiovascular, RAAS, and renal systems, which are reversed by estrogen replacement. On the other hand, androgens seem to be implicated in fetal programming of hypertension, as suggested by the higher circulating testosterone levels in animals exposed to fetal stress and by the inhibition of hypertension development upon castration (Dasinger and Alexander 2016).

The effects of sex hormones may be related to oxidative stress. Estrogens stimulate antioxidant systems and inhibit ROS-producing enzymes, while testosterone activates ROS synthesis (Maric-Bilkan et al. 2014). Furthermore, in animal models of fetal stress, ovariectomy increases vascular ROS production (Dasinger and Alexander 2016).

Sex influences on fetal programming are summarized in Fig. 4.

Gender Influences

Cardiovascular diseases have been perceived for many years as man's diseases (Lerner and Kannel 1986). This perception has been proved wrong and explained by a gender bias due to a combination of factors, such as the delay in women seeking medical care or the difficulties in the recognition of the clinical symptoms in women (Mosca et al. 2011). Moreover, epidemiological studies have focused on male-related cardiovascular risk factors, such as tobacco consumption excluding others (such as plasma tryglicerides) which are more relevant in the prediction of cardiovascular events in women (Ridker et al. 2002). The importance of heart disease in women has been gradually recognized and substantial efforts have been made to reduce gender disparities in research and clinical care.

Gender factors may also modulate some aspects of fetal development. Since social, cultural, and educational factors varies among different societies according to their economic status, their influence on fetal programming is separately analyzed in low- and high-income countries (Fig. 5).

Gender Aspects in Low- and Middle-Income Countries

One of the gender-related factors, which may influence fetal programming in poor societies, is the lack of reproductive health and family planning control. Around 180

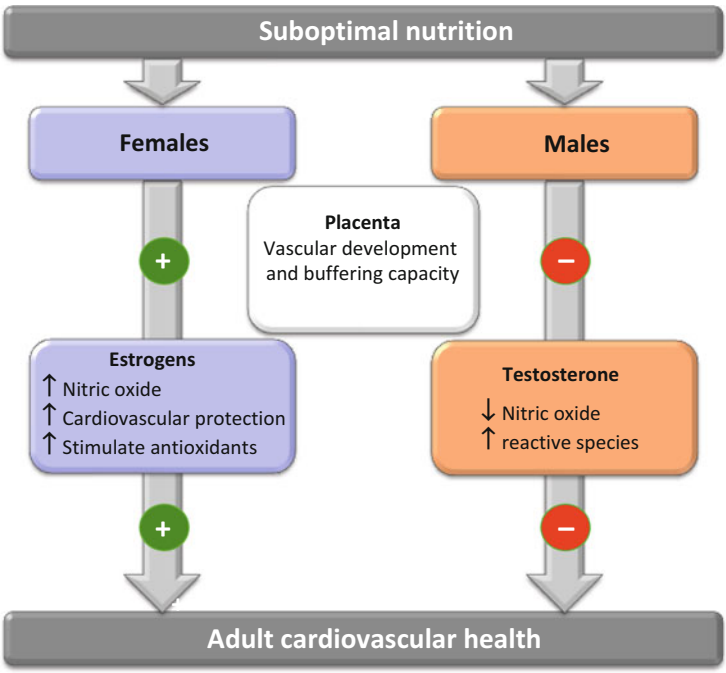

Fig. 4 Sex influences on fetal programming of cardiovascular diseases. Females are better adapted than males to suboptimal nutrition, both during fetal life, through placental adaptations, and during adult life through the cardiovascular protective actions of estrogens

million pregnancies occur in low-income and only around 2 million in high-income countries. Moreover, one-third of the world pregnancies have not been planned in poor societies, in situations of chronic poverty, starvation, and deficient hygiene conditions. The immediate consequence is LBW. In fact, LBW has been estimated in approximately 20 million per year, the majority born in poor countries (World Health Organization 2014).

In situations of poverty, pregnant women are at higher risk of malnutrition, since gestation requires an increased intake of macro- and micronutrients to cover maternal and fetal needs. Gender aspects might contribute to maternal undernutrition in societies where women have a low social status and little decision-making power, particularly in rural settings. Furthermore, the poor educational level and taboos about food lead to inadequate dietary practices, further contributing to malnutrition and poor fetal development (Shannon et al. 2008). Even if maternal diet has sufficient macronutrients, micronutrient deficiencies are very common in developing countries, particularly iron (Black et al. 2013). Many micronutrients are cofactors of antioxidant enzymatic systems or are antioxidants themselves. Therefore, as stated in previous sections, deficiencies in vitamins and minerals might also contribute to fetal programming through oxidative stress.

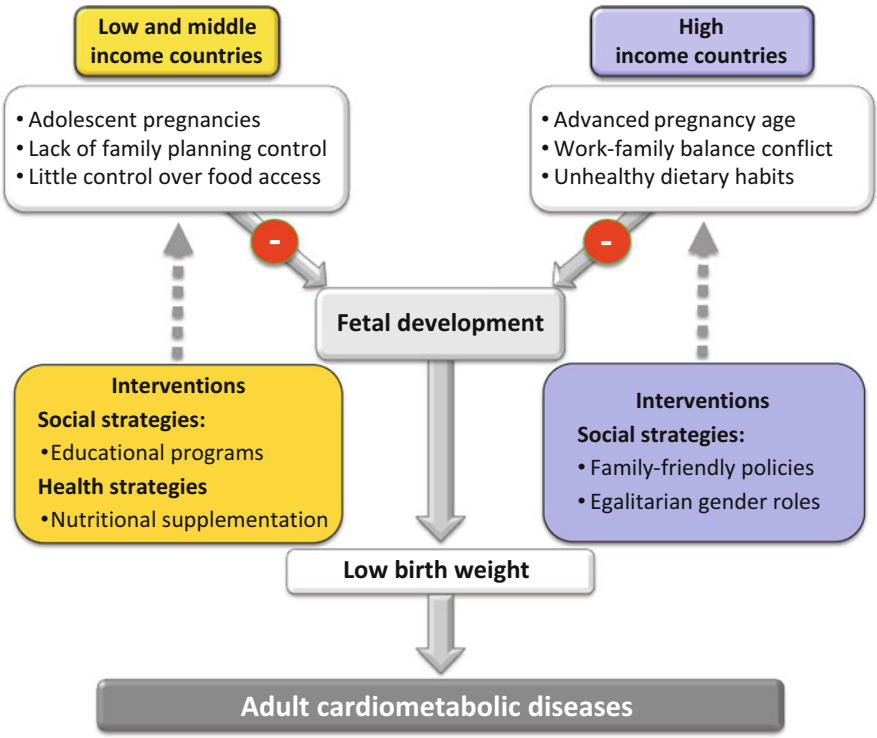

Fig. 5 Gender influences on fetal programming of cardiometabolic disease. Contribution of gender factors to low birth weight and possible intervention strategies, according to socioeconomic development level

A number of international initiatives have been taken to address the nutritional needs of women during periconceptional and gestational periods. A Cochrane database systematic review provides evidence that educational programs aimed at increasing energy intake in undernourished pregnant women reduces the risk of prematurity and LBW (Ota et al. 2015). Intervention strategies with micronutrient supplementation also demonstrate a reduction in LBW (Haider and Bhutta 2015) and an improvement of metabolic health of the offspring (Ekstrom et al. 2016). It has been put forward that educational programs should not only include pregnant women, but also engage other family members, particularly those with a high social role (Shannon et al. 2008).

In addition to maternal undernutrition, a second problem is pregnancy age. In low- and middle-income societies, it is not uncommon that the first pregnancy occurs in adolescence, which is an important developmental period. In this situation, nutrients have to cover the energy requirements for maternal and fetal growth and, in a situation of dietary deficiency, both would compete for nutrients, increasing the risk of LBW (Wemaux-Denis et al. 2017). This problem has been perceived by some

authorities who have targeted adolescent girls as a priority group for nutritional intervention (Vogt et al. 2016).

Gender Aspects in High-Income Countries

Developed societies are witnessing a progressive increase in the age of first pregnancy (Bréart et al. 2003; Ventura et al. 2009). The increase in maternity age is directly linked with a decline in fertility, which has increased the use of assisted reproduction techniques and multiple pregnancies, frequently associated with LBW and prematurity. Advanced pregnancy age also associates with obstetric complications, such as preeclampsia, gestational hypertension, or gestational diabetes, all linked to LBW. In high-income countries, these problems are not associated with perinatal mortality due to a better health care system. However, it is foreseen that, in future generations, the increase in the age of pregnancy will increase the incidence of CMD, through fetal programming (Tarrade et al. 2015).

The increase in maternity age in high-income countries is associated with the change in the social role of women and their gradual access to higher education and employment, as well as an increase in family planning control. Despite these social changes, in many developed societies egalitarian gender roles are not sufficiently developed and it is frequent that women experience a conflict between work and family, particularly in professionals of high educational background. This conflict has a direct influence on the decision to postpone maternity (Ramiro-Cortijo et al. 2016).

Another gender aspect is psychological stress derived from strenuous work, particularly in women with education and health-related jobs, where gender-specific difficulties arise and higher levels of burnout have been reported (Cassidy-Vu et al. 2017). Psychosocial stress by itself has adverse consequences for the fetus, through the effects of excess cortisol, increasing the risk of LBW and prematurity (Guardino et al. 2016). Furthermore, psychological stress might favor addictive behaviors such as tobacco or alcohol, as well as fast-food-based diets, poorer in micronutrients.

In summary, micronutrient deficiencies, obstetric complications, and psychological stress are likely to have a negative impact on oxidative balance, contributing to LBW and fetal programming of CMD. Regarding sex and gender influences, we conclude that although female sex seems to have a better biological adaptation to fetal stressors, gender inequities might counterbalance this advantage, leading to a similar risk of CMD development compared to men, or even higher after menopause. Therefore, specific nutritional interventions as well educational programs should be applied. In addition, it is desirable to increase social awareness to promote egalitarian gender roles.

Policies and Protocols

Governmental Policies This chapter points out the importance of LBW as key factor in fetal programming of CMD. In low- and middle-income countries LBW is a direct consequence of maternal malnutrition, while obstetric complications due to increase in

gestational age are the main determinants in high-income countries. Therefore, specific governmental policies aimed at counteracting these problems are required.

Low- and Middle-Income Countries

- Educational programs involving not only pregnant women, but also key family figures, would help to spread good dietary practices during pregnancy.
- Adolescent girls should be targeted as a priority group for education on nutritional aspects during gestation.
- Supplementation programs with macro- and micronutrients would help to reduce the incidence of LBW and prematurity in vulnerable populations.

High-Income Countries

- Health educational programs to raise awareness on the negative effects of alcohol and tobacco consumption on the gestational health, not only during pregnancy but also prior to conception.
- Specific governmental programs designed to extend maternity leave periods could have a positive impact on obstetric problems associated with maternity age delay.
- Specific guidelines could be designed to promote family-friendly practices at work.

In addition, environmental health policies should be applied worldwide in order to reduce toxic pollutants and their deleterious consequences on maternal and offspring health.

Dictionary of Terms

- **Antioxidants** – Substance that delay, prevent, or remove oxidative damage to molecules.
- **Epigenetic alterations** – Heritable genetic modifications without changes in DNA sequence.
- **Intrauterine growth restriction (IUGR)** – Refers to poor growth in utero evidenced by at least two ultrasound measurements.
- **Free Radicals** – Molecules or fragments of molecules containing one or more unpaired electrons. Free radicals are highly unstable and tend to react with other molecules inducing oxidative processes.
- **Gender** – Gender is used to distinguish the socio-cultural differences assigned to women and men, which vary with time and among societies.
- **Oxidative stress** – Disbalance between pro-oxidant reactive species and antioxidants.
- **Prematurity** – Broad term defining neonates born prior to 37 weeks' gestation.

- **Reactive species** – Molecules or fragments of molecules which induce oxidation to macromolecules. Biologically relevant are those derived from oxygen (Reactive Oxygen Species, ROS) and nitrogen (Reactive Nitrogen Species, RNS)
- **Sex** – Sex refers to the classification according to biological genetic differences between women and men.

Summary Points

- LBW is increasing worldwide; in low-income countries due to maternal undernutrition and in high-income countries due to obstetric complications.
- In high-income countries, the increase in obstetric complications is associated with maternity age delay.
- Epidemiological and experimental studies support the negative impact of LBW due to undernutrition and other stress factors on CMD development in adult life.
- Fetal undernutrition and programming is likely to contribute to the burden of CMD in the future generations worldwide.
- Oxidative stress is implicated in the alterations in physiological systems associated with fetal programming of CMD.
- Female placenta has a better adaptation to suboptimal conditions in utero compared to male placenta.
- Female hormones might counteract fetal programming improving placental vascular development and protecting the cardiovascular system during adult life.
- Gender aspects may counteract the better biological adaptation of female sex to fetal stress factors.
- It is necessary to expand the knowledge on the mechanisms responsible for the sexual dimorphism in fetal programming, including females in experimental animal studies.
- The influence of sex and gender in fetal programming of CMD should be further investigated in epidemiological studies.

Abstract

There are a variety of environmental insults that can occur during pregnancy which cause low birth weight and lead to poor neonatal outcomes. One such insult is maternal malnutrition, which can be further narrowed down to a low protein diet during gestation. Studies demonstrate that perinatal protein deficiencies can impair proper organ growth and development, leading to long-term metabolic dysfunction. Understanding the molecular mechanisms that underlie how this deficiency results in adverse developmental outcomes is essential for establishing better therapeutic strategies that may alleviate or prevent diseases in later life. This chapter reviews how perinatal protein restriction in humans and animals leads to metabolic disease, and it identifies, to date, some of the underlying molecular mechanisms that have been elucidated. These include alterations in transcriptional and epigenetic mechanisms, as well as as endoplasmic reticulum (ER) stress and oxidative stress. Furthermore, nutritional and pharmaceutical interventions are highlighted to illustrate that the plasticity of the underdeveloped organs during perinatal life can be exploited to prevent the onset of long-term metabolic disease.

ROS	Reactive oxygen species
SAM	Severe acute malnutrition
SGA	Small for gestational age
SIRT1	Sirtuin 1
UPR	Unfolded protein response
XBP1	X-box binding protein 1

Introduction

There are a variety of insults that can occur during pregnancy leading to intrauterine growth restriction (IUGR). IUGR is characterized by a delay in fetal growth rate; therefore, IUGR infants are often categorized as being small for gestational age (SGA) due to low birth weight. One of the most common insults that can underlies IUGR is maternal malnutrition, a global problem across all classes of socioeconomic status. Over the past half century, a sizable amount of evidence has revealed the important relationship between birth weight and postpartum development (Barker 1994; Ong et al. 2000). One of the leading contributors to this finding was Dr. David Barker, an English epidemiologist who is well known for establishing the "Predictive Adaptive Response" hypothesis (Hales and Barker 2001). This hypothesis is highly supportive of the developmental origins of health and disease (DOHaD), as it suggests that unfavorable in utero events can permanently alter physiological processes that manifest in the metabolic syndrome. The hypothesis states that fetal programming is altered in preparation of a nutritionally scarce postnatal environment, thereby producing a "thrifty" phenotype that is characterized by fetal energy conservation (Hales and Barker 2001). Unfortunately, these metabolic adaptations become harmful when the fetus is born into a nutritionally rich environment because the neonate is programmed to store energy rather than spend it. Individuals who are affected by this thrifty phenotype therefore tend to become obese early in life and have an increased risk for early-onset type II diabetes mellitus, cardiovascular disease, and stroke among other chronic conditions (Ravelli et al. 1998; Eriksson 2006; Barker et al. 2002).

The composition of maternal diet during pregnancy plays a large part in fetal development, as an absence or excess of nutrients can impact organ growth and development. Maternal malnutrition can exist in a variety of forms, including global nutrient abnormalities (i.e., high or low caloric intake) or atypical supplementation of specific macromolecules and nutrients. Regardless of the source, human and animal

studies have demonstrated that maternal malnutrition in pregnancy also leads to placental insufficiency, an idiopathic condition by which reduced maternofetal nutrient transfer leads to IUGR (Ogata et al. 1986; Simmons et al. 1992). One such model is the maternal protein restriction (MPR) model of undernutrition, which investigates the impact of perinatal protein deficiency in IUGR offspring. Amino acids have been shown to be critical for fetal growth and development, as they are the structural building blocks for all proteins (Crosby 1991; Petry et al. 2001). Inadequate supplementation of amino acids during pregnancy has been shown to cause asymmetrical IUGR, as LP animal offspring have reduced growth of organs such as the liver, muscle, and pancreas at the expense of more essential organs like the brain (Desai and Hales 1997). These offspring consequently have impaired metabolic programming that persists into adulthood, and thus exhibit a phenotype that is characteristic of the metabolic syndrome. Moreover, as Barker's hypothesis would suggest, MPR offspring that are fed a normal protein diet after birth undergo rapid growth during early periods of life (Ozanne and Hales 2004). Moreover, postnatal catch-up growth exacerbates the symptoms and incidence of metabolic deficits (Sohi et al. 2011; Bol et al. 2009; Bieswal et al. 2006), and this dietary mismatch also appears to have significant effects on lifespan (Ozanne and Hales 2004). Considering these changes to metabolism and longevity, this review aims to demonstrate the importance of maternal protein during pregnancy on long-term outcomes of the offspring, with an emphasis on how postnatal catch-up growth can modify the mechanisms responsible for regulation of glucose, lipids, hormones, and lifespan.

Protein Restriction and Long-Term Outcomes: Clinical Evidence

In 1986, Barker and his colleagues discovered birth records for over 15,000 English persons born prior to 1931. These records were collected by Miss Ethel Burnside, Lady Inspector of Midwives for Herfordshire, England, who documented birth weight and body weight at 1 year of age (Barker 2003). These follow-up records allowed Barker to assess the growth trajectory of individuals within the first year of life, and he was able to further inquire about adult health for those still living at the time. The data revealed that those who were born of low birth weight had disproportionately higher rates of coronary heart disease (Barker 2003; Ravelli et al. 1976), and these individuals also had impaired liver size and/or function at birth (Barker et al. 1993). This is not surprising, as IUGR often results in asymmetric organ development (Desai and Hales 1997). Furthermore, studies of individuals born around the time of the Dutch Hunger Winter reveal that prenatal exposure to famine confers increased risk for glucose intolerance in adulthood (Ravelli et al. 1998). This population also had high rates of obesity after exposure to famine during the first half of gestation (Ravelli et al. 1976), suggesting that timing of maternal malnutrition during pregnancy can influence long-term metabolic outcomes of offspring.

While the previously mentioned epidemiological studies are focused on caloric restriction, there is also evidence to support that protein deficiency during critical periods of development gives rise to poor metabolic outcomes. Populations of children with severe acute malnutrition (SAM) are often used to study the repercussions of malnutrition, as these individuals see the effects of a low calorie diet (marasmus) or a low protein, high carbohydrate diet (kwashiorkor; Forrester et al. 2012; Spoelstra et al. 2012). In 1967, a study of Ugandan children revealed that individuals with kwashiorkor had low serum protein levels in comparison to those with marasmus (Hadden 1967). These individuals also exhibited glucose intolerance and elevated plasma free fatty acids (Hadden 1967); however, children with kwashiorkor displayed normal glucose tolerance after a 2 week dietary intervention (Hadden 1967). It was proposed that the original impairment in glucose tolerance may be due to an inability to utilize free fatty acids as a substrate in the citric acid cycle, so adequate dietary protein may be essential for normal aerobic metabolism (Hadden 1967). More recent studies also show that children with kwashiorkor exhibit reduced lipolysis and fatty acid oxidation relative to children with marasmus (Badaloo et al. 2006), while children with kwashiorkor or marasmus have pancreatic beta cell dysfunction that contributes to glucose intolerance (Spoelstra et al. 2012). Studies have also established that SAM has early life origins, as low birth weight infants have high risk for exhibiting either marasmus or kwashiorkor when exposed to a nutrient-poor postnatal environment (Francis-Emmanuel et al. 2014). Interestingly, individuals who exhibit marasmus tend to be of lower birth weight than those who develop kwashiorkor; however, individuals from both groups of SAM tend to have poor metabolic outcomes as adults (Francis-Emmanuel et al. 2014). As mentioned previously, nutrition-induced accelerated growth influences the onset of metabolic disease in low birth weight offspring (Eriksson 2006). Unfortunately, none of the discussed human SAM studies contained data on childhood growth rate, so it remains unknown as to whether catch-up growth is involved in metabolic outcomes of individuals who experienced SAM in early life. Furthermore, because a typical kwashiorkor diet has low protein and high carbohydrate content, it is not clear whether long-term metabolic dysfunction occurs in adulthood due to low dietary protein, high carbohydrates, or both for these individuals.

Is Veganism Safe in Pregnancy?

Veganism and vegetarianism is also of interest when studying the effects of protein restriction, as a vegan/vegetarian diet relies solely on plant-sourced nutrients. Individuals who practice veganism or vegetarianism must be careful to ensure that they ingest an adequate amount of protein, often in the form of legumes, lentils, grains, etc. There are mixed opinions on whether consumption of a vegan/vegetarian diet is safe during pregnancy, as observational human studies report conflicting data on both maternal and fetal outcomes. A literature review by Piccoli et al. (2015) revealed that multiple studies found infants of vegetarian mothers to be of lower

birth weight than nonvegetarian mothers, while two different studies reported that infants of vegans/vegetarians actually have higher birth weight and length. Gestational age was not disclosed for either of these studies; therefore, the association between a vegetarian/vegan diet and high birth weight is not necessarily meaningful (Piccoli et al. 2015). It was also noted that most studies did not report maternal protein intake levels, so it is hard to conclude whether there is a relationship between veganism/vegetarianism and fetal outcomes. Moreover, a case report by Mariani et al. (2009) revealed poor short-term outcomes of an infant born to a vegan mother. The infant had been breast-fed exclusively up until 10 months of age and showed developmental delay, failure to thrive, and megaloblastic anemia among other conditions (Mariani et al. 2009). Furthermore, the infant exhibited major improvement with vitamin supplementation, so it may be that the health impairments were due to vitamin deficiencies rather than low protein (Mariani et al. 2009). Regardless of these reports, organizations such as the American Dietetic Association maintain that a vegan or vegetarian diet is safe during pregnancy (Craig and Mangels 2009). That said, physicians must assess protein intake of pregnant women who consume these diets, and future studies are warranted to determine any long-term detrimental effects on offspring.

Maternal Protein Restriction (MPR) Rodent Model: Relevance to Human IUGR

Protein and amino acids are an essential part of the human diet, and many studies have determined that amino acids have a key role in fetal growth and development (Crosby 1991; Petrik et al. 1999). An absence of amino acids is known to occur in cases of both maternal malnutrition and placental insufficiency, thereby leading to low birth weight and asymmetrical IUGR. It is for this reason that the MPR model can be used to study fetal undernutrition in response to maternal malnutrition or placental insufficiency. With the MPR model, pregnant rat dams are fed a diet of 20% (control) or 8% protein. Offspring born to control diet-fed dams continue to have a 20% "normal" protein throughout life, while offspring born to LP dams are assigned to one of three groups: low protein 1 (LP1), low protein 2 (LP2), or low protein 3 (LP3). LP1 offspring are fed an 8% protein diet throughout life, while LP2 offspring are fed an 8% protein diet until weaning (i.e., PND 21). Alternatively, LP3 offspring are exposed to a LP environment exclusively during gestation – these pups are fed a 20% protein diet from birth through adulthood. It is also important to note that the reduction in calories in the 8% protein diet is compensated for by the addition of carbohydrates (Fig. 1). This makes each diet isocaloric with each other, thereby eliciting no maternal stress and no changes in maternal food intake or weight gain (Fig. 2). Furthermore, while there are no differences in postnatal food intake across all dietary groups of offspring, LP offspring were lower in body weight in postnatal life compared to control offspring (Fig. 2). It is also important to note that the MPR diet is not

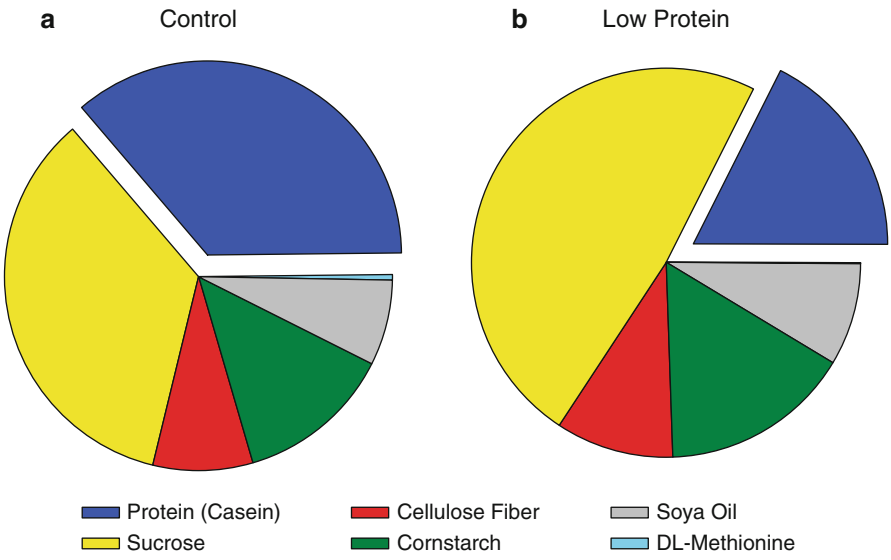

Fig. 1 Overview of control and low protein rodent diets. Composition of (**a**) Control (20% protein) and (**b**) Low protein diet (8% protein) are described. The low protein diet is attributed to decreased casein content but is made isocaloric by a slight increase (13%) in carbohydrates (i.e., sucrose)

considered to be a "high carbohydrate" diet, as the slight percent increase in carbohydrates (13%) is negligible relative to the substantial decrease in protein content (greater than 50%).

Outcomes I: Liver

Studies involving the MPR model have demonstrated that mammalian fetal liver development is impaired due to the low protein insult. While there is an overall reduction in birth weight of LP offspring (Fig. 2), there is also a significant decrease in fetal liver to body weight ratio (i.e., the liver is proportionally small; Sohi et al. 2011). This finding suggests that fetal liver growth is compromised at the expense of more "vital" organs such as the heart and brain (Williams et al. 2005). Furthermore, the timing of protein restoration appears to be significant during the neonatal period as LP2 and LP3 offspring display liver and whole body postnatal catch-up growth despite no differences in food intake (Fig. 2) (Sohi et al. 2011). Offspring having undergone asymmetrical IUGR are believed to be prone to symptoms of the metabolic syndrome, and previous studies confirm that LP2 rat offspring exhibit glucose intolerance at PND 130 due to altered hepatic gluconeogenesis (Vo et al. 2013). In addition, adult male recuperated offspring (e.g. LP2) have dyslipidemia and impaired drug metabolism due to altered expression of various hepatic cytochrome P450 enzymes (Fig. 3; Sohi et al. 2011, 2014).

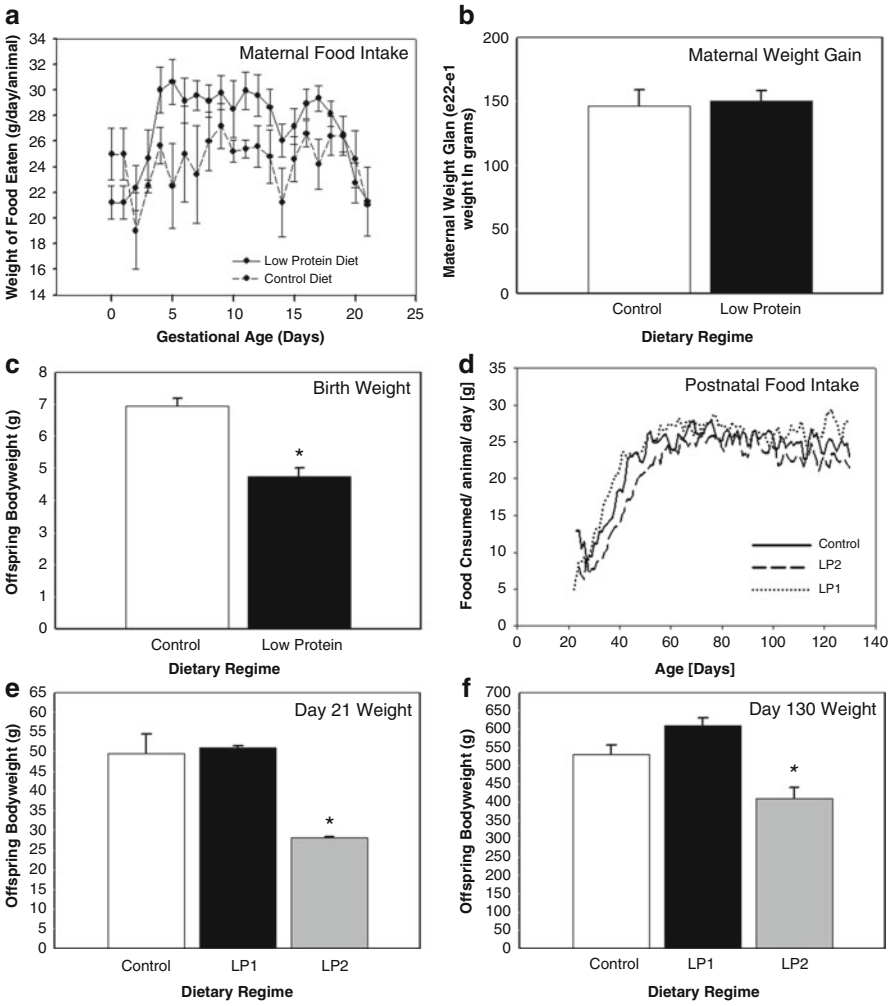

Fig. 2 Effect of maternal low protein diet on (a) Maternal food intake, (b) maternal weight, (c) birth weight, (d) food intake of offspring, (e) weight of offspring at day 21, and (f) weight of offspring at day 130. Pregnant rats were given either a control diet (20% protein) or a low protein diet (8% protein) during gestation only (LP1) and lactation (LP2). Weight of food eaten in g/day/animal and maternal weight gain from gestation day 1 to gestation day 22 in grams were measured, respectively. Total maternal food intake, maternal weight gain, and birth weight results are expressed as the mean ± SEM and significance was assessed using Student's unpaired t-test. For postnatal day 21 and 130 weight analysis, the dietary groups were compared by ANOVA and significant difference was determined by a Tukey HSD post hoc test for individual pairwise comparisons (*$P < 0.05$, indicates significance between both the control and LP1 group). $n = 5$–8/group, where each n represents an offspring derived from a different mother (Reprinted from "Higher Hepatic MiR-29 Expression in Undernourished Male Rats During the Postnatal Period Targets the Long-term Repression of Insulin-like Growth Factor 1", G Sohi et al., Endocrinology (2015) 156(9): 3069–3076, with permission from Oxford University Press)

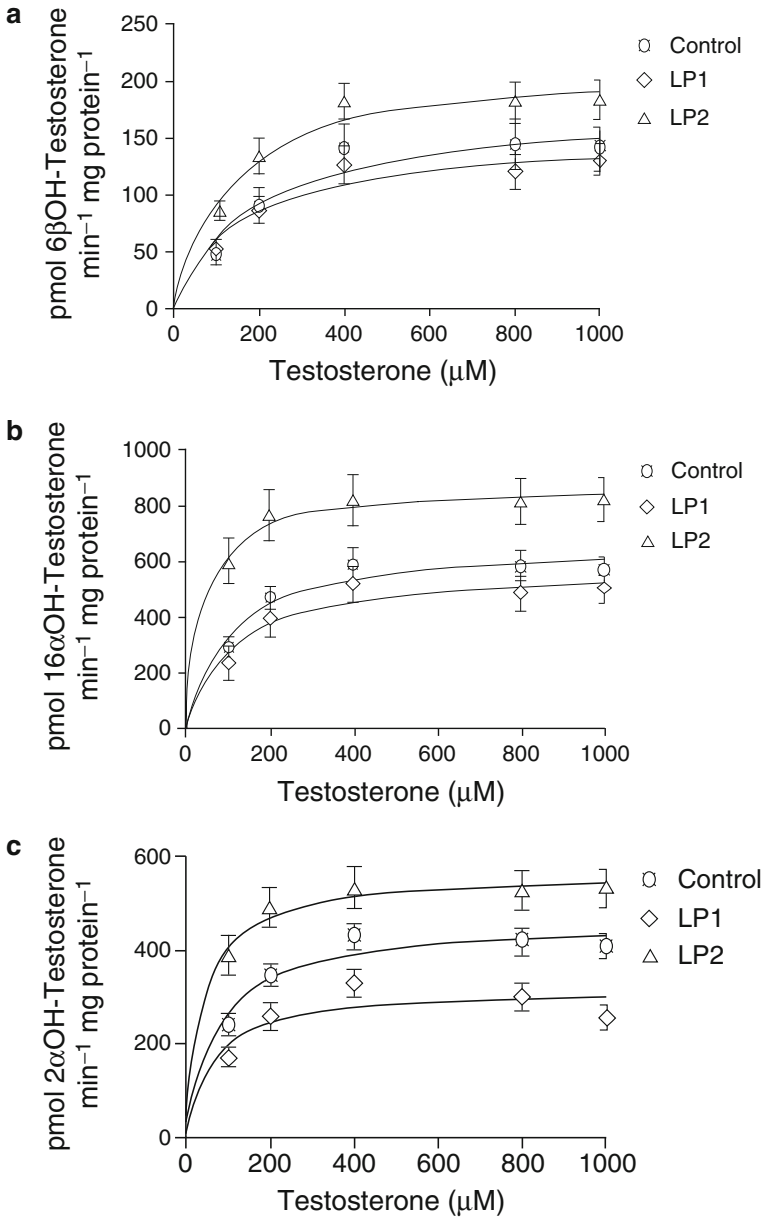

Fig. 3 Michaelis-Menten plots of (a) 6β-OH testosterone, (b) 16α-OH testosterone, and (c) 2α-OH testosterone after incubation of day 130 rat liver microsomes (Control, LP1, and LP2) with 1 mM NADPH and various concentrations of testosterone. Liver microsomes were extracted from control, LP1 (low protein all life), and LP2 (low protein diet during pregnancy and weaning) dietary regimes in postnatal day 130 offspring. Timed enzyme reactions were performed for testosterone metabolite analysis via solid-phase extraction followed by UPLC-

Outcomes II: Other Organs

The effects of MPR are not exclusive to the liver. Epidemiological studies indicate that there is an association between visceral obesity and poor fetal growth and this has been further confirmed via the MPR rat model (Guan et al. 2005). The increase in visceral adiposity occurs due to increased rates of preadipocyte proliferation, as indicated by increased incorporation of [3H]-thymidine into the DNA of primary rat preadipocytes (Zhang et al. 2007). It is also interesting that these studies showed no apparent alteration in preadipocyte differentiation, as there were no significant differences in the expression of peroxisome proliferator-activated receptor gamma (PPAR-γ) or lipoprotein lipase (LPL; Zhang et al. 2007). Early studies by Ozanne et al. (1996a) also demonstrate that MPR leads to increased insulin sensitivity of muscle at 3 months of age, as LP offspring have increased glucose uptake into skeletal muscle upon stimulation with low doses of insulin. This increased sensitivity is brought about by increased expression of GLUT4 and insulin receptors in myocyte plasma membranes (Ozanne et al. 1996a). While the mechanisms behind this are not well understood, it is also known that this enhanced glucose tolerance is lost later in adult life due to insulin resistance (Hales et al. 1996).

Fetal brain development also appears to be compromised by protein restriction, as LP-born rat offspring exhibit changes in kynurenine metabolism in the brain. Kynurenine metabolites are involved in neuronal development (Honório de Melo Martimiano et al. 2017), so an imbalance of these compounds within fetal brain tissue is believed to contribute to an increased risk for mental health disorders. Additionally, there is an increase in reactive oxygen species (ROS) within the brainstem of LP male offspring at weaning, so neuronal mitochondrial function may be diminished (Ferreira et al. 2016). Based on the extensive amount of studies concerned with this particular diet, it is clear that LP-born offspring have gross organ impairment contributing not only to metabolic dysfunction, but to the onset of other adult diseases as well.

Outcomes III: Diabetes

Long-term effects to glucose homeostasis are highly promoted by maternal protein restriction, as demonstrated by glucose intolerance and insulin resistance in adult humans and adult rat offspring (Sohi et al. 2013; Chamson-Reig et al. 2009; Phipps et al. 1993). In the liver, MPR leads to hyperglycemia in 4 month offspring due augmented expression of gluconeogenic enzymes such as glucose-6-phosphatase (G6Pase) and 11β-hydroxysteroid dehydrogenase type I (11β-HSD1; Vo et al. 2013). Moreover, Burns

Fig. 3 (continued) PDA detection. Each data point on the curves were expressed as the mean ± SEM. $n = 5–6$/group, where each n represents an offspring derived from a different mother (Reprinted from "Protein Restoration in Low Birth Weight Rat Offspring Derived from Maternal Low Protein Diet Leads to Elevated Hepatic Cyp3a and Cyp2c Activity in Adulthood," G Sohi et al., Drug Metabolism and Disposition (2014) 42: 221–228, with permission from The American Society for Pharmacology and Experimental Therapeutics (ASPET))

et al. (1997) demonstrated that MPR adult rats have significantly reduced hepatic glucokinase expression, thus contributing to increased glucose output. Impaired liver function leading to insulin insensitivity is further evident in MPR offspring when examining both phosphorylated eukaryotic initiation factor 2 α (p-eIF2α) and phosphorylation of Akt1 (Sohi et al. 2013). Adult MPR offspring with postnatal catch-up growth have increased p-eIF2α [Ser51], a marker of protein translation attenuation and ER stress, and this is associated with a decrease in the phosphorylation of protein kinase B (Akt1) [Ser473], a marker of insulin resistance (Sohi et al. 2013). Interestingly, MPR offspring have unchanged levels of p-eIF2α at embryonic day 19; therefore, the relationship between p-eIF2α and insulin sensitivity appears to be affected by postnatal catch-up growth rather than LP insult directly. This is in support of the predictive adaptive response hypothesis, as this molecular change occurs only in cases of a mismatched nutritional environment. Finally, expression of hepatic glucagon receptors was reduced fivefold in studies of MPR offspring by Ozanne et al. (1996b), along with a threefold increase in hepatic insulin receptors. These changes were reflected by reduced hepatic glucose output (relative to control animals) upon stimulation with glucagon, as well as increased glucose output with administration of insulin (Ozanne et al. 1996b). These studies clearly verify the importance of perinatal protein supplementation in fetal liver development, as the augmentation of many hepatic targets can negatively impact plasma glucose and insulin sensitivity.

In addition to poor outcomes seen in the developing liver, MPR appears to impact growth and function of other organs involved in glucose homeostasis, such as the pancreas. Epidemiological studies of adults who suffered from SAM during childhood have demonstrated that these individuals have glucose intolerance and poor insulin sensitivity later in life as a result of compromised beta cell development (Francis-Emmanuel et al. 2014). Similarly, the Preston and Hertfordshire studies by Barker and his colleagues revealed that there is an inverse relationship between birth weight, plasma glucose, and insulin concentrations of individuals exposed to famine during pregnancy (Hales et al. 1991; Phipps et al. 1993). Animal studies have since confirmed that this occurs due to reduced beta cell mass, increased islet cell apoptosis, altered beta cell cycle length and lower pancreatic islet vascularization (Petrik et al. 1999; Boujendar et al. 2003). In cases of perinatal protein restriction, this phenotype can be rescued with administration of meat-sourced amino acids (e.g., taurine) during gestation and the first weeks of neonatal life (Boujendar et al. 2002, 2003). Supplementation of a LP diet with 2.5% taurine leads to restoration of beta cell mass by PND 130 in vivo, while in vitro studies demonstrate that this is due to normalization of DNA synthesis, apoptosis, and fetal islet vasculogenesis (Boujendar et al. 2002, 2003). A study by Chamson-Reig et al. (2006) also determined that deficient beta cell development occurs in response to MPR during early, mid, and late gestation; however, males are more susceptible to this insult during late gestation and females during mid-gestation. Not only does this emphasize that there are sex-specific differences in organ development in response to MPR, but also that timing of perinatal protein deficiency plays a role in the severity of offspring outcomes.

Studies in humans and animals also support the idea that postnatal catch-up growth confers increased risk for diabetes later in life. A study of men and women

in Helsinki demonstrated that individuals who developed type II diabetes mellitus in adulthood were of low birth weight but had also caught up to average weight and height by 7 years of age. Likewise, Blesson et al. (2017) identified that female rat MPR offspring have rapid catch-up growth in the first 4 weeks of life and exhibit elevated glucose at 3 months of age. Assessment of gastrocnemius muscle from these female offspring revealed that they express altered phosphorylation of molecules involved in insulin signaling, including insulin receptor substrate-1 (IRS-1), Akt-1, and glycogen synthase. This is again in support of the idea that postnatal catch-up growth is detrimental to metabolic organ function, as in utero adaptations are not conducive in a mismatched postnatal environment. In contrast with this, Zheng et al. (2012) demonstrated that female LP offspring have increased expression of Glucose Transporter Type 4 (GLUT4) mRNA and protein in skeletal muscle at PND 38. These offspring also have increased expression of myocyte enhancer factor 2A (MEF2A), a coactivator of *GLUT4* transcription, and increased glycogen synthase (Zheng et al. 2012). The authors suggest that this may be an adaptive response to MPR during gestation, and it is possible that estrogen may be involved due to the apparent sex-specific differences (Zheng et al. 2012).

Outcomes IV: Dyslipidemia

With respect to lipids, perinatal protein appears to play a role in the maintenance of healthy cholesterol levels in adult offspring. Male rats exposed to severe MPR (4% protein) during the last third of gestation exhibit elevated LDL and reduced high-density lipoprotein (HDL; de Oliveira et al. 2016). In addition, male rat MPR offspring with catch-up growth show increases in cholesterol due to decreased expression of Cyp7a1, the critical enzyme in cholesterol metabolism (Sohi et al. 2011). While hepatic and circulating cholesterol was increased for both males and females at PND 21, there was an increase exclusively in males at PND 130 (Sohi et al. 2011). It is noteworthy that these adult offspring exclusively with catch-up growth (e.g., LP2 offspring) also have increased expression and activity of hepatic Cyp3a1 and Cyp2c11, which are involved in the catabolism of many drugs, including statins (Fig. 3, Sohi et al. 2014). Therefore, it is very conceivable that these animals that exhibit hypercholesterolemia also do not respond as well to cholesterol-controlling drugs. In addition, considering that testosterone is a major substrate for these particular Cyp enzymes, this may explain why MPR male offspring have lower circulating testosterone levels, and consequentially, the long-term sexual dimorphism that exists in this model (Chamson-Reig et al. 2009).

Besides the changes seen in expression and function of hepatic Cyp enzymes, MPR also influences cholesterol levels by way of altered insulin-like growth factor-1 (IGF-1). IGF-1 is a hormone that is known to play a large role in fetal and placental growth (Koutsaki et al. 2011), and its decreased expression has been proposed to induce dyslipidemia and hyperinsulinemia (García-Fernández et al. 2008). Administration of exogenous IGF-1 leads to significantly reduced cholesterol levels in old mice relative to untreated old mice; however, cholesterol levels in treated mice still

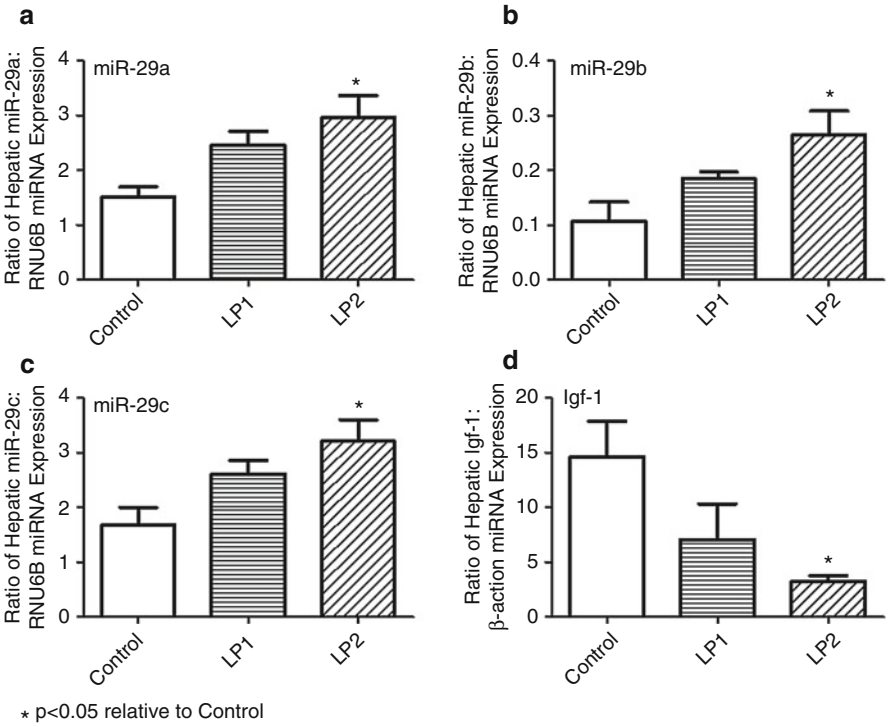

Fig. 4 **Quantitative RT-PCR microRNA analysis of** (**a**) miR-29a, (**b**) miR-29b, (**c**) miR-29c, and (**d**) Igf1 mRNA in the livers of rat offspring (Control, LP1, and LP2) derived at postnatal d130. Pregnant rats were given either a control diet (20% protein) or a low protein diet (8% protein) during gestation only (LP1) and lactation (LP2). The relative amounts of miR-29a, 29b, and 29c mRNA were normalized to that the expression of RNU6B. The relative expression of each Igf1 mRNA transcript was normalized to that of the each b-actin mRNA transcript. Results were expressed as the mean ± SEM. The groups were compared by ANOVA and significant difference was determined by a Tukey HSD post hoc test for individual pairwise comparisons (*$P < 0.05$, indicates significance between control and LP2 cohort). For Fig. 2d, given the variances were not equal, the Tukey HSD post hoc test was performed on log-transformed data. $n = 5$–8/group, where each n represents an offspring derived from a different mother (Reprinted from "Higher Hepatic MiR-29 Expression in Undernourished Male Rats During the Postnatal Period Targets the Long-term Repression of Insulin-like Growth Factor 1," G Sohi et al., Endocrinology (2015) 156(9): 3069–3076, with permission from Oxford University Press)

do not reach levels as low as those found in young, untreated mice (García-Fernández et al. 2008). Similar to uterine-ligated offspring, MPR offspring exhibit significantly reduced levels of *Igf-1* at PND 21 and 130 (Fig. 4; Sohi et al. 2015). These offspring consequentially have reduced growth rate in comparison to control offspring, as indicated by a significantly lower body weight at PND 21 and PND 130 (Fig. 2). Given that this group of offspring also exhibits dyslipidemia in adult life (Sohi et al. 2011), it seems feasible that low levels of *Igf-1* contribute to abnormally high levels of cholesterol. It is noteworthy that offspring exposed to a LP diet

exclusively during lactation exhibit an even greater reduction in expression of hepatic *Igf-1* (Sohi et al. 2015), which suggests that the neonatal window of development plays a significant role in the regulation of *Igf-1* expression.

Outcomes V: Premature Aging

Many studies have determined that there is an existing relationship between birth weight and longevity, and this is again due to alterations in fetal programming that underlie impeded fetal development. Lifespan becomes reduced when impaired fetal development is followed by postnatal catch-up growth, as demonstrated by studies of the MPR diet by Ozanne and Hales (2004). Specifically, they demonstrated that MPR offspring have reduced fetal growth and these offspring tend to have increased lifespan when maintained on a LP diet (Hales et al. 1996). Conversely, MPR offspring that undergo postnatal catch-up growth after birth have a significantly reduced lifespan relative to their LP counterparts (16.3 vs. 13.1 months; Hales et al. 1996). Additionally, expression of sirtuin 1 (SIRT1) protein, a deacetylase enzyme believed to play a role in regulation of lifespan and glucose homeostasis (Michan and Sinclair 2007), was significantly decreased in skeletal muscle of MPR animals with postnatal catch-up growth (Chen et al. 2009). These offspring also have decreased levels of insulin signaling molecules such as IGF-1 and phosphorylated IRS-1, so the authors predicted that impairments to insulin sensitivity may contribute to regulation of lifespan (Chen et al. 2009). A similar model of MPR also demonstrated that markers of cell senescence (e.g., p21 and p16) are upregulated in pancreatic islets of recuperated rat offspring, as well as significantly shorter telomere length (Tarry-Adkins et al. 2009). This further consolidates the relationship between glucose homeostasis and longevity, given the role of pancreatic islets in insulin and glucagon production. It also is noteworthy that offspring born to normal protein mothers and cross-fostered to LP-fed dams during lactation (i.e., MPR lactation only) have significantly increased lifespan in comparison to control offspring (17.0 vs. 15.1 months; Hales et al. 1996). The authors speculated that offspring might therefore benefit from slow postnatal growth; however, adequate dietary protein still remains essential during pregnancy (Hales et al. 1996).

Epigenetic Mechanisms Linking Protein Restriction and Adverse Metabolic Outcomes

It is well understood that transcriptional changes directly compromise fetal development in utero; however the role of epigenetic alterations in fetal metabolic programming has not been investigated to great extent. Epigenetic mechanisms act to influence long-term gene expression without altering the primary genetic sequence, often by modifying interactions between transcriptional and/or translational machinery with regulatory sequences. Mechanisms such as direct DNA methylation, posttranslational histone modifications, and microRNAs (miRs) have been implicated in cases of fetal

undernutrition, and LP-born offspring are no exception. In 2005, a study by Lillycrop et al. demonstrated that CpG island methylation status of hepatic glucocorticoid receptor (*GR*) and *PPARα* promoters are significantly reduced in MPR offspring, and this hypomethylated state is associated with increased expression of these genes. Interestingly, feeding of a LP diet in combination with folic acid supplementation prevented these epigenetic changes, indicating that one-carbon metabolism is essential in preventing the effects of this maternal insult (Lillycrop et al. 2005). Further studies also confirmed that this alteration exemplifies transgenerational effects, as methylation status is decreased in the F2 generation at PND 80 (Burdge et al. 2007). This is characteristic of many epigenetic mechanisms, thereby illustrating relevance of perinatal insult to health outcomes of future generations.

Chromatic structure is also greatly affected by posttranslational histone modifications, including histone acetylation, methylation, ubiquitination, ADP-ribosylation, and phosphorylation. In MPR, the long-term expression of gluconeogenic enzymes (e.g., G6Pase and 11β-HSD1) is increased due to the histone-mediated silencing of hepatic liver X receptor alpha (LXRα) at 4 months (Vo et al. 2013). LXRα is a transcription factor involved in the silencing of genes associated with glucose production. Vo et al. (2013) demonstrated that there is a significant decrease in histone H3 acetylation [K9, 14] at the transcriptional start site of *Lxrα* in 4-month protein recuperated MPR offspring. This is concomitant with decreased association of LXRα at the LXR response element (LXRE) of *G6Pase* and *11β-HSD1*, culminating in glucose intolerance (Vo et al. 2013). As mentioned previously, MPR offspring also exhibit decreased expression of hepatic Cyp7a1 leading to hypercholesterolemia in male offspring at PND 21 and 130 (Sohi et al. 2011). This reduction in enzyme expression is due to epigenetic silencing at the *Cyp7a1* promoter region, as there is increased tri-methylation and decreased acetylation of histone H3 [K9, 14], markers of chromatin condensation. It is interesting that female MPR offspring from the same cohort are protected from these histone modifications in adulthood, as they show complete opposite trends in methylation and acetylation.

In addition to DNA methylation and histone modifications, miRs have also been demonstrated to influence long-term gene expression via epigenetic mechanisms. MiRs are short, noncoding RNA molecules that act to silence target genes via target mRNA degradation or translational repression. In 2016, Su et al. investigated the role of miR-15b in pancreatic beta cell proliferation of MPR-born mouse offspring. It was discovered that miR-15b is significantly increased in the pancreatic islets of MPR offspring, accompanied by reduced expression of cyclin D1 and D2 (Su et al. 2016). Given the role of cyclins in progression through the cell cycle, it is believed that the downregulation of these molecules contributes to impaired beta cell function and thus glucose intolerance. As discussed earlier, administration of the MPR diet during pregnancy and lactation has been demonstrated to cause the upregulation of hepatic miR-29 expression in LP offspring with postnatal catch-up growth (Sohi et al. 2015). MiR-29a, miR-29b, and miR-29c were all significantly increased in livers of 3 week and 4 month old offspring, and this further caused a reduction in expression of *Igf-1* (Fig. 4; Sohi et al. 2015). With that in mind, it is possible that timing of nutritional restoration for IUGR offspring may play a role in long-term disease via modulation

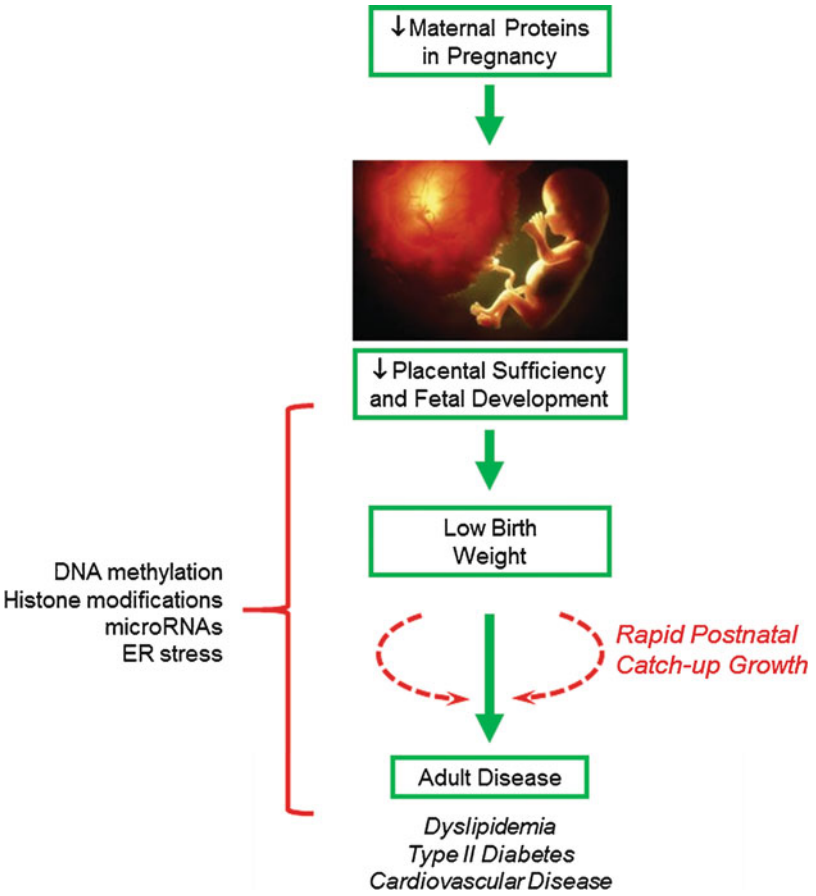

Fig. 5 Overview of the molecular mechanisms underlying how maternal protein restriction (MPR) during perinatal leads to long-term metabolic dysfunction in adulthood Direct pathways altered by maternal protein restriction are indicated by *green solid arrows*, while direct and indirect molecular mechanisms are indicated by *red arrows*

of miRs. Given that miRs also circulate in the blood, these animal studies could lead to novel therapeutic interventions with the use of miR inhibitors in neonatal treatment of the metabolic syndrome. An overview of the molecular mechanisms underlying MPR-induced metabolic dysfunction is illustrated in Fig. 5.

Other Mechanisms Linking Protein Restriction and Adverse Metabolic Outcomes

As previously mentioned, the fetal liver is proportionally small in MPR offspring at birth and undergoes rapid postnatal catch-up growth with introduction of a normal protein diet (Sohi et al. 2011; Hales et al. 1996). During this period of growth,

hepatocytes undergo rapid replication such that the neonatal liver becomes larger. It is therefore possible that ER stress may contribute to poor metabolic health outcomes in the recuperated adult MPR offspring. ER stress is a cellular event which ensues due to environmental insults leading to an increase in the presence of misfolded or unfolded proteins present within the ER (Sohi et al. 2013). In response to ER stress, the unfolded protein response (UPR) becomes activated in attempt to reverse this stress by refolding those misfolded proteins and/or attenuating protein translation through three signaling pathways (Sohi et al. 2013). In the case that the UPR cannot alleviate ER stress, apoptosis may further occur. The MPR offspring with catch-up growth exhibit hepatic ER stress at 4 months of age as indicated by increased hepatic p-eIF2α [Ser51], Grp78, and spliced Xbp1 (Sohi et al. 2013). P-eIF2α [Ser51] is known to negatively regulate the initiation stage of protein translation (Proud 2005). As with many other mechanisms discussed in this review, the LP diet itself does not a play a direct role given embryonic day 19 low protein fetuses do not exhibit ER stress (Sohi et al. 2013). In addition to affecting hepatic function directly, ER stress may also be involved in the regulation of epigenetic mechanisms such as miRs. ER stress has been shown to directly cause an increase in miR-29a expression in vitro (Nolan et al. 2016), and studies by Sohi et al. (2015) have implicated that MPR offspring with postnatal catch-up growth exhibit increased hepatic miR-29a and ER stress at 4 months of age. Considering that miR-29 targets *Igf-1*, this further suggests that ER stress may play an important role in the etiology of the metabolic syndrome in these IUGR offspring.

Conclusion

While maternal malnutrition exists in many forms, MPR has been shown to have major consequences for the long-term metabolic health of LP-exposed offspring. Epidemiological studies in humans have deduced that perinatal protein deficiency gives rise to low birth weight, and these individuals are at greater risk for development of the metabolic syndrome in adult life. Studies of individuals with SAM reveal that poor dietary protein can lead to glucose intolerance and abnormal plasma fatty acid levels. Moreover, animal studies of the MPR model have further established that LP-exposed offspring have low birth weight and asymmetrical IUGR, with liver growth and development taking a major hit relative to other organs. Additionally, the function of other organs such as the pancreas, muscle, and adipose becomes impaired, which further contributes to metabolic dysfunction. In adult life, these animals tend to have glucose intolerance, dyslipidemia, and increased visceral obesity. The onset of these deficits are further exacerbated by postnatal catch-up growth, as a nutrient-poor prenatal environment gives rise to altered fetal programming that is not beneficial in a nutrient-rich postnatal environment. Furthermore, these offspring exhibit reduced lifespan relative to animals that are fed either a control or LP-exclusive diet. While the mechanisms behind these defects are not fully understood, it is widely accepted that epigenetic alterations such as DNA methylation, posttranslational histone modifications, and miRs can influence fetal gene expression. Animal models of MPR have provided insight into what might be occurring in humans, but further investigation is warranted to better comprehend

the molecular basis of the metabolic syndrome in response to perinatal protein restriction. Until then, nutritional intervention during pregnancy is necessary to ensure that mothers consume appropriate amounts of dietary protein such that there are no negative effects to fetal growth and development.

Policies and Protocols

In this review, we have discussed the metabolic implications of perinatal protein restriction and postnatal catch-up growth in LP-born offspring. Models of protein restriction have confirmed that insufficient amino acids during pregnancy contribute to low birth weight, and this leads to the metabolic syndrome in adult life. Due to fetal adaptations that occur in utero, low birth weight offspring have rapid weight gain when presented with a mismatched postnatal environment (i.e., a "normal" protein diet), exacerbating the risk for adult metabolic disease. It is critical that primary health-care workers are informed regarding this information related to postnatal catch-up growth. Physicians, nurses, and midwives should emphasize to patients that a balance between prenatal and postnatal diet with respect to protein intake is essential. In addition, it is recommended that pregnant women ingest protein in the form of animal-sourced amino acids rather than plant-based amino acids. As previously mentioned, studies demonstrate that poor fetal pancreatic development (due to perinatal protein restriction) can be rescued with administration of taurine, a meat-sourced amino acid (Boujendar et al. 2003). While the role of animal-based amino acids has been only investigated in pancreatic development, it is conceivable that this may be the case for other metabolic organs as well. As always, prevention is a more successful strategy than treatment; therefore, it is highly encouraged that health-care workers and pregnant mothers work together to prevent maternal malnutrition for the sake of the developing fetus.

Dictionary of Terms

- **Asymmetrical intrauterine growth restriction (IUGR)** – A category of IUGR in which infants are not only small for gestational age but also exhibit disproportionately small organ size.
- **Dyslipidemia** – An increase in plasma cholesterol, triglycerides, or both, leading to the development of cardiovascular disease.
- **Epigenetics** – The study of heritable changes in gene expression without modification of the primary gene sequence.
- **Endoplasmic reticulum stress** – A cellular stress response characterized by increased accumulation of misfolded and/or unfolded polypeptides in the lumen of the endoplasmic reticulum.
- **Gluconeogenesis** – Production of de novo glucose molecules from non-carbohydrate sources.
- **Glucose intolerance** – A prediabetic condition in which affected individuals exhibit elevated blood glucose (i.e., hyperglycemia) in the fasted and/or fed

state. Glucose intolerance often precedes type II diabetes, which occurs when individuals also exhibit insulin resistance.

- **Heterochromatin** – Repressed region of DNA leading to a decrease in gene expression.
- **Malnutrition** – Either an excess or deficiency in one or more nutrients.
- **Metabolic syndrome** – A group of adverse metabolic symptoms that together confer increased risk for type II diabetes mellitus and cardiovascular disease.
- **MicroRNAs** – Endogenous, short, noncoding RNA molecules that post-transcriptionally regulate expression of target mRNA sequences.
- **Placental insufficiency** – An idiopathic condition occurring in 8% of pregnancies that leads to reduced maternofetal nutrient exchange due to inadequate placental blood flow.
- **Postnatal catch-up growth** – A period of growth after birth whereby low birth weight offspring exhibit rapid growth rate such that they "catch-up" to average body weight. Offspring that undergo postnatal catch-up growth are often referred to as "recuperated" offspring.
- **Senescence** – The process of biological aging due to loss of cellular division and function.
- **Severe acute malnutrition (SAM)** – An extreme form of undernutrition characterized by muscle atrophy and low body weight can be further categorized into cases of marasmus (extreme caloric restriction) or kwashiorkor (extreme protein deficiency).
- **Telomere** – A protective region of repetitive sequences at the end of a chromosome.

Summary Points

- In mammals, many organs are vulnerable to perinatal protein deficiency, which causes altered gene expression and leads to long-term metabolic effects in the offspring.
- Rat offspring exposed to maternal protein restriction have low birth weight and asymmetrical intrauterine growth restriction (i.e., many organs are proportionally small relative to the rest of the body).
- Given the role of the liver in glucose homeostasis, as well as the metabolism of cholesterol and a variety of drugs, impaired liver growth and development by maternal protein restriction leads to abnormal regulation of plasma glucose levels and hepatic enzymes.
- MPR indiced alterations to hepatic, pancreatic, or adipose function leads to dyslipidemia, obesity, glucose intolerance, and coronary artery disease.
- Transcriptional and epigenetic mechanisms (e.g., DNA methylation, post-translational histone modifications, microRNAs) facilitate adaptation of developing organs to amino acid deficiencies in utero; however, this can have dire consequences long-term and may have transgenerational effects.

- Endoplasmic reticulum stress is present in offspring with postnatal catch-up growth due to rapid growth of metabolic organs, and activation of the UPR further increases risk for the metabolic syndrome in adult life.

and monitoring nutritional and health status of infants and young children will be important for providing basic information to the local government to make and implement nutrition intervention to the target vulnerable groups. First, taking methods dependent on the field situation evaluate the risk of nutritional deficiency, establish an effective transportation mechanism in distributing salvage food and guide the usage of complementary food supplements in affected areas. Second, the practical experience of complementary food supplements (CFSs) in application for elder infants and young children includes multi-nutrient powder with food matrix, lipid-based nutrient supplements (LNS), and corn-soy blend (CSB), and micronutrients Sprinkles. Third, it should be particularly paid attention to the issues of safety use and quality control procedures on CFSs for elder infants and young children, implementing CFSs intervention in affected-areas after natural disaster will cover two aspects which involve in hygiene and safety to meet the nutritional requirements. Hygiene is referring to the contamination of traditional microbiology and safety of nutritional needs is related to prevent nutritional deficiencies due to poor compliance and avoid excessive intake due to overuse.

Introduction

Natural disasters such as earthquake, debris flow, floods, typhoon, severe drought, and volcanic eruptions are widespread and obvious characteristics are unpredictable and sudden, destructive, danger, and whole social emergency which make millions of people to be involved globally every year. In most of cases, a severe natural disaster might double damage to the human being, the substance and spirit disasters. Because food supply systems were severely damaged or even completely stopped, major food shortages became a primary post-disaster feature and the common characteristics were high prevalence of acute malnutrition and micronutrient deficiencies in infants and young children (Sun et al. 2013; Wang et al. 2010; Zhao et al. 2010a; Dong et al. 2014; Singh et al. 2006).

International experience has proved that even though in previously healthy population living in disaster area, elder infants and young children's morbidity and mortality resulted from acute malnutrition often dramatically increased in very short period (Singh et al. 2006) since they are the most nutritionally vulnerable group due to the supply of poor or limited food (Zhao et al. 2010a, b; Nishikiori et al. 2006; Wang et al. 2010). Malnutrition will increase the susceptibility to infectious diseases such as diarrhea and pneumonia and has an indirect association with the leading causes of death in infants and young children (Walker et al. 2013). However, malnutrition is preventable through effective nutritional intervention, for example, guiding advice on complementary feeding practices and/or giving complementary food supplements (CFSs) or multiple micronutrient supplements such as Sprinkles (Dong et al. 2013; Wang et al. 2007, 2009; Yu et al. 2007; Yin and Dong 2015). Frequently, a food supply and nutrition improving response combined with other public health interventions to reduce the risk of malnutrition will be required in those areas affected by a natural disaster (Dewey and Adu-Afarwuah 2008; Young et al. 2004; Bhutta et al. 2013). This chapter will review assessing and monitoring the nutritional and health status of infants and young children, the practical experience of CFSs in practical application, and the issues of safety use on CFSs for elder infants and young children after a natural disaster.

Quickly Assessing and Monitoring the Nutritional and Health Status of Infants and Young Children during or after Disaster

After a natural disaster, quickly assessing and monitoring nutritional and health status of infants and young children will be important for providing basic

information to the local government to implement nutrition intervention to the target vulnerable groups.

1. **Taking different evaluating methods depending on the field situation**: Infants and young children are a vulnerable group, but in the disaster-affected areas, relief and aid to such group are provided generally not to meet their needs in diversify of nutrition and quick growth development (Zhao et al. 2010; Sun et al. 2013). Therefore, we need to evaluate nutritional status of children young than 5 years through the nutrition survey, food consumption monitoring, sentinel monitoring, or the other simple and operable epidemiologic methods. Intervention measures and implementation for "assistance to such group" were based on the results obtained through evaluating or monitoring data which also can be used to evaluate the effectiveness of nutritional intervention implemented after disaster.
2. **Evaluate the risk of nutritional deficiency**: Nutritional status of populations as an early warning indicator would be very limited, because malnutrition generally is considered as a later indicator reflecting the deterioration or adverse effects of the nutritional and health status caused by natural disaster. However, we can analyze the changing trend of nutritional status of infants and young children through nutrition survey or monitoring, search the difference between present and past conditions, timely find priority nutritional problems resulted from natural disaster for implementing target intervention which include food resource, food security situation involved in availability and accessibility, food supplies and distribution, etc. (Programme 2005). Implementing evaluation on nutritional deficiency risk in infant and young children is very important after a severe natural disaster which includes malnutrition, morbidity, mortality caused by the disaster. All of these would have more practical and operable significance for effectively implementing assistance to the targeted populations.
3. **Establish an effective transportation mechanism in distributing salvage food**: Based on the results obtained from nutritional deficiency risk analysis and evaluation, we need to establish multiple-parallel support and protection ways to improve the nutritional status of infants and young children through providing food aid such as CFSs and with or without multiple micronutrient supplements progressively supplant single micronutrient. We can distribute special relief foods or CFSs to these populations through village clinics, schools, hospitals, orphanages, and other institutions or NGOs (Sun et al. 2011; Dong et al. 2013). Some organizations such as the Red Cross can provide more foods for vulnerable groups by increasing the general food ration to meet their needs.
4. **The usage of CFSs in the affected areas**: The period from 6 to 24 months of age is the most critical period because of their rapid growth and an increasing reliance on complementary food (CF). In order to improve nutritional status and reduce the mortality, adequate food-based nutrition interventions should be very important, since such interventions can play a key role in saving lives. Several strategies can be used to improve complementary feeding practices. These include education on child's caring knowledge to mothers or caretakers designed to promote healthy feeding practices; provision of CFSs offering extra energy with or without

micronutrient fortification; and increasing energy density of CFs. However, the usage of CFSs has been interested in recent years (Yang et al. 2013; Sun et al. 2011; Lopez Boo et al. 2014).

Before the intervention using CFSs, it can be best rapidly to monitor and evaluate the nutritional and health status, establish the nutritional risk and needs for infants and young children, and solve the transportation mechanisms how to effectively ship and distribute the CFSs to the affected areas.

The Practical Experience of CFSs on Application

Malnutrition children have a higher risk suffered from death and infectious diseases because of traditional CFs with a low nutrient and energy density in developing countries. Treating severe acute malnutrition (SAM) children in hospitals is not always desirable or practical, but home-based treatment will be better choice in most cases and complementary food supplement (CFS) usage can treat and prevent malnutrition in affected areas attacked by natural disaster. In those affected areas, no single of intervention measure can solve all complex nutritional problems that may exist in vulnerable groups. Malnutrition and other nutrition-related problems are generally closely related to insufficient intake of nutrients (especially micronutrients) caused by lack of animal foods, low dairy consumption, food insecurity, lack of maternal care, and poor public health environment. Therefore, implementing adequate nutrition intervention in early life is rather an opportunity for a better later life. At the present time, quickly providing CFSs at home level may play an important role in improving the nutritional status and is still considered as the overriding approach to control malnutrition of infants and young children. Home intervention has been recommended to use CFSs prepared by the career for young children. These include CFSs with food matrix such as soybean powder fortified with multiple micronutrients (Sun et al. 2011), CFSs without food matrix such as Sprinkles (provide micronutrients) (Lopez Boo et al. 2014), and commercially manufactured food such as lipid-based nutrient supplements (LNS) (Phuka et al. 2009).

Multi-Nutrient Powder with Food Matrix

Multi-nutrient powder is a CFS with food matrix for elder, infants, and young children. Through supplementing multiple-micronutrient, high-quality protein from soybean or its isolated proteins and/or cow milk, fat, and total energy could be provided which would be very useful for improving general nutritional status because these macronutrients play important role in the utilization and bioavailability and adequate reserve of micronutrients in the body. Such products are generally not water-based and relatively cheap, easy to transport from manufactured place to the mountain areas or inconvenient places, easy storing at room temperature and dry place without refrigeration for about 2 years, well compliance for long-term taking, and suitable for the mild malnutrition groups in these areas where hygiene is suboptimal after natural disaster. However, for SAM, we recommend taking ready-

to-use therapeutic food (RUTF) or increasing the dose as well as improving the quality of the complementary foods (CFs) (Wang et al. 2009; Phuka et al. 2009).

Such product can be added to the CFs or prepared and eaten directly for the elder infants and young children. For example, one kind of such product has been thoroughly evaluated and approved in China. This product (referred to as "Ying Yang Bao" in Chinese) was specially designed for the elder infants and young children based on a China's National Food Safety Standard for "CFSs" (GB 22570–2014). Essential composition of formulated supplementary foods are as follows (Nutrients/10 g/pack/d): vitamin A, vitamin D_3, vitamin B_1, vitamin B_2, iron, and zinc; the other optional ingredients include protein, calcium, magnesium, selenium, copper, vitamin E, vitamin K, niacin, vitamin B_6, vitamin B_{12}, folic acid, pantothenic acid, choline, biotin, and vitamin C. The composition in a commercial formulated CFSs and comparison with LNS and Sprinkles used in natural disaster areas or low-income rural areas for several years was shown in Table 1 and a program to market of such CFSs (Ying Yang Bao) has been implemented through the intervention efficacy in improving anemia and feeding practices in China (Sun et al. 2011).

The brewing and using methods for such product are very simply. One pack of this product was put into a small bowl with about 30 ml boiled cool water and then stir into a mud paste with a spoon, make it thick enough to stay in the spoon that would be best status for baby use. The preformed mud paste can be directly put into porridge, noodles or soup, and egg yolk or bread (or Chinese steam bread), well stir paste for baby use. For the best usage, it should take one pack daily alone or with a meal or taking half pack twice times per day for infants aged 6–12 months. Table 2 listed the effectiveness of CFSs (Yingyangbao, YYB) on improving status of elder infants and young children in low-income rural areas or affected-areas involved in natural disaster of China.

In China, a CFS (Yingyangbao, YYB) was first performed in 2001 by the International Life Science Institute and Chinese Center for Disease Control and Prevention. Such CFS has been used for the affected areas attacked by natural disasters or the intervention for nutritional improvement in poor areas since 2008, and national standard for this CFS has been established later (Huo 2017). Two prospective studies on the effectiveness of CFSs were carried out in the areas affected by Wenchuan Earthquake (Dong et al. 2013) and poor areas (Wang et al. 2015, 2017); these studies evaluated the improving role in growth rate and anemia prevalence of elder infants and young children. All children (6~18 months) in these affected areas were daily provided with formulated CFSs (compositions of this product were shown in Table 1) for up to 24 months of age. The intervention period lasted for one and half year. After the intervention, the growth and anemia status of children were significantly improved. Since YYB efficacy and effectiveness in reducing iron deficiency, underweight, and stunting have also been well documented (Wang et al. 2004; Dong et al. 2013), such kinds of products have been used in several national intervention studies for more than 10 years (Huo 2017), and Chinese government has launched a national project improving children's nutrition in poor areas since 2012. However, compliance to CFSs contributes to the improving effectiveness of nutritional and anthropometric status (Wang et al. 2017).

Lipid-Based Nutrient Supplements (LNS) and Corn-Soy Blend (CSB)

Recently, different approaches for improving nutrition status have been used for treating moderate acute malnutrition (MAM) using fortified blended flours such as enhanced versions of corn-soy blend (CSB) or lipid-based nutrient supplements (LNS) in low-income countries or emergency settings (Lazzerini et al. 2013; Campbell et al. 2016; Muslihah et al. 2016; Flax et al. 2015; Abbeddou et al. 2017; Hemsworth et al. 2016; Adu-Afarwuah et al. 2016; Chaparro and Dewey 2010). The study in Burkina Faso showed that CSB was not as readily consumed as LNS (Iuel-Brockdorf et al. 2015) or the study in Malawi indicated that LNS might be superior to CSB for underweight children (Thakwalakwa et al. 2014). Most of studies used LNS and carried out in developing countries, and the international lipid-based nutrient supplements project have been began to prevent undernutrition in vulnerable populations in 2009 (Arimond et al. 2015).

LNS are soft or crushable foods, conveniently packaged, and the low percentage of free water and energy-dense fortified pastes that typically contain high proteins, carbohydrates, and micronutrients embedded in a lipid base (Briend et al. 1999; Phuka et al. 2009). The general nutrient compositions in such product were shown in Table 1. However, manufacture for such products is flexible, the exact recipe, energy, and protein contents can be tailored to specific needs, such as those for a fast-growing child or those recovering from mild or moderate undernutrition. LNS do not require cooking or preparation except adding water before use and can be easily consumed by children from the age of 6 months; hence feeding process is not easy to be contaminated by external bacteria which are particularly useful in those areas attacked by natural disaster.

LNS are simple to store and deliver, easy to use, fast acting, affordable, culturally acceptable, have appropriate shelf-life and stability without needing refrigeration under varied climate and temperature. Table 3 listed the effectiveness of LNS on improving status of elder infants and young children in low-income rural areas or affected-areas involved in natural disaster, and most of these studies showed that interventions using LNS could significantly reduce the incidence of stunting, improve linear growth and dietary diversity, macro- and micronutrient intakes. Adu-Afarwuah et al. (Adu-Afarwuah et al. 2016) have shown that provision of LNS would have more advantages in length, length for age Z score (LAZ), weight, and weight for age Z score (WAZ) compared with those in the standard iron and folic acid or multiple micronutrient group by 18 months of age. However, some factors that may affect the effectiveness include the duration and compliance of the intervention, composition and dosage of LNS given, and baseline demographics and nutritional status of children (Wang et al. 2017; Matsungo et al. 2017).

The term of LNS refers to a range of fortified, lipid-based products, including the products like RUTF and ready-to-use supplementary food (RUSF). RUTFs have revolutionized and proven to be effectively in the community-based treatment of SAM with weight for height Z score (WHZ) <-3SD attributable to the transient effects of disease or food shortages in emergencies (Briend et al. 1999; Yang et al. 2013) and now RUTF can be made according to a standard, energy-rich composition defined by the World Health Organization (WHO) for severely malnourished infants

Table 3 The effectiveness of LNS on improving status of elder infants and young children

Date	Site	Sample size	Age (m)	Design	Observation index	Results	Reference
2009–2014	Rural Northwest Bangladesh	5499	6 m	Control group, periodic child feeding counseling; treated group, counseling plus 1 of 4 CFSs, a supplement provided 125 & 250 kcal/d for 6–11 m & 12–18 m of age for 1 year[a]	Questionnaire & anthropometry	Daily CTSs improved linear growth and dietary diversity	(Campbell et al. 2016)
2014–2015	West Madura Island, Indonesia	269	>6 m	Non-randomized, controlled trial. SQ-LNS[b] group provided 118 kcal/d; biscuits group provided 3 pieces or 30 g/d containing 135 kcal/d for 6 m.	Questionnaire & anthropometry	SQ-LN group had lower stunting incidence than in biscuit & control groups	(Muslihah et al. 2016)
2009–2010	Three municipalities in Hunduras	298	6–18 m & WHZ≥-2SD	Intervention group received LNS with 46.3 g/d and 70 g/d for 6–11 m and 12–30 m lasting for 12 m	Questionnaire & 24 h dietary recalls	LNS improved macro- and micronutrient intakes.	(Flax et al. 2015)
2010–2012	Dande Health District in southwestern Burkina Faso	2435	9–18 m	Children daily received 20 g SQ-LNS, group one, placebo tablet without Zn; group two, placebo table with 5 mg Zn; group three, placebo tablet with 10 mg Zn; & group four, 5 mg Zn tablet, lasting for 9 m	Hb in whole blood, Zn, Fe and vitamin A, ferritin, sTfR and RBP in plasma[c,d].	SQ-LNS improved Fe and vitamin A status regardless of Zn amount and source.	(Abbeddou et al. 2017)

(*continued*)

Table 3 (continued)

Date	Site	Sample size	Age (m)	Design	Observation index	Results	Reference
2009–2012	Rural communities in Malawi	748	<6 m	Control without supplement, and 3 groups received 10, 20, or 40 g LNSs[e]/d for 12 m.	24 h dietary recalls & anthropometry	10–40 g LNSs/d increased energy and macronutrient intakes.	(Hemsworth et al. 2016)
2009–2014	Semi-urban Ghana	1228	6–18 m	Randomized controlled trial. From 6 m to 18 m of age, SQ-LNS was provided with118 kcal per 20 g/d.	Anthropometry	SQ-LNSs increased child's attained length by age 18 m of age.	(Adu-Afarwuah et al. 2016)

[a]*CFSs* complementary food supplements. Four CFSs included the first product was made of chickpeas and the second product was made of rice and lentils both developed and produced in-country, the third was fortified wheat-soy blend (WSB++) fed to children as a porridge supplied by the World Food Programme, and the forth was a commercially produced, read-to-eat, peanut-based product
[b]*SQ-LNS* small quantity of liquid-based nutrient supplements
[c]*sTfR*, soluble transferrin receptor
[d]*RBP* retinol-binding protein
[e]*LNSs* lipid-based nutrient supplements

and young children in low-income countries (Yang et al. 2013; Thakwalakwa et al. 2010; Thakwalakwa et al. 2014; Siega-Riz et al. 2014; Dewey and Arimond 2012; 'Community Based Management of Severe Acute Malnutrition', 2010) because of their specialized nutrient composition, the reduced risk of contamination that it requires no preparation, and the fact that children can consume RUFT at their homes and ensures rapid weight gain provided that they are free from clinical complications. RUFTs were generally higher in energy density (>700 kcal/d) than RUFT (≤500 kcal/d).

However, RUSF provides less energy at a relatively lower cost than RUTF and enriches a child's existing diet with the goal of treating mild or MAM with WHZ between -2SD and -3SD or prevent the progression from MAM to SAM, and thus would have the potential efficacy to reduce child mortality and morbidity (Yang et al. 2013; Phuka et al. 2009; Thakwalakwa et al. 2010; Chaparro and Dewey 2010).

Although such product has a relatively higher cost, it does have well compliance and very easy for transportation, suitable for malnourished populations, particularly for those children with SAM. RUTF and RUSF must be targeted appropriately to ensure cost-effectiveness. More than two third (73%) of children aged 6~60 months were recovered from MAM after 13 weeks treatment with RUSF (Karakochuk et al. 2012) and the overall recovery from SAM with use of RUTF is 88.3% with a mortality of less than 1% and with a mean weight gain of 3.2 g/kg/d after 8 weeks treatment (Gera 2010).

Micronutrients Sprinkles without Food Matrix

Micronutrients Sprinkles is a CFSs without food matrix and single-dose sachets containing iron and other multi-micronutrients, which are easily sprinkled onto any traditional CF in a powdered form for elder infants and young children prepared in the household. Ingredients of micronutrients Sprinkles were shown in Table 1 and the other micronutrients such as iodine, vitamin B_1, vitamin B_2, calcium, and the others can be added to micronutrients Sprinkles sachets depending on local iodine or the micronutrient status. This single-dose sachets can be put in the infant's daily CF such as porridge, soup, or steamed rice to prevent iron-deficient anemia (IDA) and deficient prevalence of iron and other micronutrients (Schauer and Zlotkin 2003; Yang et al. 2004; Jack et al. 2012; Suchdev et al. 2016). The provision of multiple micronutrient supplements would be better than single iron supplement. Table 4 showed the effectiveness of home fortification with micronutrient Sprinkles on improving status of elder infants, young, and preschool children in low-income areas or affected-areas involved in natural disasters which showed that such CFS can significantly improve iron status, decrease the prevalence of IDA, and shorten hospitalization for diarrhea and fever.

These products can be added directly to infant daily foods, cannot change the color and texture of the food itself and cannot affect child's appetite. The smell produced by iron is not obvious, and it does not cause irritation to the gastrointestinal tract of infants due to fortified microencapsulated iron, but the effect of adding micronutrients Sprinkles to home-prepared foods should consider the local food culture and acceptance. Because this product uses a single-dose sachets, it is easy to

Table 4 The effectiveness of home fortification with micronutrient Sprinkles on improving status of elder infants, young, and preschool children

Date	Site	Sample size	Children age (m)	Duration (m)	Observation index	Results	Reference
2001	Baotou city, China	353	36–72	Daily use for 2.5 mo	Anthropometry, Hb, SF[a] & FEP	Improve growth & reduce Fe deficiency	(Yang et al. 2004)
2001	Central Vietnam	377	5	Daily use for 6 mo	Hb, plasma ferritin, TfR, Zn, retinol	Improve Fe status & IDA prevalence	(Phu et al. 2010)
2002	Bijie county, China	273	36–60	Daily use for 2.5 mo	Anthropometry, Hb, FEP & IQ[b]	Improve iron status and IO	(Yang et al. 2005)
2003	Rural Bangladesh	79	12–24	Daily use for 2.5 mo	Anthropometry, Hb, SF & STR[c]	Improve iron status and decrease IDA	(Hyder et al. 2007)
2004	Koforidua Ghana	98	6–12	Daily use for 12 mo	Morbidity, Hb, plasma ferritin, TfR, CRP & Zn[d]	Reduce iron deficiency & IDA	(Adu-Afarwuah et al. 2008)
2005	Rural Haiti	254	9–24	Daily use for 2 mo	Hb	Reduce IDA	(Menon et al. 2007)
2007	Kyrgyz Republic	172	6–36	Daily use for 2 m	Hb	Improve Hb levels & reduce IDA	(Lundeen et al. 2010)
2007	Western Kenya	1062	6–36	Daily use and 12 mo follow	Diarrhea, fever, cough, malaria morbidity episodes	Decrease hospitalization for diarrhea & fever	(Suchdev et al. 2013)
2007	An urban district of Iran	120	6–18	Daily use for 4 m	Anthropometry, Hb, serum ferritin, retinol, Zn, 25(OH)D	Reduce proportion of zinc deficiency	(Samadpour et al. 2011)
2009	Rural area LPDR[e]	111	6–52	Daily use for 24 m	Anthropometry & Hb	Improve Hb level & reduce IDA	(Kounnavong et al. 2011)
2009	Bahia Brazil	143	6–48	Daily use for 3 m	Diarrheal disease (DD) & acute respiratory infection (ARI)	No impact in reducing DD, ARI prevalence & nutritional status	(Sampaio et al. 2013)

[a]*SF* serum ferritin
[b]*Hb* hemoglobin, *FEP* free erythrocyte proporphyrin, *IQ* intelligence quotient
[c]*STR* serum transferrin receptor
[d]*TfR* transferrin receptor, *CRP* C-reactive protein, *Zn* zinc
[e]*LPDR* Lao People's Democratic Republic

feed to the children by their careers (Yang et al. 2004; Zlotkin et al. 2005). The costs for processing and transportation of these products are also relatively inexpensive. The other optional ingredients can also be added according to the nutritional characteristics and nutrient deficiencies in different regions.

Micronutrient Sprinkles has been used to prevent IDA and the other micronutrient deficiencies in children under 5 years of age in developing countries (De-Regil et al. 2013). Several intervention trials to the children for 2 months or more using Sprinkles have been reported in China, Canada, Ghana, and other places (Jack et al. 2012; Yang et al. 2004; Adu-Afarwuah et al. 2007, 2008), which showed that Sprinkles can significantly reduce anemic prevalence through elevating hemoglobin levels, improving motor development, and having high compliance for this product, as well as easy to transport, carry, and well mix with the other CFs; however, its improving efficacy in growth development and SAM was very limited while using it alone because such products did fortify high qualitative protein and fat as multi-nutrient powder with food matrix and LNP (Adu-Afarwuah et al. 2007, 2008). One study has reported the effect of daily and once weekly Sprinkles for 14 weeks on hemoglobin, serum ferritin, erythrocyte protoporphyrin in whole blood, prevalence of iron deficiency in preschool children. Compared with a placebo control, once weekly supplement is effective same as daily supplement in improving iron status and reducing the prevalence of iron deficiency (Yang et al. 2004; Hyder et al. 2007); however, for severely to moderately anemic children, daily supplementation was more effective in elevating hemoglobin level and reducing IDA prevalence (Kounnavong et al. 2011).

The Issues of Safety Use on CFSs for Elder Infants and Young Children

The prevalence of malnutrition remains high in developing countries in infants and young children so that intervention using CFSs or home fortification of foods with multiple micronutrient powders would be an effective measure to reduce IDA and iron deficiency and improve growth and development in such areas. However, it should be particularly paid attention to the safety and quality control procedures to prevent contamination with toxins or pathogens and ensure the product to be stable and palatable over time during the shelf-life of products.

After natural disaster or in low-income areas, providing adequate food suitable for infant and young children feeding practices in food insecure environment may not be feasible because of lack of household access to promoted foods. Implementing CFSs intervention in such areas will involve two aspects which include hygiene and safety to meet the nutritional requirements. Hygiene is referring to the problems of traditional microbiology and safety of nutritional needs is related to prevent nutritional deficiencies due to poor compliance and avoid excessive intake due to overuse. Furthermore, issue of allergy should also be considered due to individual children sensitive to certain raw materials (such as gluten, peanut, etc.) in CFSs. Therefore, it should ensure adequate and safety for the targeted populations, that is, the supplementary quantity should be sufficient to prevent malnutrition and avoid excessive intake leading to adverse health effects.

After natural disasters or in low-income areas, the design intervention strategies on CFSs should consider the reasons behind choices by households to overuse or underuse the product and increase the likelihood of its appropriate utilization through appropriate propaganda and guidance for child's caregivers in the field sites. In addition, because most of CFSs are rich in nutrients and easily contaminated and spoiled which could lead to feeding injuries to infants and young children, too many products should not be distribute to the children every time, especially in those places where poor environmental conditions such as high temperature and high humidity, and no refrigerator or other cold storage facilities.

In summary, nutrient requirements of infants and young children have particularly high for their growth and development so that meeting their nutritional needs are challenging in settings where the ration is limited to a few food commodities, with little access to a diverse diet and bioavailable sources of micronutrients during and/or after a natural disaster or in the developing countries. Therefore, the nutritional interventions using CFSs will be most efficient in reducing IDA and/or preventing malnutrition and promoting adequate growth and development of infants and young children. However, many factors may affect the acceptability and thereby the beneficial effect of nutritional intervention of CFSs, such as cost, taste, texture, shelf-life, how they are used, as well as its nutrient composition; all of these should be considered when implementing nutrition intervention in such areas.

Policies and Protocols

Policies

In this chapter, we have described the importance of complementary food supplements for elder infant and young children after disasters. Based on China's successful experience on Ying Yang Bao (YYB) distribution in poor areas or affected-areas after natural disaster during recent 10 years, the policy and protocols should cover the following aspects:

Governmental Policies

- Central government domination should be the guarantee of successful promotion and distribution of CFSs, which include guarantees in legislation, technology, professionals, and funding. For example, the study on YYB was performed in 2001, a National food standard on CFSs was established in 2008, and such standard has been updated to China's National Food Safety Standard for CFSs (GB 22570 – 2014) in 2014.
- Assessing and monitoring the nutritional and health status of infants and young children after a natural disaster will provide basic information for the center and/or local government to implement intervention to the target vulnerable groups in affected areas.

- Center and/or local governments should prepare and store certain complementary food supplements for elder infant and young children for emergency at ordinary times.
- Government should regularly monitor and evaluate the safety and quality of complementary food supplements to prevent contamination with toxins or pathogens, and the company should ensure their products to be stable and palatable over time during the shelf-life of products.
- Government-leading interventions in improving nutrition status of infants and young children are conducive to maximizing in resource uses and working sustainably in promoting publicity.

Protocols

For the procedures and extent of intervention using complementary food supplements to the elder infants and young children after disasters, the protocol describes as follow:

- Basal evaluation and monitor on nutritional and health status of infants and young children will be important for finding nutrition issues and providing basic information to the local government to implement intervention to the target vulnerable groups after a natural disaster.
- Up to now, more than ten nutrition intervention projects using YYB to elder infants and young children have been carried out in poor rural areas or those areas affected by natural disaster.
- Re-evaluation will be useful to find the intervention efficacy and what kind of questions existed in those areas affected by natural disaster.
- Quality control system will be important involving survey methods, training investigators, and the quality of complementary food supplements providing for the target vulnerable group.
- Through systematic review and or meta analysis on the intervention studies, it would be useful for us to evaluate the intervention efficacy, experience, and existing problems and to help spread such intervention to the other places. For example, based on summing up the above experience, since 2012, Chinese government has launched a project named "improving children's nutrition status in poor rural regions" covering more than four millions of infants and young children aged 6–24 months in 341 counties from 21 provinces located in western and middle regions by the end of 2015.

Dictionary of Terms

- **Elder infants and young children** – The children are defined as elder infant after 6 months of birth and young children with 12–36 months after birth.
- **The period of complementary feeding** – The period during which other foods or liquids are introduced along with breast milk after 6 months of birth is considered as the period of complementary feeding.

- **Complementary food** – Any nutrient-containing foods or liquids other than breast milk given to elder infants and young children during the period of complementary feeding are defined as complementary foods.
- **Complementary food supplements** – Complementary food supplements used for elder infants and young children are fortified with multi-nutrients including multi-nutrient powder with food matrix, lipid-based nutrient supplements and corn-soy blend, and micronutrients Sprinkles.
- **Multi-nutrient powder with food matrix** – Multi-nutrient powder is a complementary food supplement with food matrix for infants and young children. High-quality protein and total energy as well as multi-nutrients are suitable for mild malnutrition children.
- **Corn-soy blend** – Corn-soy blend is micronutrient-fortified cereal-legume (corn and soy flours) mixtures generally used for low-income countries.
- **Lipid-based nutrient supplements** – Lipid-based nutrient supplements contains peanut butter, milk powder, cooking oil, sugar, and micronutrients, which includes ready-to-use supplementary food and ready-to-use therapeutic food.
- **Micronutrients Sprinkles** – Micronutrients Sprinkles is a complementary food supplements without food matrix and single-dose sachets containing iron and other multiple micronutrients, which are easily sprinkled onto any child's traditional complementary food in a powdered form for elder infants and young children prepared in the household.

Summary Points

- This chapter focuses on complementary food supplements (CFSs) used for elder infants and young children after disasters.
- Obvious characteristics of natural disasters are unpredictable and sudden, destructive, danger, and whole social emergency which make millions of people to be involved globally every year.
- Elder infants and young children's morbidity and mortality often dramatically increase in very short period since they are the most nutritionally vulnerable group due to poor or limited food choices after disasters.
- After a natural disaster, quickly assessing and monitoring the nutritional and health status of infants and young children will be important for providing basic information to the local government to make intervention.
- The practical experience of CFSs mainly includes multi-nutrient powder with food matrix, lipid-based nutrient supplements (LNS) and corn-soy blend (CSB), micronutrients Sprinkles without food matrix, etc.
- Home-based treatment to severe acute malnutrition will be better choice in most cases and complementary food supplement (CFS) can treat and prevent malnutrition in affected areas.
- Therefore the nutritional interventions using CFSs are most efficient in reducing IDA, preventing malnutrition, promoting adequate growth and development of infants and young children.

- Many factors may affect the acceptability and the beneficial effect of nutritional intervention of CFSs, such as cost, taste, texture, shelf- life.
- In those affected areas attacked by disasters, no single intervention measure can solve all complex nutritional problems that may exist in vulnerable groups.
- Final, we should pay attention to the safety and quality control procedures on CFSs to prevent contamination with toxins or pathogens and ensure the product to be stable and palatable during the shelf-life.

List of Abbreviations

ALP	Atherogenic lipid profile
CF	Complementary food
CFS	Complementary food supplement
CFs	Complementary foods
CFSs	Complementary food supplements
CHD	Coronary heart disease
DBC	Disturbed blood coagulation
DM	Diabetes mellitus
IDA	Iron-deficient anemia
MAM	Moderate acute malnutrition
NCDs	Noncommunicable diseases
NGOs	Nongovernmental organizations
PAD	Peripheral arterial diseases
SAM	Severe acute malnutrition
SGL	Standard glucose load
SR	Stress responsiveness

Introduction

Famines are widespread and frequent occurrences in human history, which generally are resulted from or secondary to natural disasters include severe droughts, floods and mudslides, earthquake, volcanic eruptions, tsunamis, etc. Such famines generally have obvious characteristics by sudden, destructive, danger, social and emergency which often affect millions of people globally every year (Nutrition 1993–2005). In most of famine cases, food supply systems were severely damaged or even completely stopped, major food shortages became a primary post-disaster or famine feature and the common characteristics were high prevalence of acute malnutrition and micronutrient deficiencies in vulnerable groups such as

elder infants and young children (Sun et al. 2013; Zhao et al. 2010a; Dong et al. 2014).

In those areas affected by severe natural disaster or famine, elder infant and young children's morbidity and mortality resulted from malnutrition often dramatically increased in very short period (Nutrition, 1993–2005) since they are the most nutritionally vulnerable subgroup due to poor food choices and decreased accessibility to certain foods rich in proteins, lipids, and micronutrients (Nishikiori et al. 2006; Wang et al. 2010a; Zhao et al. 2010b). Malnutrition will lead to susceptibility to preventable infectious diseases such as diarrhea and pneumonia and has an indirect association with the leading causes of death in young children (Walker et al. 2013). The majority of epidemiological studies clearly show that exposure to famine during prenatal life increases risk for metabolic syndrome; postnatal famine exposure in childhood also seems to raise risk for nutrition-related non-communicable diseases (NCDs). These findings demonstrate the hypothesis of fetal programming, which indicates that maternal nutrition status before and during pregnancy has short-term and long-term impact through mediating fetal structure and physiology, growth, and future health status and susceptibility to NCDs. Furthermore, postnatal environment, such as nutrition status (deficiency or excess) at infancy, has also been shown to induce powerful, lasting programming effects on growth and development trajectories, body composition, tissue differentiation and functional development, as well as long-term health, performance, and the risks for NCDs until old age. Even after controlling socioeconomic conditions and other factors in the home environment, malnutrition in early life had a negative impact on cognitive and behavioral functioning throughout childhood and adolescence. Short- and long-term effects of exposure to famine on health status during early life were shown in Fig. 1.

This chapter will review the short-term impact-related nutritional problems existed in infants and young children and the short-term intervention efficiency of timely improving nutritional status of infants and young children after famine, and the long-term effects of exposure to the famine before and during pregnancy on adult chronic diseases.

The Short-Term Effect on Nutrition-Related Diseases

Severe natural disaster or famine often occurs in the poverty and developing areas and affects millions of people worldwide each year. After a serious destructive event, the quantity and quality of daily supply foods markedly decreased and the general nutritional status of populations gradually deteriorated, especially in infants and young children because the nutritional quality of the food commodities provided in such situation might be insufficient to meet their nutritional needs, the prevalence of acute malnutrition and micronutrient deficiencies such as iron-deficient anemia would significantly increase and become more serious public health priority to be solved (Dong et al. 2013, 2014; Wang et al. 2010a; Zhao et al. 2010b; Eriksson 2007).

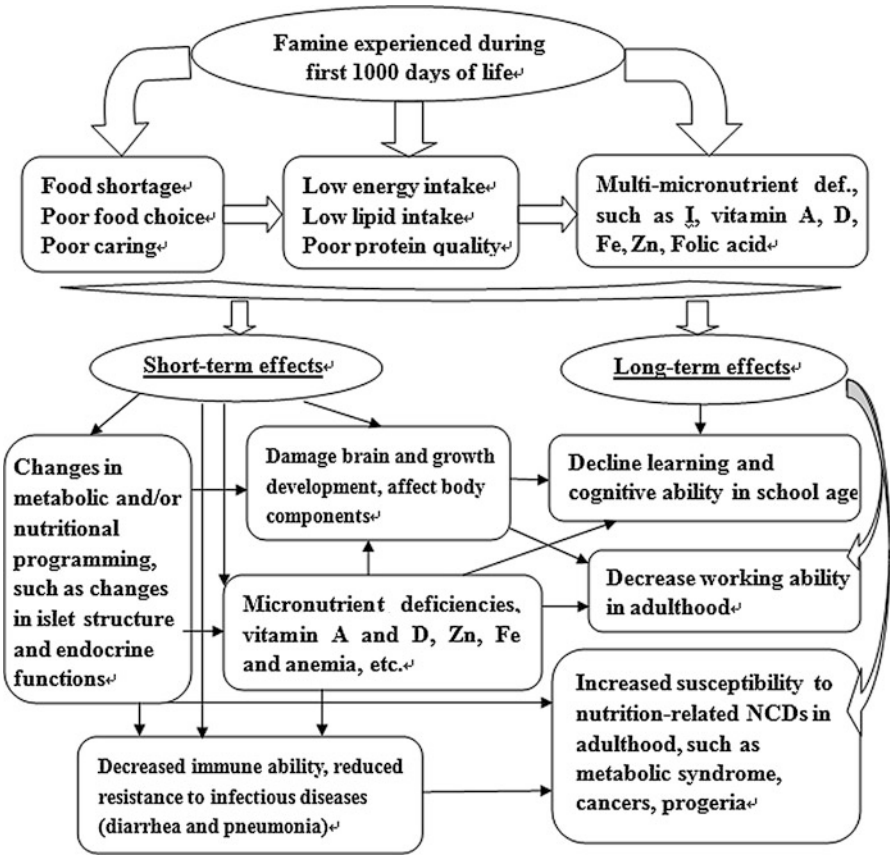

Fig. 1 Diagram of short- and long-term effects of exposure to famine on health status during early life

1. *Protein – energy malnutrition*. During and after famine, the prevalence of acute malnutrition including severe acute malnutrition (SAM) and moderate acute malnutrition (MAM) in young children may be significantly increased due to the shortage of food, food insecurity, poor sanitation, etc., and hunger was a contributing factor to the increased mortality due to infectious diseases and diseases of digestive system (Lumey and van Poppel 1995). For example, during Dutch famine (1944–45), the estimated number of deaths from undernutrition were 20,000–30,000 in Western Netherlands (Stein and Susser 1975; Trienekens 2000); the Chinese Great Famine (1959–61) had resulted in about 30 million deaths of children and adults due to severe protein-energy malnutrition (Smil 1999). "District food supply crisis" in southern Africa caused by the drought and widespread crop failures resulted in significant increase in acute malnutrition and mortality in some areas during 2001–2002 (Renzaho

2007). In drought-affected desert areas of western Rajasthan of India in 2003, the percentages of stunting and underweight of children aged 0–5 years were reported to be high up to 53% and 60% (Singh et al. 2006). The rates of underweight were respectively 15.6% and 9.1% and stunting percentages were 26.0% and 24.2% in Beichuan and Li counties of Sichuan Province of China after Wenchuan Earthquake on May 12, 2008, which indicated the presence of SAM (Wang et al. 2010a); the stunting prevalence of children aged from 2 to 5 years living in affected areas of Sichuan, Shanxi and Gansu Province of China was up to 13.6% after 11 months of Wenchuan Earthquake which showed that such situation was closely related to protein and energy malnutrition (Zhao et al. 2010b).

2. *Iron-deficiency and anemia (IDA)*. The elder infants and young children are at higher risk susceptible to iron-deficiency and IDA (Medicine, 2001). If foods rich in iron or supplements with iron could not be provided, these vulnerable groups would be more easily suffered from IDA (Rim et al. 2008). For example, in those areas affected by Wenchuan earthquake, the iron deficiency and IDA in children were reported to be higher prevalence (Zhao et al. 2010a, b; Wang et al. 2010a). Children suffered from anemia not only increase susceptibility to infectious diseases (Zhao et al. 2010a) but also will have a higher risk died of such diseases (Walker et al. 2013). After 4 months of Wenchuan Earthquake, the children aged from 6 to 23 months had a higher prevalence of anemia up to 49.6% and 78.8% in Beichuan and Li counties of Sichuan Province, and the highest prevalence was the infants aged from 6 to 11 months (Wang et al. 2010a). The average prevalence of anemia in children aged 0 to 24 months living in the affected areas of Sichuan, Shanxi, and Gansu Provinces of China was 45.7% after 11 months of Wenchuan Earthquake (Zhao et al. 2010b). It has been reported that the anemia prevalence of children long-term living in refugee camps in Africa was up to 60% and iron-deficiency was much higher with the range of 23% to 75% from four refugee camps (Seal et al. 2005).
3. *Vitamin A deficiency and decrease in resistance to infectious diseases*. It has been reported that the prevalence of vitamin A deficiency and marginal deficiency in children was generally quite high in most of the developing countries (Yin and Lai 2002; Akhtar et al. 2013; Sherwin et al. 2012). This would predict that young children were more vulnerable to have vitamin A deficiency during famine due to a single species of food and very limited food supply suitable for them. After 11 months of Wenchuan Earthquake, the prevalence of vitamin A deficiency was significantly increased (15.4%) in children aged 24–60 months living in affected areas from Sichuan, Shanxi, and Gansu Provinces of China which was significantly higher than that of national level (Dong et al. 2014). The results from international surveys indicated that vitamin A deficiency was much higher in children long-term living in refugee camps which was up to 20.5~61.7% (Seal et al. 2005).
4. *Vitamin D deficiency and rickets*. Vitamin D deficiency is associated with adverse effects in children such as growth failure and rickets, which should

adversely affect children's normal growth and bone development. Using serum $25(OH)_2D_3$ less than 12 nmol/L for vitamin D severe deficiency, 12~48 nmol/L for vitamin D deficiency, and 48~78 nmol/L for vitamin D marginal deficiency, vitamin D severe deficiency, deficiency, and marginal deficiency in children living in earthquake-affected areas from Sichuan, Shanxi, and Gansu Provinces of China were 1.5%, 61.8%, and 28.6%, respectively, and total of vitamin D deficiencies and marginal deficiency were over 90% after 11 months of Wenchuan Earthquake (Dong et al. 2014). The reasons resulted in such higher vitamin D deficiency or poor status in children in those areas were related to the lower intake of animal foods rich in vitamin D and no vitamin D supplements as well as lack of adequate sunlight exposure in winter and spring or rainy season which resulted in the decrease of vitamin D synthesis in body so that the young children living in these areas would have high risk for rickets (Zhu et al. 2012; Gordon et al. 2008).

5. *The other multi-micronutrient deficiencies*. After a natural disaster or lasting famine, the provided foods were very limited and low percentages of animal foods, fresh fruits, and vegetables in affected areas; the children were very easy to have zinc, vitamin B_2, vitamin B_{12}, vitamin C, and iron deficiencies which could affect children's appetite and diminished sense of taste, and manifest pica, angular cheilitis, glossitis, and other clinic symptoms as well as stunting, underweight, and nutritional anemia (Zhao et al. 2010a, b; Wang et al. 2010a; Dong et al. 2013). For example, during 2000 and 2003, scurvy outbreaks in Afghanistan were documented, although this country had a relative low incidence of acute malnutrition (3–12%) (Young et al. 2004). After 1 year of the Wenchuan Earthquake, the percentages of vitamin B_{12} marginal and deficiency of children aged 24–60 months were 8.6% and 10.6%, and the prevalence of zinc deficiency including marginal and deficiency was 65.5% in the affected areas (Dong et al. 2014). Lasting multi-micronutrient deficiencies resulted from famine would have the current and long-term effects on cognitive and behavioral development in children under 5 years. The brain is vulnerable to the effects of insults during critical periods of brain development from the second trimester of pregnancy until 2 years of age. Malnutrition experienced at these ages will have lifelong consequences that are not reversed by adequate nutrition.

As mentioned about, nutritional problems and overall deterioration mentioned above in the general health conditions that resulted from natural disasters or famine in young children were related to some public problems in food insecurity and/or social unrest and lack of complementary foods (CFs) suitable for them; many infants from 6 to 10 months of age without breastfeeding ate the same foods as adults as the families could not prepare infant's foods (Zhao et al. 2010a; Wang et al. 2010b). All of these should affect the nutritional and health status of children and make them facing high risk suffered from infectious diseases such as diarrhea and pneumonia which should significantly increase the risk for mortality (Zhao et al. 2010a, b; Nishikiori et al. 2006; Singh et al. 2006).

The Short-Term Intervention Efficiency of Timely Improving Nutritional Status of Elder Infants and Young Children During and/or After Famine

A common representative characteristics in public health would be the increasing risk of malnutrition and mortality by nutrition-related diseases in infant and young children after famine (Nutrition, 1993–2005; Nishikiori et al. 2006; Young and Jaspars 1995; Singh et al. 2006). These children were not only facing high risk of SAM due to food shortage and insecurity but also easily suffered from some nutritional and infectious diseases so that the synergistic effect would cause exponentially significant increase in mortality (Nishikiori et al. 2006; Singh et al. 2006). Therefore, effectively targeted intervention using CFSs to prevent and control nutritional deficiencies must be carried out. The intervention by CFS usage would quickly achieve the following benefits:

1. *Effectively improve children's nutritional status.* Providing CFS, micronutrient supplements or the other fortified foods for the targeted populations not only meet the energy and macronutrient requirements but also effectively improves the micronutrient status to prevent nutritional deficiencies because these micronutrients participate in the metabolic and transforming process of energy and macronutrients in the body. Taking comprehensive measures to improve the nutritional status of the young children in the affected areas will reduce or prevent the prevalence of malnutrition and mortality. The relief and assessment of the nutritional and health status of vulnerable populations carried out after Earthquake in Wenchuan showed the importance to provide efficiently nutritional support and protection for these subgroups through nutritional intervention using CFSs (Sun et al. 2011; Dong et al. 2013).
2. *Decrease the risk suffered from malnutrition and infectious diseases.* Under many natural disasters or after famine, due to the deterioration of living place and surrounding environment, food shortage, very irregular or uneven eating, and family member death, children in the affected areas would be in a very sensitive status for malnutrition and infectious diseases (Walker et al. 2013). In such situations, requirements for a variety of micronutrients would be significantly increased so that supplementing multiple micronutrients or providing CFSs as well as meeting macronutrient and energy needs would improve the general nutritional status and reduce or alleviate stress conditions and prevent infectious diseases, which is particularly important for protecting those vulnerable populations.
3. *Decrease mortality of elder infants and young children:* The period from 6 to 24 months of age is the most critical period because of their rapid growth and an increasing reliance on complementary food (CF) and or CFSs. In order to improve nutritional status and reduce the mortality, adequate food-based nutrition interventions using CFSs should be very important, since such interventions might play a key role in saving lives through their impact on the nutrition and health. Several strategies can be used to improve complementary feeding

practices. These include education related to nutrition and child care knowledge to mothers or caretakers designed to promote healthy feeding practices, provision of CFSs offering extra energy with or without micronutrient fortification, and increasing energy density of CFs. However, the usage of CFSs has been interested after famine or natural disaster in recent years (Sun et al. 2011; Lopez Boo et al. 2014; Zhang et al. 2016). Malnutrition of young children is preventable through effective nutritional intervention by implementing complementary feeding practices and giving CFSs or multiple micronutrient supplements (Dong et al. 2013; Wang et al. 2009, 2015). Frequently, a food supply and nutrition improving response, together with other public health interventions to reduce the risk of malnutrition, will be required in such situation (Young et al. 2004; Bhutta et al. 2013).

The Long-Term Effects of Prenatal, During or Postnatal Exposure to the Famine on Adult Diseases

The lasting effect of early life exposure to famine on fetus is predicted by the fetal origins hypothesis (Barker 1992), which postulated that nutritional deprivations during the fetal period could lead to higher prevalence of nutrition-related NCDs at adulthood, and such findings have been supported by several cohort studies based on Dutch famine and China's great famine. Poor maternal nutrition during gestation may contribute to restricted fetal growth, leading to increased susceptibility to nutrition-related NCDs in later life which is supported by animal studies that undernutrition during gestation is associated with reduced life span and increased disease susceptibility at adulthood, and these findings could be explained by the thrifty gene hypothesis (de Rooij et al. 2014). Historical severe famines, the Dutch famine (1944–45) and the Chinese great famine (1959–61), have provided a unique opportunity to study the long-term impact of human maternal nutrition status during specific periods of gestation on the risk for nutrition-related NCDs at adulthood (Lumey et al. 2011).

1. *Long-term persisting impact on child's subsequent growth and development*. Food supply shortage, simple species of food aid with low quality would be difficulty to meet the nutrient requirements for infants and young children during famine (Young and Jaspars 1995). Because these groups for nutrient requirement are usually higher than the general populations, they are much more susceptible to nutritional deficiencies and such adverse effects on their growth and development may continue for a long period of time and will increase the risk suffered from NCDs at adulthood. The findings from Chen and Zhou's 1959 birth cohort showed that on average the individuals who did not experience Chinese great famine born in the year 1958 would otherwise have grown 3.03 cm taller in adulthood, worked longer hours, and earned more income (Chen and Zhou 2007); the data from Li and An's study from the China Health and Nutrition Survey indicated that children with both parents born in the Great Famine were

significantly shorter by 0.37 SD (1.89 cm for boys and 1.78 cm for girls) compared to children with parents who have not experienced the mass starvation (Li and An 2015). Therefore, intervention through CFSs will be a benefit for preventing or minimizing irreversible adverse impact of malnutrition and anemia on development of cognitive as well as growth development and this beneficial effect shall be lasting for a long time (Grantham-McGregor and Ani 2001).

2. *Dutch famine cohort studies*: Dutch famine located in the Western Netherland occurred from October 1944 until the surrender of the German Forces on 7 May 1945, and the period of most intense starvation was February to April 1945. Based on a cohort study in Wilhelmina Gasthuis in Amsterdam from the Dutch famine (1944–45), the findings of long-term effects of prenatal exposure to the famine on NCDs at adulthood are shown in Table 1 (Roseboom et al. 2000, 2006; Painter et al. 2006a, b; Portrait et al. 2011). The results showed that exposure to famine in early gestation increased the risk for coronary heart disease (CHD), atherogenic lipid profile (ALP), disturbed blood coagulation (DBC), stress responsiveness (SR), and serum glucose levels 2 h after a standard glucose load (SGL) (Roseboom et al. 2000, 2006); the subjects at ages of 11–14 years with exposure to severe undernutrition would have higher risk for developing diabetes mellitus (DM), and peripheral arterial diseases (PAD) at ages of 60–70 in women (Portrait et al. 2011); the women exposure to famine in utero would have more risk for a history of breast cancer than unexposed women (Painter et al. 2006a); and any famine exposure at least 10 week duration during gestation was associated with elevated systolic and diastolic blood and hypertension prevalence in middle age (Stein et al. 2006).
3. *China's great famine cohort studies*: China's great famine (1959–61) was one of the worst human catastrophes during the twentieth century and affected all regions of a vast and diverse country, which provides a unique cohort case for studying the long-term effects of exposure to famine during fetal and childhood period on NCDs at adulthood (Chen and Zhou 2007). In the past decades, the findings from extensive epidemiologic or cohort studies indicated that early-life conditions, such as nutrition status, influence later risk of nutrition-related NCDs such as metabolic syndrome (Wang et al. 2017; Zheng et al. 2012; Li et al. 2010) as shown in Table 2. Undernutrition in early life may participate in the origins and development of abdominal obesity (Huang et al. 2010; Liu et al. 2017), insulin resistance and type 2 diabetes (Liu et al. 2016, Wang et al. 2010a), fatty liver disease (Wang et al. 2010b), hypertension (Yu et al. 2017), and hyperlipidemia (Li et al. 2010). The present findings also suggest that exposure to famine in early life had sex-specific association with MS and the adverse effects of malnutrition might extend beyond the "first 1000 days and last 9 years" (Wang et al. 2017).

   In addition, some studies also showed that exposure to the Chinese famine (1959–61) in early life (poor nutrition status) was related to the other adult chronic diseases such as higher prevalence of anemia (Shi et al. 2013), organ function damage in liver and kidney (Li et al. 2014), higher level of proteinuria in women (Huang et al. 2014), increased risk of arthritis (Xu et al. 2017) and osteoporosis in post-menopausal women (Kin et al. 2007), and prevalence of osteoporosis during early life were significantly higher in males than in females

Table 1 Long-term effects of prenatal exposure to the famine on adult disease in later life based on studies from the Dutch famine (1944–45) from a cohort study in Wilhelmina Gasthuis in Amsterdam

Authors	Surveyed age	Aim/objective of the study	Methods	Results
Roseboom et al. (2006)	50–58 years	To study the effects of restricted prenatal nutrition during different periods of gestation on adult diseases in later life	Trace 2414 people born around the time of the Dutch famine	Exposure to famine in early gestation had more CHD[a], ALP[b], DBC[c], increased SR[d], and more obesity

(Chen et al. 2016), which would be related to severe malnutrition resulted from famine during gestation and early period.

4. *The effect of exposure of famine in early life on mental health at adulthood*: The substance disaster and/or famine might be temporary but the spirit disaster and/or famine might influence the affected-area victims' life for many years and even longer time, and the famine or disaster changed the people's moral world in varying degrees. Numerous results from animal models, epidemiological surveys, and some intervention trials have shown that exposures' nutritional deficiency during critical periods (fetal or early life) of development can result in structural and metabolic alterations that would have lasting influences on mental and physical well-being.

The majority of study on maternal prenatal exposure to famine and risk for mental illness such as schizophrenia at adulthood or adult offspring are mainly based on the "Dutch famine of 1944–45" or "the Chinese great famine of 1959–61." The related studies have been ongoing since the 1970s using birth cohort of Dutch famine and emerging in recent years using birth cohort of Chinese famine. For example, exposed famine group at the first trimester of gestation had twofold increase in the incidence of schizophrenia and the prevalence of clinical central nervous system anomalies compared with unexposed group during the Dutch Hunger Winter of 1944/1945 (Hulshoff Pol et al. 2000). Through the 1987 Chinese National Disability Sample Survey, the post-famine cohort (1963–1965) had a higher risk (OR = 1.32, 95% Cl = 1.03–1.69) of developing schizophrenia than the pre-famine (1955–58) or famine cohorts (1959–62) in the rural population, and there was virtually no difference in schizophrenia risk between the pre-famine and the famine cohorts

Table 2 Long-term effects of prenatal exposure to the famine on adult disease in later life based on studies from the Chinese great famine (1959–61)

Authors	Surveyed time	Aim/objective of the study	Methods	Results
Wang et al. (2017)	2014-SPECT-China[a]	To explore exposure to Chinese famine during fetal and childhood period was related to MS[b] in adulthood	6445 subjects from SPECT-China were divided into fetal-exposed (1959–62), childhood-exposed (1949–58), adolescence/young adult-exposed (1921–48), non-exposed (1963–74)	Exposure to famine in fetal- and childhood-exposed women had significantly higher prevalence of MS with OR 1.47 and 1.80 ($P < 0.05$), but not in men
Li et al. (2011)	2002-CNNHS[c]	To examine exposure to Chinese famine during fetal life and early childhood is related to the risks for MS and effect of later life environment on such association	7874 adults born between 1954 and 1964 from 2002 CNNHS were divided into non-exposed, fetal-exposed, early childhood, mid-childhood, or late childhood exposed groups	Adults exposed to this famine during fetal life or early childhood had significantly higher risk for MS compared with non-exposed subjects
Zheng et al. (2012)	2008 annual physical examination	To determine exposure to Chinese famine during fetal life and early childhood is related to a greater risk of MS in later life	5040 subjects were categorized by birthday into control (1963–64), fetal-exposed (1960–61), and postnatal-exposed (1957–58) groups	Women in fetal- and postnatal-exposed groups had higher prevalence and risk for MS than in control group ($P < 0.05$)
Wang et al. (2012)	Mar–Sep 2010	To assess impact of exposure to Chinese famine during fetal and infancy period on the risk for hypertension at adulthood	12,065 adults (46–53 years) born 1957–64 from a cross-sectional health survey in Nanhai and Zhongshan Municipalities of Guangdong province	Exposure to the famine during the first trimester, during infancy, or both increased the risk of hypertension at adulthood
Huang et al. (2010)	1993–1996	To assess the impact of famine exposure on height, BMI, and hypertension at –32 years of age	35,025 women born in 1957–63 from China–US CPNTD[d] were divided into groups born before 1957–58, during 1959–61(the famine), and after 1962–63	Postnatal exposure during 2–3 years of life reduced height and increased BMI and hypertension, whereas exposure during pregnancy and infancy reduced BMI

Table 2 (continued)

Authors	Surveyed time	Aim/objective of the study	Methods	Results
Li et al. (2010)	2002-CNNHS	Examine exposure to Chinese famine during fetal life and childhood with the risk for hyperglycemia and type 2 diabetes at adulthood	7874 rural adults born between 1954 and 1964 were from 2002 CNNH	Fetal exposure to the famine had higher risk of hyperglycemia at adulthood, and OR values were significantly different between groups from severe and less severe famine areas ($P = 0.001$)
Wang et al. (2016a)	Apr–Oct 2013	Investigate exposure to Chinese famine (1959–61) during fetal stage or childhood (0–9 years) is related to T2Dd[e] and hyperglycemia at adulthood	7801 retirees from Dongfeng-Tongji cohort were divided into late-, mid-, and early-childhood exposed, fetal exposed, and unexposed groups. 16.2% were exposed to Chinese famine and 71.7% were exposed to this famine during childhood	Exposure to the famine in childhood was related to increased risk for T2D in adult, particularly in women. Subjects experienced famine in middle childhood had a high hyperglycemia risk compared with unexposed group ($OR = 2.06$)
Wang et al. (2016b)	2014-SPECT-China	Explore the association between adult NAFLD[f] and fetal or childhood exposure to Chinese famine (1959–61)	5306 subjects from 2014 SPECT-China were divided into fetal-exposed (1959–62), childhood-exposed (1949–58), adolescence/young adult-exposed (1921–1948), and non-exposed (1963–74) groups	Fetal- and childhood-exposed women but not men had a higher prevalence of moderate-severe steatosis compared with non-expected group, which indicated that malnutrition in early life affected the development of adult NAFLD
Liu et al. (2017)	Qingdao, China in 2006	Evaluate the association between famine exposure during early life and obesity at adulthood	8185 subjects from cross-sectional surveys were divided by famine exposure into unexposed born in 1962–71, fetal/infant exposed born	Exposure to famine in early life was associated with increased risks of obesity and $obesity_{max}$[g] at adulthood. Compared with

(*continued*)

Table 2 (continued)

Authors	Surveyed time	Aim/objective of the study	Methods	Results
			in 1959–61, childhood exposed born in 1949–58, and adolescence exposed born in 1941–1948	unexposed group, OR values were 1.59, 1.42, and 1.86 for fetal/infant, childhood, and adolescence exposed, respectively
Wang et al. (2010b)	Chongqing, China in 2006–2008	Investigate an association between early nutritional status during the famine and the risk for overweight and obesity at adulthood	17,023 subjects from annual physical evaluation were categorized by birthday into childhood-exposed (1956–58), fetal-exposed (1959–61), and unexposed control (1962–64)	The groups of childhood and fetal exposed to famine had significantly higher body weight and BMI and lower height compared with unexposed control

(Song et al. 2009). However, in another large mental health epidemiology survey conducted between 2001 and 2005, which included 4972 subjects born between 1956 and 1963, the potential impact of exposure to famine in utero and during the early postnatal life on adult mental illness was estimated and evaluated by difference-in-difference models. Compared with women born in 1963, women born during the famine years (1959–61) had higher risk of mental illness (OR = 2.08; Cl = 1.23–6.39) (Huang et al. 2013). These findings support that exposure to nutritional deficiency during fetal life may be a risk factor for developing mental illness such as schizophrenia, which might be related to an increase in clinical brain abnormalities resulted from aberrant early brain development (Table 3).

However, there are several limitations on such cohort studies related to undernutrition effects of prenatal exposure to the famine on NCDs in later life. Underestimating famine exposure or fuzzy time during gestation and associated outcomes related to NCDs in later life; lack of information on exact food intake and experienced duration of the Dutch famine or Chinese famine so that it is impossible to use the size of the effects in such study to estimate the importance of maternal nutrition for public health in prevention of NCDs; and using famine as a natural experiment in itself do not guarantee correct statistical inference about the

Table 3 The effect of malnutrition in early life on adult mental health based on studies from the Chinese great famine (1959–61)

Authors	Surveyed time	Aim/objective of the study	Methods	Results
Clair et al. (2005)	Wuhu and its surrounding counties in Anhui Province 1971–2001	Determine whether those who endured Chinese great famine (1959–61) had a higher risk of schizophrenia at adulthood	All psychiatric case records for the years 1971–2001 were examined and divided into born before (1959), during (1959–61), or after the famine years (1962)	Prenatal exposure to famine increased risk of schizophrenia in later adulthood, adjusted risk for schizophrenia increased from 0.84% in 1959 to 2.15% in 1960 and 1.81% in 1961
Xu et al. (2009)	Liuzhou and its surrounding counties in Guangxi AR[a] 1971–2001.	Test prenatal malnutrition and adult schizophrenia in a second Chinese population and also determine whether risk differed between urban and rural areas	All psychiatric case records in Liuzhou psychiatric hospital for the years 1971–2001 were examined; exposed birth years 1960–61, compared groups 1956–58 and 1963–65	Mortality-adjusted RR for schizophrenia was 1.5 for 1960 and 2.05 for 1961 compared with the other years and the absolute rate of schizophrenia was higher in rural than in urban
Song et al. (2009)	The 1987 CNDSS[b]	Test the hypothesis that prenatal exposure to famine increases schizophrenia risk at adulthood	Recruit 1,579,316 residents from all 29 provincial level administrative units in China including 3907 with a mental disorder and 2574 with schizophrenia; 294,365 subjects were born between 1955 and 1965, and 494 with schizophrenia	Urban population conceived and born during the famine had higher risk for schizophrenia at early adulthood, compared with the pre-famine and post-famine cohorts, and rural population had the highest risk
Huang et al. (2013)	ZJ, SD, QH, and GS[c] provinces 2001–2005	Investigate the potential impact of famine exposure in utero and during early postnatal life on mental illness at adulthood	4972 subjects born between 1956 and 1963, and divided into famine exposure in utero and early postnatal life from a series of epidemiological surveys on mental disorders of four provinces	Long-term consequences of early life famine exposure include both the selection of the hardiest and enduring deleterious effects of famine on those who survive in the risk for mental illness at adulthood

Fig. 2 What did they dream or think after natural disaster?

long-term health impacts of prenatal malnutrition when other analytical challenges remain unresolved (Xu et al. 2016).

In summary, during famine, the important task for healing the spiritual wounds and stabilizing the people's mood in the affected areas was the contact and communication to the outside and especially to the local and/or central government, which is important to include early and comprehensive interventions to reverse not only medical conditions resulting from malnutrition but also cognitive and behavioral deficits arising from famine. Young children what are their dreams or thinking about tomorrow's life should be considered for us during famine as the situation we can see after Wenchuan earthquake in Fig. 2. What can we do for them would be important priority task to be considered and solved for us.

Policies and Protocols

In this chapter we have described the short-term and long-term impact of exposure to famine during, prenatal or postnatal gestation on human health status. In some cases of short-term effect due to famine, malnutrition such as protein-energy and anemia, especially some diseases resulted from micronutrient deficiencies became more serious public health priority to be solved because this period was considered as a unique window of opportunity (the first 1000 days of life) to decide children's healthier and more prosperous future; long-term impact will focus on future health status and susceptibility to nutrition-related NCDs at adulthood. The findings based on epidemiological investigation, early intervention, and cohort studies on the effect of exposure to famine to human health have shown very clear implications for making public health policy and improving national nutritional status for the entire population, and investing the improvement of children's nutrition status in the early years of life has reached a consensus at international level and has been considered as one of the least investments and the biggest benefit for a country.

Dictionary of Terms

- **Famine** – When a country or region has "more than half of the population directly or indirectly facing death caused by hunger or dying situation" can be regarded as "famine" or when a country or region has doubles of the mortality rate due to severe food shortage and more than 20% of children suffered from malnutrition can be generally defined as "famine."
- **Dutch famine** – Dutch famine, located in the Western Netherland, occurred from October 1944 until the surrender of the German Forces on 7 May 1945, and the period of most intense starvation was February to April 1945.
- **China's great famine** – China's great famine (1959–61) was one of the worst human catastrophes during the twentieth century and affected all regions of a vast and diverse country.
- **Cohort study of exposure to famine** – The studies related to the effect of exposure to malnutrition during, prenatal or postnatal gestation due to famine were to observe the long-term effects on NCDs at adulthood.
- **Metabolic syndrome (MS)** – MS can be diagnosed with three or more of the following conditions based on the Chinese Diabetes Society: BMI $\geq$25.0 kg/m^2, serum triglyceride $\geq$1.70 mmol/L or drug treatment for elevated triglyceride, serum high-density lipoprotein cholesterol $<$0.90 mmol/L in men or $<$1.00 mmol/L in women or drug treatment for decreased high-density lipoprotein cholesterol, systolic blood pressure $\geq$90 mmHg or drug treatment for hypertension, fasting plasma glucose $\geq$6.1 mmol/L or drug treatment for diabetes.
- **Fetal origins hypothesis** – This hypothesis postulated that nutritional deprivations during the fetal period or early life could lead to higher prevalence of nutrition-related NCDs or increase the susceptibility to NCDs at adulthood.

Summary Points

- This chapter focuses on short-term and long-term effect of exposure to famine during early life on human health status and susceptibility to nutrition-related NCDs at adulthood.
- The short-term impacts include protein-energy malnutrition, iron-deficiency and anemia, vitamin A deficiency and decrease in resistance to infectious diseases, vitamin D deficiency and rickets, and other multi-micronutrient deficiencies.
- Malnutrition during early life will lead to susceptibility to preventable infectious diseases such as diarrhea and pneumonia and has an indirect association with the leading causes of death in young children.
- The long-term effects include the impact on child's subsequent growth and development, and the susceptibility to NCDs and mental health at adulthood.
- During and/or after famine, timely nutrition intervention to elder infants and young children can effectively improve their nutritional status and decrease the mortality resulted from malnutrition and infectious diseases.

- Dutch famine occurred in the Western Netherland from October 1944 until the surrender of the German Forces on 7 May 1945, and the period of most intense starvation was February to April 1945d.
- Dutch famine cohort studies intend to evaluate the relationship of exposure to famine during fetal and childhood period and the risk for NCDs in adulthood.
- China's great famine was one of the worst human catastrophes during the twentieth century and affected all regions of a vast and diverse country (1959–61).
- China's great famine cohort studies indicate that early-life conditions, such as nutrition status, influence later risk of nutrition-related NCDs such as metabolic syndrome.
- Exposure to famine in early life has impact on mental health at adulthood based on Dutch famine and China's great famine cohorts.

Abstract

Stunting or linear growth deficit is the most prevalent form of undernutrition globally and is internationally recognized as an important public-health indicator for monitoring health in populations. In 2015, 23.2%, or just under one in four children under the age of 5 worldwide had stunted growth and the number of children affected fell from 255 million to 156 million. Stunting has long-term effects on individuals and societies, including diminished cognitive and physical development, reduced productive capacity, poor health, and an increased risk of degenerative diseases such as diabetes. Metabolic syndrome is a multicomponent risk factor for cardiovascular disease and type 2 diabetes mellitus that reflects the clustering of individual cardiometabolic risk factors related to abdominal obesity and insulin resistance. Estimates have indicated that nearly one quarter of the world's adult population suffers from metabolic syndrome. The aim of this study was to investigate the association between childhood stunting and metabolic syndrome components in adulthood. A systematic review was undertaken to address this question. Eight relevant articles were located. In the majority of the studies, the metabolic syndrome components were measured in adolescence or early adulthood. An outcome measured in later adulthood was observed in only one study, and earlier onset of metabolic risks was observed in men who had a timing of early peak height velocity. The results in this literature indicated that the consequences of stunting were complex and likely to depend on local environment, diet, and developmental timing. On concluding this review, the evidence for the association between early childhood stunting and metabolic syndrome was unclear.

Introduction

Growth Faltering in Childhood: Definition of Stunting

Stunting or linear growth deficit is the most prevalent form of undernutrition all over the world and is internationally recognized as an important public-health indicator for monitoring health in populations. Moreover, children who suffer from growth retardation tend to be at higher risk of suffering illness and death. The percentage of children with low height-for-age reflects the cumulative effects of undernutrition and infections since birth, and even before birth. This measure, therefore, should be interpreted as an indication of poor environmental conditions and/or long-term restriction of a child's growth potential. Linear growth is the best overall indicator of children's well-being and stunting, measured by the child's length/height for the same age and sex, is defined as being minus 2 standard deviations below the value of the World Health Organization (WHO) Child Growth Standards median (WHO 2014a). Nearly half of all deaths in children under 5 years of age are attributable to undernutrition. This translates into the unnecessary loss of about three million young lives a year. Undernutrition puts children at greater risk of dying from common infections, increases the frequency and severity of such infections, and contributes to delayed recovery. In addition, the interaction between undernutrition and infection can create a potentially lethal cycle of worsening illness and deteriorating nutritional status. Growth failure begins in utero and continues for at least the first 2 years of post-natal life; poor nutrition in the first 1,000 days of a child's life can also lead to irreversible stunted growth, associated with impaired cognitive ability and reduced school and work performance (Black et al. 2013; UNICEF/WHO/Word Bank 2016). Growth failure in early life has profound adverse consequences over the life course on human, social, and economic capital (Hoddinott et al. 2013).

Stunting is one of the global nutrition targets for 2025 adopted by the World Health Assembly, in 2012 with the aim of reducing linear growth deficit by 40% by 2025 (WHO 2014a). According to De Onis and Branca (2016), this increased international attention has resulted from the greater significance of stunting as a major public health problem for five reasons: it affects large numbers of children globally; has severe short-term and long-term health and functional consequences; there is consensus regarding its definition and a standard to define normal human growth that is applicable everywhere; there is agreement on a critical time-frame from conception through the first 2 years of life – when linear

growth is most sensitive to environmentally modifiable factors; and it is a cross-cutting problem calling for a multisectoral response. Stunting results from a complex interaction of household, environmental, socioeconomic, and cultural influences that are described in the World Health Organization Conceptual Framework on Childhood Stunting (Stewart et al. 2013).

Worldwide Patterns and Recent Trends

In September 2016, United Nations Children's Fund (UNICEF), WHO, and World Bank Group released the 2016 edition of the joint child malnutrition estimates for the 1990–2015 period, representing the most recent global and regional figures. In 2015, 23.2%, or just under one in four children under the age of 5 worldwide had stunted growth. Having said that, overall trends are positive. Between 1990 and 2015, stunting prevalence globally declined from 39.6% to 23.2%, and the number of children affected fell from 255 million to 156 million. In developing countries this percentage was 25.4%. In 2025, the estimate of stunting in children under 5 years of age around the world is 19.1%; whereas, in children from low and middle income countries it is 20.8%. Africa has made only limited progress on stunting since 2000 (−17%) compared with other regions such as Asia (−36%), Latin America and Caribbean (−39%). Western Africa accounts for half of the increase in stunting in Africa. There were 4 million more stunted children in Western Africa in 2015 than in 2000. Progress on stunting within Asia has been uneven since 2000; rates in Eastern Asia have dropped by more than two thirds since 2000 (−69%), compared with Southern Asia, where stunting declined by less than one third during the same period (−30%). More data are needed to generate reliable estimates for Oceania. Based on available data, stunting rates in Oceania have been stagnant for the past 15 years, but confidence intervals are very large. Progress in Latin America and Caribbean is aligned with global goals. Improvements in malnutrition in the region are encouraging. The graphs show trends (1990–2025) in child malnutrition indicators for stunting global and by United Regions (UNICEF/WHO/Word Bank 2016) (Fig. 1).

The percentage of stunted children under 5 years of age, according to WHO Regions in 2015 is shown in Fig. 2. Three regions have stunting rates exceeding 25%.

In almost all countries that have available data, stunting rates are higher among boys than girls. While analyses to determine underlying causes for this phenomenon are underway, an initial review of the literature suggested that the higher risk for preterm birth among boys (which is inextricably linked to lower birth weight) is a potential reason for this sex-based disparity in stunting (UNICEF 2014).

Of all stunted children, 32.6% live in lower-middle income countries and 37.3% live in low-income countries. The other 7.6% of all stunted children live in upper-, middle- or high-income countries, with only 2.6% living in the latter (high-income) group. Percentage of stunted children under the age of 5, by country and income classification in the period from 2000 to 2015 is shown in Fig. 3 (UNICEF/WHO/Word Bank 2016).

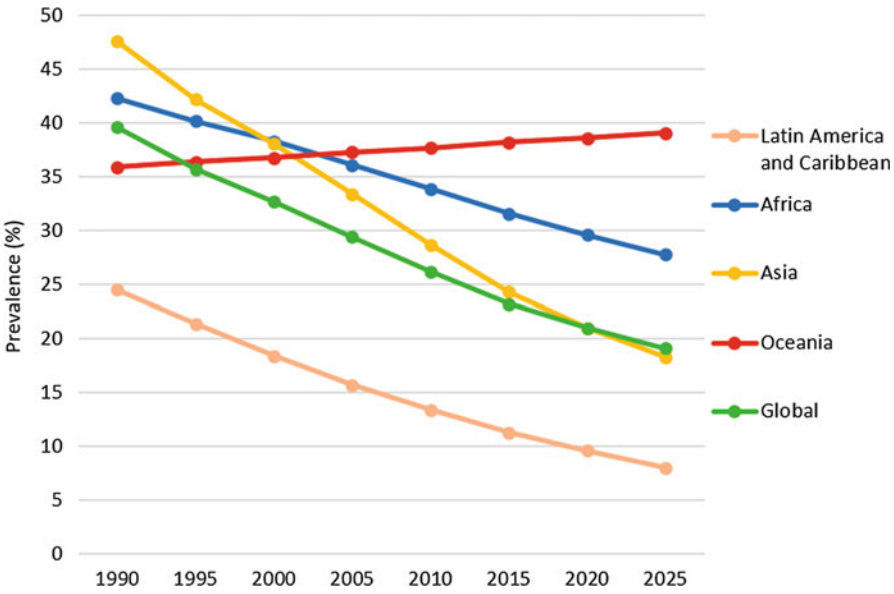

Fig. 1 Percentage of stunted children under 5 years of age, global and by United Regions, 1990–2025 (Source: United Nations Children's Fund, World Health Organization, World Bank Group joint malnutrition estimates, 2016 edition. Note: Oceania excluding Australia and New Zealand)

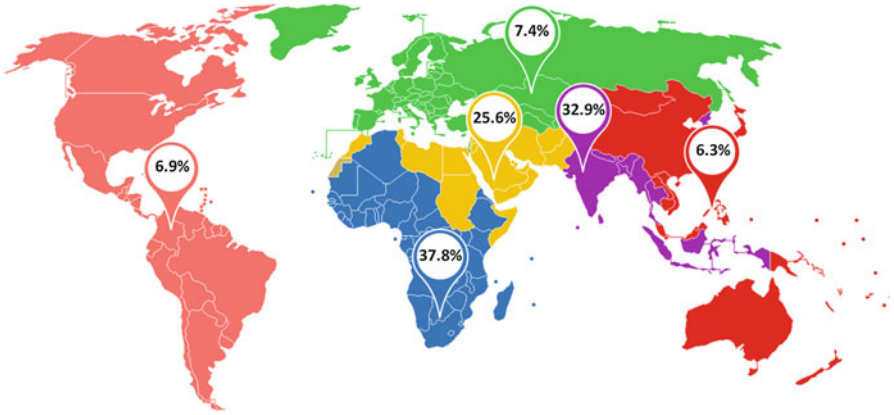

Fig. 2 Percentage of stunted children under 5 years of age, by World Health Organization Regions, 2015 (Source: United Nations Children's Fund, World Health Organization, World Bank Group joint malnutrition estimates, 2016 edition)

Consequences of Stunted Growth

Stunting is associated with increased morbidity and mortality from infections, in particular pneumonia and diarrhoea (Black et al. 2013; Prendergast and Humphrey

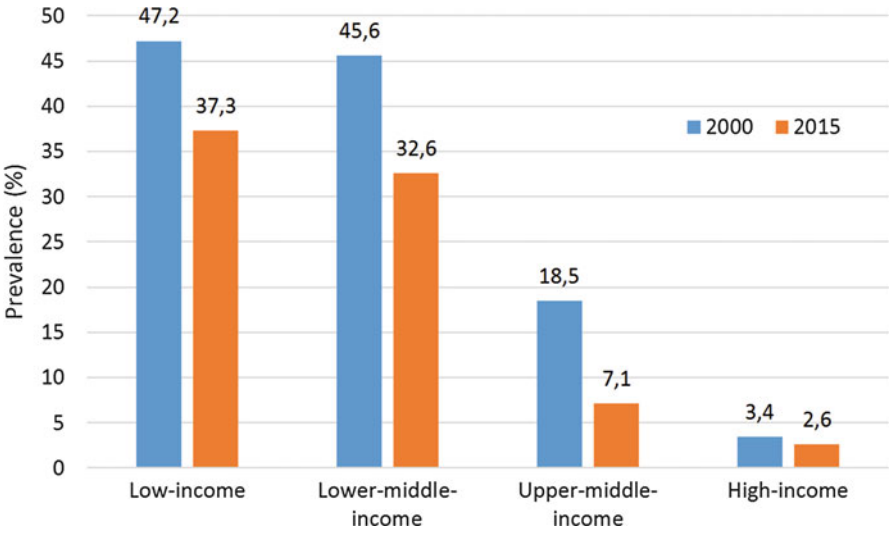

Fig. 3 Prevalence of stunted children under 5 years of age, by country income classification, 2000 and 2015 (Source: United Nations Children's Fund, World Health Organization, World Bank Group joint malnutrition estimates, 2016 edition)

2014), and it serves as a marker for multiple pathological disorders such as loss of physical growth potential, reduced neurodevelopmental and cognitive function, and an elevated risk of cardiovascular disease (CD) in adulthood (Prendergast and Humphrey 2014; De Onis and Branca 2016).

Definition of Metabolic Syndrome

Metabolic syndrome (MetS) is a multicomponent risk factor for CD and type 2 diabetes mellitus (T2DM) that reflects the clustering of individual cardiometabolic risk factors related to abdominal obesity (AO) and insulin resistance (IR). The defining components of metabolic syndrome that cluster together are AO, IR, high blood pressure (HBP), and dyslipidemia (Kaur 2014, O'Neil and O'Driscoll 2015; Benjamin et al. 2017).

Reports of clustering of metabolic risk factors date back to the early 1920s (Sarafidis, Nilsson 2006). However in 1988, Reaven observed that several risk factors (dyslipidemia, hypertension, hyperglycemia) tended to occur together; this set was named syndrome X (Reaven 1988).

Several groups have attempted to develop diagnostic criteria for the diagnosis of the MetS. The first attempt with the name MetS like diagnostic entity with defined criteria was made by a World Health Organization Diabetes Group (WHO) in 1998 (Alberti and Zimmet 1998); subsequently, the European Group for the Study of Insulin Resistance (EGIR) countered with a modification of the WHO definition in

1999 (Balkau and Charles 1999). In 2001, the National Cholesterol Education Program Adult Treatment Panel (NCEP: ATPIII) released its definition (Cleeman 2001). In 2003 the American Association of Clinical Endocrinologists (AACE) offered its views (Einhorn 2003) and in 2005 the International Diabetes Federation (IDF) proposed a new definition of the metabolic syndrome a single unifying definition (International Diabetes Federation 2006; O'Neil and O'Driscoll 2015). Although several different clinical definitions for MetS have been proposed, in 2009 the IDF; National Heart, Lung, and Blood Institute (NHLBI); American Heart Association (AHA); and others proposed a harmonized definition for MetS (Alberti et al. 2009) (Table 1).

This definition stated that obesity and IR were not pre-requisites for MetS but that three of the five components would suffice for a diagnosis of MetS, with the thresholds for measuring waist circumference requiring ethnic and nation specificity (Table 2).

Prevalence

The existence of varying definitions, which differ in small defining values, has impeded determination of the true prevalence of MetS; however, it has generally been accepted by all groups that there was increasing prevalence of MetS (O'Neil and O'Driscoll 2015). The IDF estimated that nearly one quarter of the world's adult population was suffering from MetS (International Diabetes Federation 2015). Data on the prevalence of MetS from several regions have been compared, defined by NCEP: ATPIII criteria (National Cholesterol Education Program 2002) (Table 3).

Components of Metabolic Syndrome

Abdominal Obesity

The link between obesity, poor health outcomes, and all-cause mortality is well established. Obesity increases the likelihood of diabetes, HBP, CD, stroke, certain cancers, obstructive sleep apnea, and osteoarthritis. There has been increasing obesity in all countries. In 2014, 39% of adults aged 18 years and older (38% of men and 40% of women) were overweight. The worldwide prevalence of obesity nearly doubled between 1980 and 2014. In 2014, 11% of men and 15% of women worldwide were obese. Thus, more than half a billion adults worldwide are classed as obese (WHO 2014b).

From the epidemiological point of view, the growing epidemic of obesity is connected with the increase in CD and MetS. Obesity can be defined as an increase in percentage of total body fat, in relation to a standard, which is reflected at cellular level by an increase in the number and/or size of the adipocytes. Much more importance has been given to the distribution of adipose tissue than to its volume. There is good evidence that associates AO with cardiovascular and metabolic risk,

Table 1 Criteria as set out by the different associations for MetS definition

Criteria	WHO (1998)	EGIR (1999)	NCEP:ATPIII (2001)	AACE (2003)	IDF (2005)	IDF + AHA/ NHLBI (2009)
Insulin resistance	High insulin level + two of the following:	Plasma insulin >75th percentile + two of the following:	Any three of the following:	Fasting plasma glucose 110–125 mg/dL	≥ 110 mg/dL	≥ 110 mg/dL
Abdominal obobesity	Waist to hip ratio >0.90 (male) and > 0.85 (female) Body mass index >30 kg/m^2	Waist circumference > 0.94 (male) and >0.80 (female)	Waist circumference >102 cm (male) and >88 cm (female)		Waist circumference ≥94 cm (Europid male) and ≥ 80 cm (Europid female), ethnicity specific values for other groups	Population and country - specific definitions
TG	≥150 mg/dL	≥150 mg/dL	≥150 mg/dL	≥150 mg/dL	≥150 mg/dL	≥150 mg/dL
TG HDL-C	<35 mg/dL (male) <39 mg/dL (female)	<39 mg/dL (male and female)	<40 mg/dL (male) <50 mg/dL (female)	<40 mg/dL (male) <50 mg/dL (female)	<40 mg/dL (male) <50 mg/dL (female)	<40 mg/dL (male) <50 mg/dL (female)
Blood pressure	≥140/90 mmHg	≥140/90 mmHg or hypertensive medication	≥130/85 mmHg	≥130/ 85 mmHg	≥130/85 mmHg	≥130/ 85 mmHg
Other	Microalbuminuria or albumin: creatinine ratio ≥30 mg/g	Fasting glucose ≥6.1 mmol/L	Fasting glucose ≥110 mg/dL

South Asia (Aryal and Wasti 2016)	2016	26.1
United States (Liu et al. 2014)	2014	26.7

because of its high relationship with perivisceral fat. Intra-abdominal or visceral fat is a risk factor irrespective of IR, intolerance to glucose, dyslipidemia, and HBP, all of which are components of the MetS (Carr et al. 2004).

Several studies have shown that intra-abdominal fat, measured by the abdominal circumference was independently associated with each one of the criteria of the MetS and suggest that it may play a central role in the pathogenesis of MetS (International Diabetes Federation 2006; Pineda 2008).

Insulin Resistance

IR is a pathophysiological phenomenon in which the biological action of insulin is altered in the different tissues of the body and causes compensatory hyperinsulinemia. When the body cannot maintain this response, hyperinsulinemia – often associated with T2DM – develops; but in the opposite case, if hyperinsulinemia is sustained, a series of changes (mainly of the metabolic type)

occur, which increase the risk of CD. Most people with MetS show evidence of IR; its complications are major causes of death in most countries (Pineda 2008). People with T2DM are at higher risk of developing a number of disabling and life-threatening health problems than people without T2DM; such as serious diseases affecting the heart and blood vessels, eyes, kidneys, and nerves, in addition to increased risk of developing infections. In 2015, the global prevalence of diabetes was 8.8% in individuals between 20 the 79 years of age; the number of people with diabetes was 415 million (International Diabetes Federation 2015).

Dyslipidemia

In the MetS, dyslipidemia is characterized by the presence of low levels of HDL-cholesterol (HDL-C) and elevated levels of triglycerides (TG).

Dyslipidemia is another important feature that can be included in all the criteria mentioned above. Dyslipidemia associated with MetS is considered highly atherogenic. Low HDL-C and elevated TG are predictors of cardiovascular risk factors in patients with MetS. The combination of low HDL-C and elevated basal glycemia has been shown to be a predictor of coronary disease (International Diabetes Federation 2006; Pineda 2008).

Hypertension

Raised blood pressure is one of the leading risk factors for global mortality and is estimated to have caused 9.4 million deaths in 2010. A reduction in systolic blood pressure of 10 mmHg has been associated with a 22% reduction in coronary heart disease, 41% reduction in stroke in randomized trials, and a 41–46% reduction in cardiometabolic mortality in epidemiological studies. The global prevalence of raised blood pressure (defined as systolic and/or diastolic blood pressure $\geq$140/90 mmHg) in adults aged 18 years and over was around 22% in 2014. The proportion of the world's population with HBP or uncontrolled hypertension fell modestly between 1980 and 2010. However, because of population growth and ageing, the number of people with uncontrolled hypertension has risen over the years (WHO 2014b).

A meta-analysis of 242 studies (n = 1.5 million adults) reported that 32.3% (95% CI = 29.4–35.3%) of adults had hypertension, with the highest prevalence in the Latin America and Caribbean region. Hypertension prevalence estimates were highest across upper-middle-income countries (37.8%, 95% CI = 35.0–40.6%) and lowest across low-income countries (23.1%, 95% CI = 20.1–26.2%) (Sarki et al. 2015; Benjamin et al. 2017).

Metabolic Syndrome Characteristics Following Early Childhood Stunting

The systematic literature review included searches for articles in the PubMed, MEDLINE, LILACS, and SciELO databases. Various combinations using multiple search terms of Health Sciences Descriptors were used ("metabolic syndrome"; "stunting or height for age deficit"; "cohort studies") and a search was conducted for association between "metabolic syndrome and stunting." Articles published until February 2017 were considered. The reference lists were compared and the relevant articles selected by title and abstract. All the apparently relevant articles were obtained and reviewed by the authors. Of the articles read, 98 were selected for reference in the review and 65 were published in the last ten years. Of these, 27 titles were selected and eight abstracts were chosen for reading of the complete manuscript. Of all eight articles read, four were chosen for this review. In addition, four studies were identified in the references of the articles. These eight studies are presented in the following sections.

In a birth cohort study conducted in Southern Brazil (Grillo et al. 2016), the association between stunting at the age of 2 years and MetS components in early adulthood was investigated. Individuals with stunting showed significantly higher prevalence of altered HDL-C; however, when the analyses were adjusted for socioeconomic variables and maternal characteristics, this association vanished.

In another study (Sun et al. 2014) with a sample that consisted of 431 adults (213 males and 218 females) from the Fels Longitudinal Study, the subjects' childhood height data had been recorded to capture the age at peak height velocity, as well as sufficient serial MetS risk-factor data that had been collected later in life. The peak height velocity was around 13.5 years for boys and 11.5 for girls. Females who had early peak height velocity tended to develop more AO than girls who had a late peak. Boys who had early peak height velocity tended to have a higher risk for the MetS, with elevated levels of fasting plasma glucose, elevated TG, and low HDL-C.

A retrospective cohort study of school-aged children was conducted in Chile and the national individual identification number was used to link information gathered at school with perinatal data collected by the civil registry (Mardones et al. 2014). The lowest and highest categories of birth length were associated with a twofold increase in the risk of HBP and birth length categories below 50 centimeters seemed to increase the risk for IR when adjusting for fat mass, sex, and Tanner stage among Chilean school-aged children.

A birth cohort study from India investigated the linear growth and fat and lean tissue gain during discrete age periods from birth to adolescence, and the findings showed that linear growth (up to age 2 years) was unrelated to cardiometabolic risk factors (Krishnaveni et al. 2015).

The Avon Longitudinal Study of Parents and Children (ALSPAC) was established in 1990 when pregnant women, expected to deliver between April

1991 and December 1992, were enrolled in a cohort study. Around 14,000 live born children were followed up with questionnaires, and from the age of 7 years, at regular clinical visits to obtain data relative to anthropometric, behavioral, cardiovascular factors, and metabolic phenotypes. The conditional height growth was positively associated with systolic blood pressure in the 3230 boys and 3346 girls from ALSPAC, at 10 years of age (Jones et al. 2012).

In another birth cohort study from Southern Brazil (Menezes et al. 2012) the independent effects were investigated relative to weight and length/height gains in different periods during childhood on blood pressure and on measures of obesity and central fat distribution in adolescence. The findings showed that length/height gain increased systolic blood pressure at 14–15 year of age, but it was not associated when adjusting for body mass index in adolescence, suggesting that the increase in length/height without excessive weight gain was beneficial for the development of body composition.

Peak height velocity in infancy and metabolic outcomes at the age of 31 years was also studied in a population-based birth-cohort study of 3,778 Finns (1966–1998). Growth data were collected from communal health clinics and eight height measurements were obtained per person, on an average, from birth to age 2 years. A peak height velocity that was higher by 8 cm/year was positively associated with systolic and diastolic blood pressure, waist circumference, and a nonsignificant 13% higher risk of MetS ($P = 0.08$) that completely disappeared when adjusting for body mass index ($P = 0.32$). The positive associations were attenuated after adjusting for birth weight and body mass index at the age of 31 years but remained significant (Tzoulaki et al. 2010).

The association between linear growth and cardiometabolic risk factors was also investigated in the five prospective birth cohort studies included in the Consortium for Health Orientated Research in Transitional Societies – COHORTS (Adair et al. 2013). Faster linear growth was strongly associated with a reduced risk of short adult stature (age 2 years: 0.23, 95% CI = 0.20–0.52; mid-childhood: 0.39, 95% CI = 0.36–0.43) and elevated blood pressure (age 2 years: 1.12, 95% CI = 1.06–1.19; mid-childhood: 1.07, 95% CI = 1.01–1.13). Linear growth and relative weight gain were not associated with dysglycemia.

The relationship of birthweight (Würtz et al. 2016) or preschool weight (Graversen et al. 2014) with metabolic risk has been shown in birth cohort studies. However, less is known about the effect of height on MetS. In our review the effects of length/height measured during childhood occurring later in life were mainly assessed by means of blood pressure, and the results showed that there was a positive association between height gain and blood pressure that generally disappeared after adjusting for weight or body mass index. The effect on MetS was investigated in only one study (Tzoulaki et al. 2010). It is important to highlight that in the majority of studies, the components of metabolic syndrome were measured in adolescence or early adulthood. Outcome measured in

later adulthood was observed in only one study (Sun et al. 2014) and earlier onset of metabolic risks was observed in men who had an early timing of peak height velocity. On conclusion of this review, the evidence for the association between early childhood stunting and MetS was unclear.

Protocols

Stunting

In this chapter we have described that stunting or linear growth is the most prevalent form of undernutrition globally and is internationally recognized as an important public-health indicator for monitoring health in populations. Stunting often begins in utero and continues for at least the first 2 years of post-natal life. Stunting is identified by assessing a child's length or height (recumbent length for children less than 2 years old and standing height for children aged 2 years or older) and interpreting the measurements by comparing them with an acceptable set of standard values. There is international agreement that children are stunted if their length/height is minus 2 standard deviations below the values of the World Health Organization Child Growth Standards median for the same age and sex. The use of cut-off points is required to determine the limits of normality. Children are considered severely stunted if their length/height is minus 3 standard deviations below the values of the World Health Organization Child Growth Standards median for the same age and sex.

Metabolic Syndrome

The metabolic syndrome is a complex of interrelated risk factors for cardiovascular disease and diabetes. Although several different clinical definitions have been proposed for metabolic syndrome, according to the new harmonized metabolic syndrome definition, it is diagnosed when any three of the following five risk factors are present:

- Fasting plasma glucose: $\geq$100 mg/dL or undergoing drug treatment for elevated glucose
- HDL-cholesterol: <40 mg/dL in males or <50 mg/dL in females or undergoing drug treatment for reduced HDL-cholesterol
- Triglycerides: $\geq$150 mg/dL or undergoing drug treatment for elevated triglycerides
- Waist circumference: Ethnicity and country-specific thresholds can be used for diagnosis in the groups
- Blood pressure: $\geq$130 mm Hg systolic or $\geq$85 mm Hg diastolic or undergoing drug treatment for hypertension, or antihypertensive drug treatment in a patient with a history of hypertension

Dictionary of Terms

- **Stunting** – Length/height is minus 2 standard deviations below the values of the World Health Organization Child Growth Standards median for the same age and sex.
- **Metabolic syndrome** – Three abnormal findings out of five would qualify a person for the metabolic syndrome: elevated waist circumference, elevated triglycerides, reduced high-density lipoprotein cholesterol, elevated blood pressure, and elevated fasting glucose.
- **Abdominal obesity** – Excessive abdominal fat around the stomach and abdomen that has built up to the extent that it is likely to have a negative impact on health.
- **Insulin resistance** – A decreased sensitivity to the action of insulin. Conditions in which the increased amount of insulin are inadequate to induce normal insulin responses in insulin-sensitive tissues (liver, skeletal muscles, adipose tissues).
- **Dyslipidemia** – It is an abnormal amount of lipids (example, triglycerides, cholesterol, and/or fat phospholipids) in the blood.
- **Hypertension** – This, also known as high blood pressure, is a long term medical condition in which the blood pressure in the arteries is persistently elevated.

Summary Points

- Stunting or linear growth deficit is the most prevalent form of undernutrition globally and is internationally recognized as an important public-health indicator for monitoring health in populations.
- Factors that contribute to stunted growth and development include poor maternal health and nutrition, and inadequate infant and young child feeding practices and infection.
- The 1,000 days between a woman's pregnancy and her child's 2nd birthday offer a unique window of opportunity to build healthier and more prosperous futures.
- Growth failure in early life has profound adverse consequences over the life course on human, social, and economic capital.
- In 2015, 23.2%, or just under one in four children under the age of 5 worldwide had stunted growth, globally affecting 156 million children. In developing countries this percentage was 25.4%.
- Percentage of stunted children under the age of 5, by World Health Organization Regions, was found in Africa: 37.8%, South East Asia: 32.9%, Eastern Mediterranean: 25.6%, Europe: 7.4%, Americas: 6.9%, and Western Pacific: 6.3%.
- Metabolic syndrome is a multicomponent risk factor for cardiovascular disease and type 2 diabetes mellitus that reflects the clustering of individual cardiometabolic risk factors related to abdominal obesity and insulin resistance.
- The prevalence of metabolic syndrome in the different geographical regions ranged from 11.9% to 78.2%.

- For the systematic literature review, 98 articles were selected for reference in the review and 65 were published in the last ten years. Of these, 27 titles were selected and eight abstracts were chosen for complete reading of the manuscript.
- In the majority of the studies, the components of metabolic syndrome were measured in adolescence or early adulthood. Outcome measured in later adulthood was observed in only one study, and earlier onset of metabolic risks was observed in men who had an early timing of peak height velocity.
- The results in this literature indicated that the consequences of stunting were complex and likely to depend on local environment, diet, and developmental timing.
- On conclusion of this review, the evidence for the association between early childhood stunting and metabolic syndrome was unclear.

Abstract

Lebanon is a small country located in the Middle East region which is undergoing rapid demographic transition. Among Arabic countries Lebanon has the fastest growing elderly population, and by the year 2025, older adults above 65 years are expected to represent more than 10% of the population. Nutrition is a key factor during the aging process and may help to prevent age-related diseases. However with increase in age, malnutrition is more frequent and might become an important health problem in the future. The prevalence of malnutrition among elderly people is particularly high in hospital environment and nursing homes compared to community settings, where mainly frail and dependent elderly are affected. Numerous factors are contributing to malnutrition such as age-related changes, social, physical, and psychological factors which are mostly acting in combination. The danger of malnutrition is related to its negative health consequences with increased risk of morbidity, functional decline, and decreased quality of life. Early detection and nutritional intervention may allow preventing negative health outcomes and increasing chance for healthy aging.

This review presents the results of several surveys mainly carried out in the community and institutional settings. The principle goal of these studies was to estimate the prevalence of malnutrition and identify factors associated with malnutrition. The importance of increased awareness and early detection of malnutrition is highlighted.

Introduction

Lebanon is a small country (area 10,000 km^2 or 4000 square miles) which lies on the Eastern shores of the Mediterranean (Fig. 1). Bordered by Syria to the north and east and Israel to the south, the country is composed of a narrow western coastline, along which runs a central mountainous chain known as Mount-Lebanon, which culminates at 2500 m (8200 ft.). To the east of Mount-Lebanon lies the fertile inner valley of the Bekaa, separated from Syria by another chain, the Anti-Lebanon which culminates at Mount Hermon (2800 m or 9200 ft.).

Historically, the coastline had been settled since the Neolithic (6000 BC), and in the last millennium BC had witnessed the flourishing of the Phoenician civilization, in maritime trading cities such as Tyr, Sidon, and Byblos. For centuries, the coastline and the inner valley were obligated paths for invaders including the Egyptians, Assyrians, Babylonians, Persians, and Greeks. Less than a century after Alexander the Great's invasion of Phoenicia (circa 330 BC), the country became part

Fig. 1 Map of Lebanon (Central Intelligence Agency, the World fact Book. Accessed https://www.cia.gov/library/publications/resources/the-world-factbook/geos/le.html). The map presents Lebanon and its principal cities which are mainly located in the coastal area. Lebanon is bordered by Syria in the North and East and Israel in the South

of the Roman (later Byzantine) Empire and eventually adopted Christianity. The Arab conquest in the seventh century AD brought Islam to Lebanon. The two monotheistic religions have coexisted and interacted in ways which still contribute to the pluralistic cultural specificity of Lebanon today. The Ottomans who occupied the country in 1514 established a semiautonomous feudal system headed by the "Emir of Mount Lebanon," which would become the nucleus of the nation of Lebanon. After the fall of the Ottoman Empire (1918), Lebanon and neighboring Syria were placed by the Society of Nations under French Mandate, while the other Arab lands of the Levant (Iraq, Transjordan and Palestine) were placed under English Mandate.

Lebanon became independent in 1943, as a parliamentarian democratic republic, and joined the League of Arab States. Since then, Lebanon had to withstand a series of major crises: the influx of Palestinian refugees displaced by the creation of the state of Israel in 1948, a protracted civil war (1975–1991), during which Israel occupied 10% of the country (1978–2000) and Syria all the rest (1977–2005). Hardly had national sovereignty been restored that a new refugee crises started, now with Syrians escaping civil war in their country starting 2011. By 2014, refugees were believed to compose at least 30% of the population of Lebanon, estimated at 5.5 million (Ministry of Public Health [MOPH] 2014).

Amidst troubled times, Lebanon was nevertheless undergoing several important sociological, cultural, economic, and epidemiological transitions. During the decades preceding the civil war, the population of Lebanon was in majority rural, but trends toward urban migration had started to be noted. By 2015, about 90% of the population had been urbanized (International Organization for Migration [IOM] 2015). The highest concentration of the population is found now in the Greater Beirut (GB) area, which includes the capital city Beirut and its immediate suburbs. Located in the middle of the coastline, GB is the seat of government. It concentrates the oldest universities, most advanced tertiary care centers, major business offices, banking headquarters, a busy port, and the only civilian airport of the country. Urbanization has been accompanied by important changes in the composition of the Lebanese population. Nuclear families are replacing extended families, and exogamy replacing regional endogamy (Ferrante 2014). Throughout the last decades of the twentieth century, fertility had been declining. Up till the mid-1970s, the fertility ratio was still about four children per woman in reproductive age. This meant that the burden of caring and supporting aging parents was fairly distributed among siblings. It is now at less than two children per woman, very likely the lowest ratio in the Arab world. Improved health care and better socioeconomic conditions have created a transition to increased survival to later stages of life. Life expectancy is nearing now 80 years (MOPH 2014). Before the Syrian refugee influx, the country was graying rapidly, with consistent increase in the relative proportion of elderly persons. Projections suggested that the population over 65 years of age will constitute more than 10% of the population by the year 2025, mostly concentrated in urban areas (Sibai et al. 2015). Figure 2 shows the demographic pyramid of Lebanon for the year 2016 based on current estimations (US Census Bureau 2017).

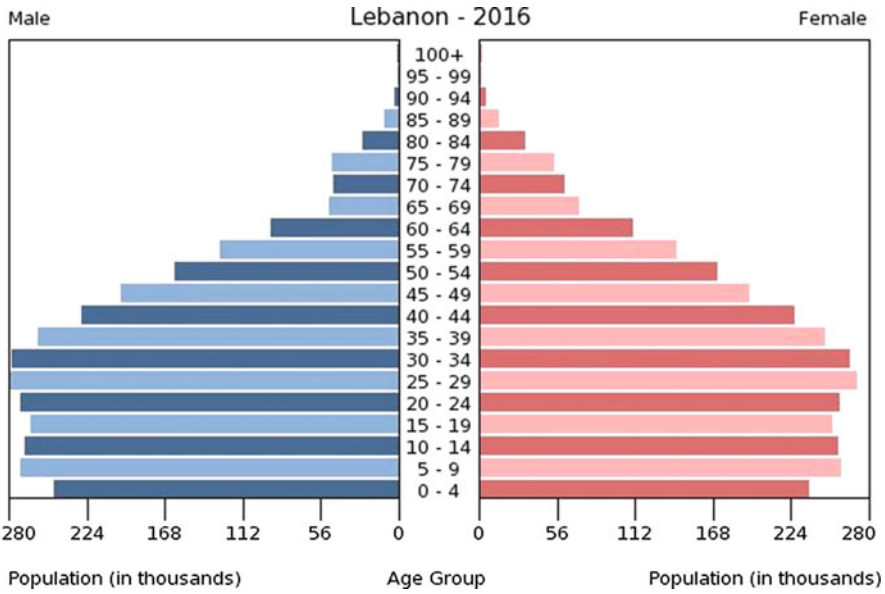

Fig. 2 Population Pyramid Lebanon 2016 distributed by gender (US Census Bureau 2017). Population pyramid of Lebanese population following estimations for year 2016, distributed by gender

Aging in Lebanon was not perceived as a major public health priority until the first decade of the twenty-first century. Strong family and community structures traditionally embraced seniors and kept them inserted within the social network. The civil war, often accompanied with forced displacement, and the difficult recovery period which followed, dismantled many neighborhood/village ties. Families have been affected by the massive emigration of the active members (Kasparian 2010). The case of elderly parents living alone in Lebanon, with no children within driving distance, has ceased to be exceptional. Concerned public agencies and stakeholders from the civil society are acutely aware of the low national level of preparedness in response to the increasing health and well-being needs of the aging population. In the early 2000s, the Ministry of Social Affairs established a special Office for Ageing. Nevertheless, special dispositions for the elderly are still scarce. Geriatric services and geriatricians are still rare, and the primary and secondary care systems do not generally cater to the specific problems of aging citizens. To make the situation worse, employees lose their health insurance through social security when they retire, at the exact moment when their need for care starts increasing. Few are able at that point to obtain an affordable private insurance. More than 2/3 of elderly persons have to rely on their families to be able to cover the cost of their chronic medications and hospitalizations (Abyad 2001).

Unfortunately for the aging population, the priority given to their issues in the early 2000s has been largely affected by the overwhelming and more immediately pressing

needs of the Syrian refugees, of whom at least 500,000 are infants and children. Despite this shift in visibility, geriatric issues have continued to generate research and calls for services (Haddad 2000). In particular, nutrition in that subpopulation has emerged as a concern because of the multiple implications of malnutrition on the overall health and well-being of older persons (Miller and Wolfe 2008).

Malnutrition is an underestimated and underreported problem in the elderly population as stated by several authors (Correia and Waitzberg 2003). It is one of the main public health challenges among geriatric populations in both developed and developing countries, and will become a growing concern with continued demographic trends (Zohoori 2001). Among elderly individuals, malnutrition refers in general to undernutrition which is the result of a chronic deficiency in food intake (Pirlich and Lochs 2001), and/or increased energy expenditure due to hypercatabolism frequently associated with acute disease and hospitalization (Visvanathan 2003). Depending on the definition used and the living situation, the prevalence of malnutrition shows a wide international range. For example in developed countries, the prevalence of malnutrition and risk of malnutrition may range from 4.2% to 27.4% among community-dwelling elderly, and 27.2% to 52.1% in elderly living in nursing homes (Cereda 2012). In developing countries, the phenomenon remains less explored although some papers suggest higher rates of malnutrition among elderly (Amirkalali et al. 2010; Rodríguez-Tadeo et al. 2012).

Social isolation is one important and overall recognized risk factor for malnutrition among elderly persons (Cacioppo et al. 2011). When the extended rural family was the predominant pattern in Lebanon, older women presided over the "mouneh" activity, which refers to the transformation of spring-summer food products into winter provisions. With the slow disappearance of large rural families, the isolated older persons still holding on in mountain villages are unable to secure those provisions and do not have an easy access to markets where all sorts of food products are always available (El Bcheraoui et al. 2015). Fortunately, the majority of older Lebanese lives now in urban and suburban areas. While access may still remain a problem for an older person even in urban areas, it is less acute than in rural remote regions. The main obstacle for good nutrition in this case becomes the affordability of nutritious food, which may be limited for seniors with poor financial conditions.

This chapter reviews evidence accumulated since the end of the civil war in 1991, concerning the nutritional status of the elderly Lebanese and its particular determinants. Papers have assessed the situation of urban and rural elderly persons, in open community as well as in institutions. The review will conclude with practical recommendations meant at improving the situation of elderly persons in Lebanon and in neighboring countries undergoing similar transitions.

Epidemiology of Malnutrition in the Geriatric Population of Lebanon

The overall epidemiology of malnutrition among the elderly population in Lebanon is characterized by its fragmentation and often by the small numbers of subjects involved. These gaps reflects the relatively lower interest that geriatric issues

generate so far in Lebanon, added to the overall misperception that malnutrition cannot exist in this country. Added obstacles to valid and comprehensive assessments include the difficulty to reach mentally competent elderly persons, and the limited freedom to participate when confronted with reluctance or opposition from their care-taking entourage (in the community) or the institution in which they live. Various surveys have also differed in the exclusion criteria selected, with most excluding more deteriorated elderly. This has regularly led to an under-estimation of risks, as demonstrated by the marked difference found in one study with less stringent exclusion criteria (see below). On the positive side, the methodology used in various assessments since the first decade of the twenty-first century has tended to be uniform and to rely heavily on the same Arabic version of the Mini Nutritional Assessment (MNA) which is the most used nutritional assessment tool among elderly independently of their living situation (Guigoz et al. 1996). This version, despite not being validated yet under international standards, has nevertheless the advantage of reducing interobservers variability in outcome assessment.

In various small and large studies, malnutrition in the elderly has so far been described using three parameters: the geographic distribution (urban versus rural), living conditions (community versus institutions), and health status. A summary of the studies is presented in Table 1.

Malnutrition by Geographic Distribution

Two population-based surveys were performed to evaluate the nutritional status of the noninstitutionalized, community-dwelling elderly population (Fig. 3). The first survey included a randomly selected sample of 1200 elderly individuals aged $\geq$65 years living in rural districts of Lebanon. The nutritional status of all participants was measured through the MNA, combined with anthropometric measures (Body Mass Index or BMI). Individuals on artificial nutrition were excluded. The overall prevalence of malnutrition and risk of malnutrition were 8.0% and 29.1% respectively. Both were more prevalent among females (9.1% and 35.3% respectively) than males (6.9% and 22.9% respectively) (Boulos et al. 2013).

A second survey conducted a few years later used largely the same methodology on a sample of older persons living in the Greater Beirut (GB) urban/suburban area. The survey included 905 elderly aged $\geq$65 years. Unlike the rural study, this survey excluded elderly with cognitive dysfunction. Malnutrition was less prevalent than in rural areas (2.8%), while risk of malnutrition was higher (45.5%). Furthermore, there were no significant differences in poor nutritional status (malnutrition or risk of malnutrition) by gender (Mitri et al. 2016).

Malnutrition by Living Conditions

A study published in 2003 was one of the first to compare the nutritional status of 100 community-dwelling elderly persons to 100 elderly living in institutional settings (Sibai et al. 2003). Results showed that the energy, calcium, zinc, magnesium,

Table 1 Summary of studies on nutritionals status of elderly subjects carried out in Lebanon. This table presents the methods and results of the surveys carried out in Lebanon between 2003 and 2016. Most studies were performed in community and institutional settings reporting estimates of malnutrition/risk of malnutrition as well as factors associated with malnutrition. All studies except one used the Mini Nutritional Assessment tool. Inclusion and exclusion criteria show variations among the different studies

Studies	Setting and participants	Inclusion/exclusion criteria	Measures	Main results
Boulos et al. (2014), (2017)	Community (rural) N = 1200[a]	Age ≥ 65y/terminal illness, artificial nutrition	MNA, SES, health, functional status, cognitive status, mood, frailty	MN = 8%, at risk = 29.1% MN was independently associated with lower income, comorbidities, chronic pain, depressive disorders, cognitive dysfunction, social isolation, and loneliness
Mitri et al. (2016)	Community (urban) N = 905[a]	Age ≥ 65y/ bedridden, cognitive impairment MMS <24	MNA, SES, health, functional status, mood, GOHAI	MN = 2.8%, at risk = 45.5% MN was independently associated with poor SRH, comorbidities, POQL, depressive disorders, and dependency
El Zoghbi et al. (2014)	Nursing home N = 111[a]	Age ≥ 65y/renal dialysis, MMS <14	MNA, SES, health, functional status, cognitive status, mood, frailty	MN = 12.6%, at risk = 48.7% MN was independently associated with frailty, depressive disorders, being sedentary, and cognitive decline
Doumit et al. (2014)	Nursing home N = 221[a]	Age ≥ 60y/MMS <20, terminal disease, being blind or deaf, admitted since <3 month	MNA, SES, health and functional status, mood	MN = 3.2%, at risk = 27.6%
Sibai et al. (2003)	Community and nursing home N = 200[a]	Age ≥ 65y/terminal illness, cognitive impairment, admitted since <3 month	SES, BMI, dietary intake (3 days), albumin	Community elderly >BMI > nursing home residents Energy, Ca, Zn, mg, Vit A, D, E below recommended intakes in both samples
El Helou et al. (2014)	Hospital N = 115[b]	Age ≥ 70y, MMS ≥ 24, able to communicate/ hypercatabolic state, artificial nutrition, malabsorption	MNA, GOHAI	MN: 6%; at risk = 37.4%; POQL associated with 2.84 fold increased risk of MN

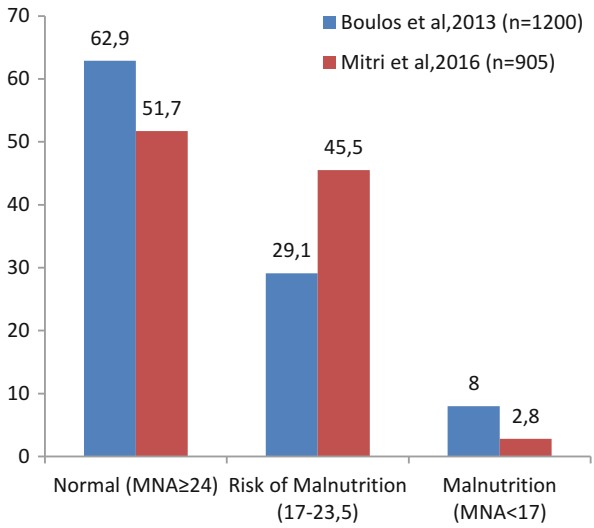

Fig. 3 Nutritional status among community dwelling elderly Lebanese. This figure shows the with prevalence of malnutrition and risk of malnutrition assessed through MNA among community dwelling elderly Lebanese living in rural (Boulos et al. 2013) and urban areas (Mitri et al. 2016)

alpha-tocopherol, and vitamin A and D intakes were all below the recommended levels in both groups. However, community-dwelling elderly had a higher mean BMI and waist circumference compared to the institutional residents. After adjusting for potential confounders, the risk of having a BMI above 30 kg/m^2 was significantly lower for those living in the institution compared with community dwelling elderly.

Two separate studies were subsequently carried out among the elderly living in long-term institutions (Fig. 4). A survey of 36 nursing homes outside the GB area (out of a total of 49 homes) was carried out between 2007 and 2009, on a sample composed of 148 women (67%), and 73 men (33%). Based on the MNA, the prevalence of malnutrition was 3.2% and the risk of malnutrition 27.6%, with no

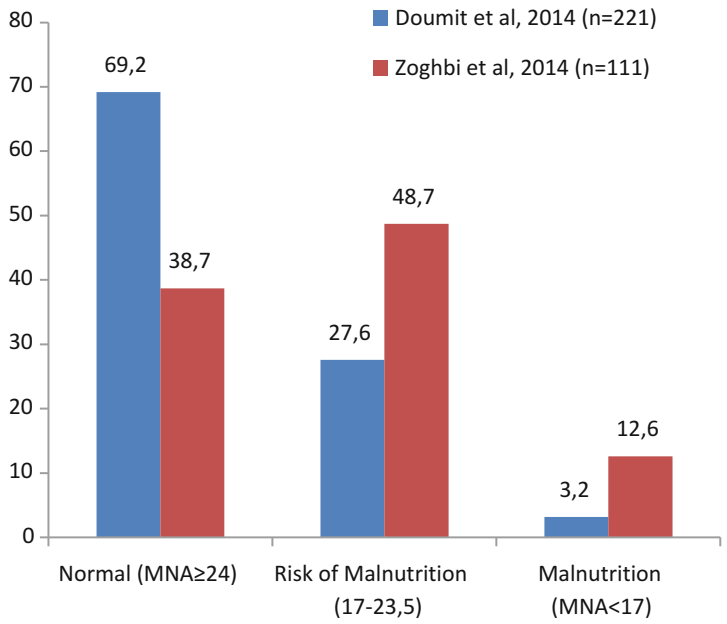

Fig. 4 Nutritional status among institutionalized elderly Lebanese. This figure shows the prevalence of malnutrition and risk of malnutrition assessed through MNA among elderly Lebanese living in nursing homes in Greater Beirut (El Zoghbi et al. 2014) and in other regions of Lebanon (Doumit et al. 2014)

significant difference between genders (Doumit et al. 2014). The other study conducted during 2012 reported the prevalence of malnutrition among the elderly living in three out of the five long-term geriatric institutions in GB. Only 111 persons could be assessed. Among those, the prevalence of malnutrition was estimated at 12.6% and the risk of malnutrition at 48.7% respectively (El Zoghbi et al. 2014). The higher estimates of malnutrition in this study compared to the previous one might be explained by selection bias in the former, where only those who scored above 20 on the Mini-Mental State (MMS) assessment of cognitive aptitude were included (see Table 1).

Distribution by Health Status

Elderly persons suffering from multiple chronic conditions are at high risk of acute exacerbations which is frequently followed by hospital admission. Among these acute care patients, malnutrition is a common and unrecognized problem which worsens mostly during hospital stay due decreased food intake, polymedication, lack of nutritional training, lack of assistance, and many other reason (Kubrak and Jensen 2007).

A small pilot study was performed in 2013 to assess malnutrition among hospitalized elderly in association with oral health. The study included 115 older adults

aged ≥70 years admitted to the largest public tertiary care hospital in Lebanon, located within the GB area. Among other findings, the prevalence of malnutrition among these hospitalized seniors, using the MNA, was 6%, with an additional 37.4% who were at risk of malnutrition (El Helou et al. 2014). The same objective was targeted by another survey of elderly aged ≥65 years drawn from two primary care clinics over a period of three consecutive months. Using the MNA, this survey of 201 older adults found a malnutrition prevalence of 8.5%, and a risk of malnutrition of 33.8% (El Osta et al. 2014).

Determinants of Poor Nutritional Status

Poor nutritional status is the results of multiple factors acting mostly in combination such as age-related physiological changes, poor socioeconomic condition, health-related problems, and psychological factors (Pirlich and Lochs 2001). Table 1 presents those factors that were associated with higher risk of malnutrition in our studies.

Socioeconomic and Life Style Factors

Poor socioeconomic status is a main risk factor for malnutrition (Pirlich and Lochs 2001; Timpini et al. 2011). Accordingly, among community dwelling rural Lebanese, reporting a higher monthly income was independently associated with a reduced risk of malnutrition (ORa 0.77; CI:0.61-0.97) (Boulos et al. 2014). Inversely, this relation was found neither among the urban community dwellers nor among institutional residents (El Zoghbi et al. 2014; Mitri et al. 2016). Furthermore, none of the performed surveys reported a significant association between educational status and malnutrition. As for physical activity, among institutionalized elderly living in GB, doing regular physical exercise was associated with a lower risk of malnutrition (El Zoghbi et al. 2014). In addition, among community living elderly, both social isolation and perceived loneliness were independently associated with an increased risk of malnutrition (Boulos et al. 2017).

Physical Health Status

Comorbidities and poor health status are often associated with decreased food intake and therefore can be considered as major risk factors for poor nutritional status (Kubrak and Jensen 2007). Similar finding were reported by Boulos et al. (2014) in the rural community survey where both variables, reporting more than three chronic diseases and suffering from chronic pain were respectively associated with a 1.2 fold and a 1.7 fold increased risk of malnutrition. Moreover, a poorer perception of general health and a higher number of chronic diseases were independently associated with an increased risk of poor nutritional status among older adults living

in GB. In this study, elderly suffering from disability were also at higher risk of malnutrition (Mitri et al. 2016).

In addition, among the nursing home population of GB (El Zoghbi et al. 2014), the authors found that frailty, a syndrome which recently received major attention in geriatric practice and research, was a significant correlate of nutritional risk.

Mental Health Status

Mental health problems, such as depression and dementia, are main issues among geriatric population and may affect food intake and nutritional status in various ways (Shatenstein et al. 2007). Accordingly, in both, the rural and the urban community survey, depressive disorders were associated with a 1.6 fold increased risk of malnutrition (Boulos et al. 2014; Mitri et al. 2016). Similar findings were described among residents of urban nursing homes (El Zoghbi et al. 2014). Moreover, among rural community dwellers and institutionalized urban elderly a significant association was found between cognitive decline, assessed through MMS, and malnutrition (Boulos et al. 2014; El Zoghbi et al. 2014). In the two other studies, elderly with dementia were initially excluded from the study sample.

Oral Health Status

Two studies focused specifically on the relation between oral health and nutritional status. Both found a significant relation between oral health related quality of life and poor nutritional status. For example, El Osta et al. (2014) reported a 2.9 fold increased risk of malnutrition in presence of poor oral health related quality of life among 201 outpatients. Similar findings were reported in urban community dwellers (Mitri et al. 2016). Furthermore, among outpatients, complaining about xerostomia and having less than four posterior dental functional units were associated with a higher risk of malnutrition (El Osta et al. 2014).

Recommendation and Future Research Perspectives

This review showed that among Lebanese elderly living in various settings, malnutrition is a common finding which might have negative effects on different health outcomes. These results highlighted the need for better awareness of malnutrition among the different parties which might be concerned by the health and well-being of elderly people. First, among health care professionals, who have to consider to detect malnutrition through simple available screening tools and to intervene as soon as possible. Second, among people caring about elderly in their homes or in institutions to understand that nutritional care is a major factor in disease prevention which contributes to health and quality of life. In Lebanon, community dispensaries depending on the Ministry of Social Affairs are implemented all over the country.

One of the first steps would be to integrate dieticians within the team of nurses and social workers in these centers with a special focus on nutritional screening and care for elderly individuals. In a second step, these dieticians have to educate employees of these centers to learn how to detect malnutrition through an easy-to-use screening tool and to give simple advices. If necessary elderly with poor nutritional status or special needs might be oriented toward the dietician. Furthermore nursing homes and hospitals should be targeted and those responsible must be convinced that nutritional care of elderly should become one of the main goals helping to improve the quality and efficiency of hospital and institutional care. In addition clinicians have to be equipped with simple non-time-consuming tools that may easily identify this frequently underdiagnosed condition. We suggest changes at the level of undergraduate studies curricula to increase elderly malnutrition knowledge and tools' use in future practice.

Another important issue is the access to health care among elderly in Lebanon. Unfortunately, upon retirement, Lebanese elderly lose their health insurance coverage and thus are often relying on the financial support of other family members. This may also be one of the reasons for limited access to dental care and therefore poor oral health, which may increase the risk of malnutrition (El Helou et al. 2014; El Osta et al. 2014). Another reason for decline in oral health might be the lack of knowledge about the importance of maintaining good oral health in order to guarantee adequate nutrition. In fact, poor oral health can affect food choices and consequently lead to a monotonous diet with risk of multiple nutrient deficiencies (Bailey et al. 2004). Unfortunately buccodental care is not only neglected by the individuals themselves but also by the clinicians, who mostly are not aware about the physiological changes which occur during normal aging and which may influence oral intake. Therefore integrating oral health into medical care of elderly patients would be of great importance. Finally, during their curriculum, future dentists have to be more educated regarding specific changes and oral health needs of elderly people.

In addition, there is still an important lack regarding malnutrition among hospitalized elderly. Studying the particular role of oral supplementation and enteral nutrition in reducing malnutrition, accelerating recovery and decreasing infectious diseases incidence is also necessary. Only a pilot study was performed reporting poor nutritional status among 43% of elderly without cognitive impairment (El Helou et al. 2014). More comprehensive data are needed through studies based on representative sample from hospitals in different regions. Also several tools, especially the MNA which is the most used screening tool among elderly needs to be validated among Lebanese elderly. MNA is already available in Arabic language and has been used in several studies in Lebanon; however cross-cultural validation or generation of culturally adapted new tools studies are still lacking.

Finally supplementary research is needed in the field of elderly nutrition. As a first step, studies estimating dietary intakes among elderly living in different settings have to be planned in order to assess the current energy and protein intake and to identify special deficiencies in micronutrients. Measurement of vitamins and minerals among elderly individuals would be also of interest, such as vitamin D, that is known to be deficient in the majority of the Lebanese population (Gannagé-Yared et al. 1998, 2000) as well as vitamin B9 and B12 who may influence cerebral function

and homocystein metabolism (Dangour et al. 2010). In addition, food habits and dietary patterns have to be explored with a special focus on traditional Lebanese dietary patterns as described by Jomaa et al. (2016), and its relation with health outcomes. As for the latter, longitudinal studies would be of high interest in order to better understand the way how eating habits may affect the process of aging and the appearance of chronic diseases. As for the traditional Lebanese diet, its protective effect on cardiovascular and other chronic diseases is still to be established, as it was demonstrated for other Mediterranean types of diet (Sofi et al. 2010). However some interesting results have recently be published regarding a possible protective effect of these type of diet on metabolic disorders associated with overweight and obesity (Matta et al. 2016).

As a final point, we suggest the establishment of research-oriented postgraduate studies and projects at the national level to clarify the points suggested above.

Policies and Protocols

Policies

Countries in demographic transition like most Arab nations must reorient services and resources to address the mounting proportion of aged citizens. Seniors' particular needs may be obvious, such as medical problems which require specialized health care departments with health professionals trained in geriatric care. Other needs are less salient but equally as crucial for the health and well-being of elderly persons. Of those, the threat of malnutrition requires a multisectoral approach aiming at avoiding the deterioration of the social insertion of older persons, and of their financial capacity to access nutritive food and adequate preventing care, most notably dental care. Full protective packages can use the abundance of young adults with no immediate employment path to create a "visitation" system which supports an older persons' autonomy within their own familiar settings as long as such an option can be safely obtained. In nations such as Lebanon with inadequate funding for social protection in postretirement ages, policies need to be drawn to help citizens invest in secure financial projects which can ensure an adequate income when needed.

Protocols

In this chapter we reported a summary of studies on malnutrition among Lebanese elderly within different setting. Nearly all these surveys except one were based on the MNA, a specific geriatric tool, used for nutritional screening and assessment among older adults. It is a simple and well-validated instrument developed by Guigoz et al. (1996) with a high specifity, sensitivity, and reliability. The MNA can be used in various settings and is recommended by many international clinical and scientific organizations (Vellas et al. 2006). It has been translated in more than twenty languages and is also available in Arabic language; it can be performed by a

variety of health professionals including doctors, dietitians, nurses, or research assistants (Vellas et al. 2006). The MNA contains 18 questions including anthropometric measures, mobility, cognition, dietary intake, and health condition. Based on the total score, the subjects were classified into three categories: malnourished (<17), at nutritional risk ($17\leq$ score <24), and adequate nutritional status (≥ 24) (Guigoz et al. 1996). The MNA has shown to predict adverse health outcome, functional decline, length of hospital stay, and mortality (Vellas et al. 2006).

One of the mentioned studies used a combination of anthropometric measures (BMI), albumin, and dietary intake (Sibai et al. 2003). BMI was calculated as weight (kg) divided by the square of height (m). Cut-off values were defined according to the World Health Organization categories: underweight (BMI <18.5), normal (18.5–24.9), overweight (25–29.9), and obesity (BMI >29.9). Anthropometric measures have the advantage of being easy to perform and inexpensive; however they may not be reliable indicators of nutritional status in the presence of edema or ascites and should therefore be combined with other markers (Harris and Haboubi 2005). Among biochemical markers, albumin has frequently been used in studies because of its ability to predict mortality. However the level of albumin is also influenced by inflammatory status, hydration, and physical activity, which limits the usefulness of this marker in elderly suffering from acute disease and/or reduced mobility (Harris and Haboubi 2005; Kuzuya et al. 2007).

Finally, dietary intake can be obtained through different ways. In the present study, a prospective 3-day food record was used including 1 weekend day. Food records needs motivation and compliance of the participants and have to be reviewed by a dietician for reliability and completeness. Daily intake of nutrients and energy were obtained through specific nutritional software and compared with recommended nutritional intakes.

Dictionary of Terms

- **Frailty** – A state of increased weakness and vulnerability toward serious health outcomes and disability as a result of age-related, physical, mental, and social changes during life course of elderly people.
- **Homocystein** – Homocystein is an amino acid derived from methionine which is a risk factor for cardiovascular and cerebrovascular disease; the level of homocysteine is influenced by vitamin B9, B12, and vitamin B6 status.
- **Hypercatabolism** – Excessive increase in basal metabolic activity with breakdown of body tissue due to various situations such as infection, burns, traumas, severe organ failure, etc. Hypercatabolism is often associated with anorexia and weightloss.
- **Nuclear families** – Families that include two parents and one or more children, in contrast to single-parent families and extended families (aunts, uncles, cousins, etc). Nuclear families are characteristic of modern societies.
- **Oral health–related quality of life** – Reflects individual's personal satisfaction with oral health and comfort when eating, speaking, and during social interaction.

- **Posterior dental functional units** – A measure to assess the functional masticatory status of the subject. Individuals who have less than four posterior dental functional units are considered to have an altered functional status.

Summary Points

- This chapter reviews the prevalence of malnutrition and associated factors among Lebanese elderly living mainly in the community and in institutions.
- The results show that poor nutritional status is an important concern among older adults in Lebanon.
- A high proportion of elderly were categorized as at risk of malnutrition, meaning that these people may benefit from corrective measures as far as they are recognized early.
- Screening for malnutrition has to be implemented among special risk groups (those suffering from comorbidities, disability, depressive disorders, poverty and those who are widowed and advanced in age).
- Dieticians need to be integrated into an interdisciplinary care team on both, community and institutional levels, to prevent early decline of nutritional intake and malnutrition.
- Special attention has to be given to oral health among elderly as it is a major factor influencing food intake and long-term health outcomes.

Abstract

Globally, the population is ageing, a process which is associated with a range of physiological changes linked to increased morbidity, with consequent increases in healthcare expenditure. Malnutrition is common in older adults due to a myriad of factors including physiological changes of ageing; thus, with growth in numbers, we can expect the burden of malnutrition and associated negative outcomes such as impaired immunity, loss of physical function, and independence to increase. Both malnutrition and the physiological changes of ageing can manifest in poor nutritional status, due to simple starvation, either through poor food intake or through changes in absorption and metabolism of nutrients in the body. Good nutrition is a modifiable factor which can help to minimize the effects of nutrient deprivation and reduce the impact of ageing on individuals and the community, as well as the healthcare budget. This chapter explains the importance of nutrition in the ageing population and present evidence of the consequences of malnutrition.

The older generation is a heterogeneous group who are quite different to younger people. Yet, there is a lack of specific nutrient reference values especially for adults in advanced age and recommendations are often based on evidence extrapolated from younger adults. Energy needs vary across age groups based on gender, age, and level of activity; however, in older adults, the variation is exacerbated by the physiological changes of ageing and inflammation from illness. Further, many of the assumptions behind calculations of energy requirements, often based on younger people, are not valid in the older population; thus, assessments may not be accurate. Protein requirements are known to be higher in this group, at the very least to attempt to preserve muscle mass, but there is insufficient research to be able to establish guidelines. Fat is an important energy source particularly for older adults whose appetite may be diminished. The evidence suggests that adults of advanced age eat fat in excess of recommendations; however, there are no age-specific guidelines to help interpret the implications of this overconsumption.

Generally, if older people eat a healthy balanced diet, they will meet micronutrient requirements. Micronutrient deficiencies can nevertheless arise from decreased food intake often due to the aforementioned physiological changes of ageing, poor health, and polypharmacy. Key micronutrients of interest in older adults are calcium, magnesium, selenium, zinc, and iron, vitamin B_{12}, vitamin D, and folate. Of particular concern is vitamin D as food sources are limited and exposure to sunlight is often reduced. Given the need for vitamin D for adequate calcium absorption and the roles of calcium in the body, not least for bone strength, older adults may benefit from routine vitamin D supplementation.

EUGMS	European Geriatric Medicine Society
g/kg	Grams per kilogram
HBV	Higher biological value
HRQOL	Health-related quality of life
IQR	Interquartile range
kg	Kilogram
MJ/d	Mega Joules per day
NHANES	National Health and Nutrition Examination Survey
NHMRC	National Health and Medical Research Council
NZ	New Zealand
RDA	Recommended dietary allowance
RDI	Recommended daily intake
RNI	Reference nutrient intake
UK	United Kingdom
USA	United States of America

Introduction

Meeting the nutritional needs of older people is an immediate challenge with life expectancy at its highest throughout many parts of the world. Not only is the number of older people ≥65 years increasing rapidly, but the population of adults of advanced age is expanding due to the steady rise in life expectancy and decrease in later life mortality. The European Commission's 2015 ageing report suggests that the percentage of those aged ≥80 years in the total population in Europe will increase from 5% in 2013 to 12% in 2060 (European Commission (DG ECFIN) and Economic Policy Committee (Ageing Working Group) (2015)).

Older adults are a heterogeneous population with unique nutritional needs and the process of ageing occurs at different rates in different people. Nutritional requirements of individuals may be influenced by a myriad of factors including reduced mobility and independence, financial constraints, higher rates of hospitalization, chronic diseases and disabilities, changes in body composition, sensory deficits, taste perception, and digestion and absorption of food, all of which place older adults at increased risk of nutritional deficiencies. Furthermore, the process of ageing affects nutritional needs; requirements for some nutrients may be reduced while requirements for others may be increased.

There is a close relationship between nutritional status and health in the general population. While the main health risk for younger population groups is weight gain

and being overweight, older adults are vulnerable to consuming too little energy with associated weight loss. The range of physiological changes that contribute to reduced food intake has been termed the "anorexia of aging" (Morley, 1997). Social, psychological, and medical factors may also negatively impact the desire to eat.

In general, healthy older people tend to consume smaller meals, fewer snacks, eat more slowly, and become satiated after meals more rapidly than younger people, and daily intake of food may decrease by an average of 30% between the ages of 20 and 80 years (Wurtman et al., 1988). Most of the age-related decrease in energy is a response to the decline in energy expenditure with age; however, for many older people, the decrease in energy intake tends to be greater than the decrease in energy expenditure with a resultant loss of body weight, particularly muscle mass.

The age-related changes which predispose older adults to a decrease in food intake may lead to malnutrition, especially in the presence of additional health and social risk factors (Wham et al. 2015). Consequently, malnutrition is widespread among vulnerable older adults especially in those who are institutionalized. In developed countries, it has previously been estimated that malnutrition is present in 5–30% of community-living older people, 23–60% of those who are hospitalized, and up to 70% of those living in residential aged care or nursing homes (Agarwal et al. 2013). Among community-living older people in Europe, it has been estimated that 20% of those aged between 75 and 80 years are malnourished (Ljungqvist et al. 2010). Along with its associated health complications, undernutrition is estimated to cost the European health and social care system approximately 120 billion Euros per year (Ljungqvist et al. 2010).

Malnutrition is associated with functional impairment, increased comorbidity (in relation to immune dysfunction, anemia, reduced cognitive function, and poor wound healing), delayed recovery from surgery, higher hospital and readmission rates, and mortality (Chapman 2006). Studies of older people also show a relationship between malnutrition risk and health-related quality of life (Kvamme et al. 2011; Johansson et al. 2009), which underpins the importance of optimizing the nutritional health of older people.

Good nutrition is a modifiable factor which may help to prevent health problems. Improvements in nutritional status can also allow for greater health expenditure to be directed toward keeping older people well for longer. Screening for malnutrition risk, a process which can identify factors related to nutritional status that could lead to malnutrition, can act as a preventative health measure. Validated nutrition screening tools provide a reliable method to identify those at high risk of malnutrition. Early identification and nutrition intervention is important because it can be difficult to reverse adverse effects, once malnutrition is established. In the absence of formal screening procedures, more than half of older adults at risk of malnutrition in various settings may not be recognized or referred for treatment (Elia et al. 2005). As early identification and intervention in malnourished older adults can improve clinical outcomes and reduce health care use, guideline recommendations for nutrition screening and assessment provide an important safeguard.

Understanding nutrients of concern for older people is critical for the prevention and management of chronic disease and other health problems. Policy is an important vehicle to implement actions for the improvement of nutrition. Country-specific food and nutrition guidelines are formulated to protect the health of populations in the context of other relevant policies and strategies. Dietary guidelines are based on the nutritional needs of a population; however, little is known about the dietary habits and nutritional status of the very old. Although adults of advanced age are physiologically different to their younger counterparts and are more prone to inadequacy of energy and certain nutrients than younger adults, there are no specific dietary guidelines for those aged ≥85 years. Generally, older people are underrepresented in nutrition surveys and data for older adults are aggregated for those ≥65 or 70 years with recommendations in many cases based on evidence from younger adults. Indeed, in some countries, dietary recommendations for healthy adults (≥19 years) are applied to older adults (≥65 years). The lack of nutrition surveillance data for older adults makes it difficult to establish their nutritional needs and to develop policies to protect this vulnerable group. Given the heterogeneity of older people, it has been suggested that future guidelines may need to identify the nutritional needs of older people in relation to their functional ability and morbidity (Suominen et al. 2014).

In this chapter, the nutritional needs of older people will be examined. Adequacy of food intake of adults of advanced age has been reported from longitudinal studies of ageing. More recently, the macronutrient and micronutrient intakes of the very old were investigated from three cohorts of advanced age from the UK and New Zealand (NZ) (Mendonca et al. 2016a, b; Wham et al. 2016a, b). Dietary information was collected using a repeated multiple-pass recall (2×24h recalls) in 793 85-year olds (302 men and 491 women) living in North-East England (the Newcastle 85+ study) and in 216 Māori and 362 non-Māori from the Bay of Plenty and Rotorua regions of New Zealand participating in Life and Living in Advanced Age: A Cohort Study in New Zealand (LiLACS NZ). The nutritional enquiry included in these cohort studies of ageing provides a preliminary assessment of nutritional status in the very old.

Energy

The energy needs of older adults vary widely according to gender, body size, and physical activity. Those with good health and physical function may have similar energy needs to younger adults. Typically, both lean body mass, total body water, and basal metabolic rate tend to decline with age, concurrent with body composition changes slowly over time, and body fat may increase proportionally. There is a decrease in skeletal muscle, smooth muscle, and muscle that affects vital organ function. This reduction in lean body mass, basal metabolic rate (BMR), and overall physical activity contributes to an overall reduction in the energy needs of older adults compared with younger people. Changes in body composition affect the body's metabolism, nutrient intake, nutrient metabolism, and overall nutrient requirements. As BMR declines proportionately with the decline in

muscle tissue, an older person's energy requirement per kilogram of body weight tends to be reduced.

Based on data from the US Institute of Medicine of the National Academies database for individuals aged between 20 and 100 years, a progressive decline in total energy expenditure and physical activity level with advancing age is evident (Roberts and Dallal 2005). Maintaining an adequate energy intake and weight can be a challenge especially in advanced age. Older people are less able than younger adults to make compensatory increases in their energy intake and are less able to regulate weight and therefore regain any lost weight.

Food intake in older people may be compromised due to taste changes, sensory deficits, and impaired sensory-specific society which leads to less variety-seeking behavior. Physiological changes in gastrointestinal function that occur with ageing may have an adverse impact on appetite and contribute to an overall decrease in food intake. Combined with poor dentition, chronic illness, and adverse social and psychological factors such as bereavement and depression, older adults tend to be less hungry than younger adults.

Among older adults showing characteristics of frailty, meeting energy requirements can be particularly difficult. Eating at least three meals a day and, where possible, energy- and nutrient-dense snacks, is especially important for the frail old. An overall decline in food intake may compromise dietary variety which is positively associated with nutritional quality and positive health outcomes. A lack of energy intake from food may lead to nutrient deficiencies and can augment functional decline which may contribute to further deterioration of health. Nevertheless, with adequate consumption of a variety of foods from the main food groups, older individuals can meet recommended macronutrient and micronutrient intakes and energy balance can be achieved.

Estimates of total energy requirements for older adults are problematic given the evidence to suggest that the desirable healthy weight range should be set higher for improved health outcomes and the potential that the current estimates are based on predictive equations that have not been validated in this age group and may therefore overestimate requirements as a result of the decline in muscle mass with age (NHMRC (National Health and Medical Research Council) 2006). In general, data on the energy requirements of people over 80 years are scarce. Among 87 octogenarians (mean age 82 $\pm$ 3.1 years) participating in the Health, Aging, and Body Composition (Health ABC) study, energy requirements based on doubly labelled water measures of total energy expenditure were 9.24 $\pm$ 1.57 MJ/d for men and 7.59 $\pm$ 1.41 MJ/d for women (Cooper et al. 2013).

Among octogenarians participating in three cohorts of advanced age in the UK and New Zealand, a wide range of energy intakes were reported. Median (IQR) energy intakes reported in the Newcastle 85+ study were generally low; 7.73 (6.36–9.20)MJ/d for men and 6.15 (5.09–7.25)MJ/d for women (Mendonca et al. 2016a) with only 20% of cohort meeting the EAR (UK) (Scientific Advisory Committee on Nutrition (SACN) 2011). Similar energy intakes were reported in LiLACS NZ: Māori men 7.45 (6.05, 9.13)MJ/d and women 6.06 (4.80, 7.21)MJ/d and non-Māori men 7.90 (6.70, 9.57)MJ/d and women 6.27 (7.50, 7.50)MJ/d

(Wham et al. 2016a). These dietary energy intakes also appear comparable to energy intake reported in previous European studies which included octogenarians. For example, median energy intakes (MJ/d) for men and women, respectively, were from the European Prospective Investigation into Cancer and Nutrition (EPIC) (The EPIC-Oxford Study, 2010–2014) 9.84 and 9.02 and Dutch National Food Consumption Survey (DNFCS) 2010–2012 (Ocke et al. 2013) 7.4 and 7.30.

Protein

Older adults have a higher requirement for protein compared to younger adults. However, older adults usually eat less, including less protein, but have higher protein needs to offset the reduction in muscle protein synthesis (anabolic resistance) as well as the elevated metabolism of inflammatory conditions such as chronic obstructive pulmonary disease (COPD) (Deutz et al. 2014). There is mounting evidence that the existing recommended dietary intakes (RDI) for protein are too low for older people (Bauer et al. 2013) and do not take into consideration age-related changes in metabolism and immunity (Clegg et al. 2013). Findings suggest that protein intake greater than the RDI can help older people to improve immune status and wound healing, as well as muscle mass, strength, and function (Wolfe et al. 2008).

Although there is insufficient longer term research with defined health outcomes to specify an optimal intake for protein, there is mounting evidence that increasing protein intake beyond 0.8 g/kg may enhance protein anabolism and help reduce the progressive loss of lean mass with ageing. Protein intake has been demonstrated to be an important determinant of muscle mass and function. Among a group of healthy older women with protein intake 0.45 g/kg bodyweight/day, muscle mass and strength decreased over a period of 9 weeks. By contrast, in women who consumed twice that amount of protein (0.92 g/kg bodyweight/day), muscle mass remained stable and muscle strength improved (Castaneda et al. 1995). It has also been demonstrated that chronic ingestion of the recommended dietary allowance (RDA) (USA) for protein results in reduced skeletal muscle size in weight-stable older adults with no change in muscle function (Campbell et al. 2001). Findings from the Health ABC cohort indicate lower energy-adjusted protein intake in 2066 healthy older adults aged 70–79 years is associated with a larger loss of lean body mass over a period of 3 years of observation (Houston et al. 2008) with a median protein intake between 0.7 g/kg (lowest quintile) and 1.1 g/kg (highest quintile) resulting in a reported loss in lean mass of 0.85 and 0.45 kg, respectively; i.e., 40% less decrease in lean mass over 3 years suggesting a clear linkage between protein intake and muscle change in older adults. Furthermore, data from the InChianti and the Women's Health Initiative cohort studies indicate that higher protein intake is associated with reduced risk of muscle strength loss and incident frailty (Beasley et al. 2010; Bartali et al. 2012).

Evidence from recent cohort studies suggests that observed weight-adjusted protein intake of octogenarians tends to meet respective nutrient reference values for people over 70 years but may be low when compared to newer recommendations

(1.0–1.2 g/kg/day to preserve and regain lean body mass and function) made by the PROT-AGE Study Group (Bauer et al. 2013). In the Newcastle 85+ study, the daily median (IQR) weight-adjusted protein intake for men was 1.04(0.81–1.32)g/kg and for women was 0.96(0.75–1.17)g/kg higher than the Reference Nutrient Intake (RNI) (UK) of 0.75 g/kg (Department of Health: Committee on Medical Aspects of Food Policy (COMA) 1991). Overall, 78.1 and 67.4% of men and women, respectively, had higher protein intakes than the RNI. In LiLACS NZ, the median weight-adjusted protein intake for Māori and non-Māori men was 1.05 and 0.98 g/kg/day, respectively; for Māori and non-Māori women 0.87 and 0.91 g/kg/day, respectively. Similarly, the reference standard was met by 66% of Māori and 73% of non-Māori women (EAR (Australia/NZ) 0.75 g/kg/day) and by 65% of Māori and 72% of non-Māori men (EAR 0.86 g/kg/day) (NHMRC (National Health and Medical Research Council) 2006).

Not only do older adults usually eat less protein compared to younger adults, they often consume less high biological value (HBV) animal protein such as meat (Gaffney-Stomberg et al. 2009) due to factors such as difficulty chewing, fear of increasing fat and cholesterol and cost and accessibility of these sources. Although muscle mass decreases in older people, the formation of muscle protein can be stimulated by HBV proteins, so it is prudent that an adequate protein intake is maintained. An adequate protein intake is especially important to maintain a healthy functional status and decrease the risk of prolonged infections that may lead to hospitalization. The pattern of protein intake may also be important to stimulate protein synthesis in older adults and there is some evidence that spreading protein intake evenly over meals may be beneficial (Bouillanne et al. 2013). However, further studies are needed to determine the optimal pattern of intake to improve muscle strength and function.

The optimal protein intake for older adults to maintain nitrogen balance and to preserve muscle mass and function remains to be ascertained. Recent recommendations from the European Society for Clinical Nutrition and Metabolism (ESPEN) suggest higher dietary protein intakes for older adults ($\geq$65 years) compared to younger adults (Deutz et al. 2014). It is suggested that diet should provide between 1.0 and 1.2 g protein/kg body weight/day for healthy older people (Cruz-Jentoft et al. 2010) and between 1.2 and 1.5 g protein/kg body weight/day for older people who are malnourished or at nutrition risk (Deutz et al. 2014). To limit age-related decline in muscle mass, strength, and function, resistance exercise training is also recommended (Lanza et al. 2008).

Notably, higher protein intakes are now recommended by the PROT-AGE Study Group appointed by the European Geriatric Medicine Society (EUGMS) (1.0–1.2 g protein/kg body weight/day for healthy older people, $\geq$1.2 g protein/kg body weight/day for active and exercising older adults, and 1.2–1.5 g protein/kg body weight/day for older adults who have acute or chronic disease (Bauer et al. 2013)). Similarly, in Norway, the Nordic Nutrition Recommendations suggest a safe intake of 1.2–1.5 g protein/kg body weight/day for healthy older people or approximately 15–20% of total energy intake (Pedersen and Cederholm 2014).

Fat

Based on the acceptable macronutrient distribution range (AMDR) (Australia/NZ), participants in both the Newcastle 85+ study and LiLACS NZ met or exceeded the minimum of 15% energy from fat proposed to ensure adequate consumption of total energy, essential fatty acids, and fat-soluble vitamins. Fat intake, as median percent energy was above the maximum AMDR range (20–35%), for participants in Newcastle is 36.8%, for Māori 38.5%, and for non-Māori 36.7% (NHMRC (National Health and Medical Research Council) 2006). These intakes are greater than reported for New Zealand adults aged 71+ years in the New Zealand Adult Nutrition Survey (33%) (University of Otago and Ministry of Health 2011). A lack of evidence for age-specific dietary recommendations for the oldest old hinders the interpretation for higher energy from fat but suggests that octogenarians eating patterns may differ from younger adults.

Micronutrients

Generally, an older adult who is eating well in terms of quality and quantity and is not experiencing or recovering from an acute illness will achieve an adequate intake of all micronutrients. While some micronutrients are required in larger amounts in older age, these amounts can be achieved within a healthy, well balanced diet which meets energy and macronutrient recommendations.

Micronutrient deficiencies tend to arise due to a reduction in food intake in response to a decline in energy needs with age. BMR and energy expenditure for physical activity may be reduced (Roberts and Rosenberg 2006) while vitamin and mineral needs remain unchanged or are increased (Zhu et al. 2010). Physiological changes may impact the metabolism of micronutrients and poor health and medications may compromise nutrient absorption. Eating habits affected by poor oral health and social isolation may further contribute to lower food intake and nutrient deficiency (Elmadfa and Meyer 2008). As micronutrient deficiencies are associated with adverse functional outcomes (Inzitari et al. 2011), they may impact the independence of older adults.

Calcium

Vital for bone health, calcium is consistently recommended in higher amounts for older compared to younger adults. Food sources high in calcium include milk, cheese, yoghurt, fortified foods (e.g., juice, breakfast cereal, breads), and some fish (e.g., sardines) and are recommended in favor of supplementation due to the unexpected finding that calcium supplementation was associated with increased cardiovascular events in osteoporosis trials (Reid et al. 2011).

Across various studies of older adults, dietary calcium intake does not meet dietary recommendations (Zhu et al. 2010). A similar shortfall of calcium intake was also observed for octogenarians in the Newcastle 85+ study median (IQR) 731 (554–916)mg and in LiLACS NZ for Maori 563 (424–778)mg and for non-Maori 702 (541–905)mg. More than 85% of octogenarians In LiLACS did not meet the EAR (Australia/NZ) for calcium (1100 mg). Calcium is not as well absorbed by the oldest age group and increased intake is needed. Novel ways of increasing dietary intake and intervention trials that study dose–response relationships to outcomes are needed as not enough is known about calcium requirements during ageing.

Magnesium

Magnesium requirements appear to change with age, but clear conclusions are absent to set higher requirements. Data from the National Health and Nutrition Examination Survey (NHANES) III showed a progressive decrease in daily magnesium intake with age (Ford and Mokdad 2003) with mean intakes for older men (225 mg) and women (166 mg) being well below the recommended daily allowance (RDA) (USA). A comprehensive review suggests that the dietary intake of magnesium is inadequate in elderly populations (Vaquero 2002), and this has previously been observed in older people in New Zealand (Horwath et al. 1992). In octogenarians participating in the Newcastle 85+ study, >20% of participants were below the lower NRI (UK) for magnesium (Mendonca et al. 2016b), and in Lilacs NZ, the EAR (Australia/NZ) for magnesium was not met by most (Wham et al. 2016b).

In older adults, magnesium is associated with physical performance (Veronese et al. 2014), adequate bone mineral density (Orchard et al. 2014), and inflammation (Chacko et al. 2010); hence, low intakes are of concern. Rich food sources of magnesium include nuts, legumes, whole grains, and most green vegetables, but despite a wide distribution in the food supply, older adults are less likely than younger adults to consume sufficient to meet their needs (Barbagallo et al. 2009).

Selenium

Selenium is an important antioxidant and contributes to a strong immune system and healthy thyroid function. It may also play a role in cancer prevention but this is an ongoing area of research. Good food sources of selenium include Brazil nuts and oily fish; however, the food content may depend on the local geographical area. Whole population estimates from NHANES do not show low intakes of selenium (Fulgoni et al., 2011; however, in the USA, frail older people have been found to be more likely to be deficient in selenium than other population groups (Smit et al., 2013). In the Newcastle 85+ study in the UK >20% of participants

had selenium intakes below the lower RNI (UK) (Mendonca et al., 2016b). Selenium intakes among octogenarians in LiLACS NZ were marginal with over two-thirds of participants falling below the EAR (Australia/NZ) (Wham et al. 2016b), similar to the NZ Adult Nutrition Survey for those aged over 70 years (University of Otago and Ministry of Health 2011). However New Zealand soils are low in selenium and New Zealand population blood selenium concentrations remain lower than those reported in other Western countries (Thomson 2004). Intakes in vulnerable older populations need to be examined in relationship to serum levels and outcomes over time to fully understand the significance of low intake.

Zinc

Zinc plays an important role in immunity but also has a role to play in wound healing and maintaining the senses of taste and smell, important for the enjoyment of food and optimal health of older adults. Zinc can be found in reasonable amounts in a range of foods including pulses, nuts and legumes, wholegrain cereals, and dairy products. Among octogenarians in LiLACS NZ, most men did not meet the EAR (Australia/NZ) for zinc intake (Wham et al. 2016b). Expressed on a per MJ food energy basis, zinc intake for all participants was 1.2 mg/MJ lower than for European men (aged 70+ y) in the Zenith study (Andriollo-Sanchez et al. 2005). Data on zinc status in normal ageing are lacking and the implication of low intake is unknown. An adequate intake of zinc nevertheless appears to be important for prevention of oxidative stress, immunity, and cognitive functions.

Iron

Iron plays a number of important roles in the body but is primarily concerned with transport of oxygen from the lungs to the cells of the body. Approximately, 70% of the body's iron is to be found in red blood cells in the form of hemoglobin. Iron in food is found as heme iron, from animal products, or non-heme iron, from non-animal-based products. Good sources include red meat, dark green leafy vegetables, and fortified breakfast cereals. Iron deficiency occurs in around two-thirds of the world's population with signs and symptoms being fatigue and decreased immunity. The most probable cause of iron deficiency anemia among older adults is inadequate dietary intake or blood loss from conditions such as ulcers, polyps, or intestinal cancer. There is no evidence that heme iron absorption is impaired in older adults. Iron deficiency in older adults is reported to be especially common over the age of 80 years (Fairweather-Tait et al. 2014). Prevalence of anemia in the USA has been reported to be approximately 10% at age 65 years and up to 60% in older adults in residential aged care.

Vitamin D

Older people are especially susceptible to vitamin D insufficiency due to reduced mobility, decreased sun exposure, and a decline in cutaneous synthesis of vitamin D with age (Heaney 2006). Unfortunately, food sources of vitamin D are limited (e.g., some fish, fortified foods, and liver) and while exposure to sunlight provides an endogenous source, disease or disability can prevent adequate exposure especially among the housebound or those in residential care. Most community-living octogenarians (>95%) in the Newcastle 85+ study had vitamin D intakes below the RNI (UK) (10 μg/d) (Mendonca et al., 2016b). Similarly in LiLACS NZ, the adequate intake (AI((Australia/NZ) for vitamin D (15 μg/d) was not met by >95% of participants (Wham et al. 2016b). To ensure adequate vitamin D status of older people, supplementation and food fortification may be needed; targeting those at high risk of insufficiency and providing vitamin D supplementation is likely the most cost-effective approach.

Vitamin B_{12}

Recommendations for dietary vitamin B_{12} intake are generally not different to younger adults. Increasing risk of deficiency among older people, despite adequate intakes, appears to be related to physiological changes in the gut with age that may prevent the release of vitamin B_{12} from natural food sources (McNulty and Scott 2008). Pernicious anemia is a further cause of deficiency in older people (Andres et al. 2004). Vitamin B_{12} is mostly found in animal products such as fish, poultry, meat, eggs, and dairy; hence, vegetarians may be at higher risk; however, it is increasingly found in fortified foods, particularly breakfast cereals. Vitamin B_{12} deficiency commonly manifests as fatigue, anemia, and depression which may be corrected through diet or supplementation.

Folate

Folate is found across a wide range of foods including fruit and vegetables, legumes and nuts, dairy, poultry, meat, and eggs. Despite being commonly found in the food supply and older adults not generally having any greater requirement than younger adults, folate can become a nutrient at risk if access and availability of fresh food is limited or there is a significant decline in appetite. Of particular concern for older people is that natural food folates found in foods such as green vegetables can be unstable under typical cooking conditions, and this can substantially reduce the folate content even before it is ingested. Folic acid found in supplements and fortified foods such as breakfast cereals is however a very stable and highly bioavailable form of the vitamin (McNulty and Scott 2008). Many developed countries mandatorily fortify grain flours, including wheat, with folic acid, e.g., Australia, USA, while others fortify voluntarily, e.g., NZ, to address public health

concerns related to folate insufficiency. This largely relates to neural tube defects; however, the older population is likely to benefit from the increased availability in the food supply. The primary clinical sign of deficiency is megaloblastic anemia, commonly manifesting as fatigue, weakness, and headache.

Dictionary of Terms

- Malnutrition is a broad term referring to both over- and undernutrition; however, in this context, it is exclusively used to describe undernutrition occurring as a result of inadequate nutrient intake, which may be due to insufficient food intake or illness.
- Māori are the indigenous people of Aotearoa, New Zealand comprising 14% of the total population and 2% of those aged over 80 years.
- Macronutrients are those which are required by the body in large amounts, and which contribute to energy intake, i.e., protein, fat, carbohydrate, alcohol.
- Energy (calories or kilojoules) is the fuel gained from macronutrients which is used by the body for all processes and activities including breathing, sleeping, thinking, and walking.
- Acceptable macronutrient distribution ranges (AMDR) are the recommended ranges for % energy from macronutrients required to reduce chronic disease risk, e.g., protein 15–25%, fat 20–35%, carbohydrate 45–65% (Australia/NZ).
- Nutrient reference values referred to throughout this chapter, e.g., RDA, RDI, AMDR, etc., are population-level recommendations based on thorough and systematic review of current scientific knowledge.

Summary Points

- This chapter reviews the current understanding of energy, macronutrient, and key micronutrient requirements for older people including the oldest old.
- Ageing is associated with a range of physiological and psychosocial changes which can result in poor nutritional health and consequently poor general health.
- Older people tend to be nutritionally vulnerable with advancing age as typically they eat less food, consume smaller meals, fewer snacks, and become satiated after meals more rapidly than younger people; daily intake of food may decrease by a third between the ages of 20 and 80 years.
- Understanding nutrients of concern for older people is critical for the prevention and management of chronic disease and other health problems.
- Dietary guidelines are based on the nutritional needs of a population; however, little is known about the dietary habits and nutritional status of the very old.
- Energy requirements vary with age, gender, body size, and physical activity. While healthy active older adults may have similar energy needs to younger adults, energy expenditure tends to decline progressively between the ages of 20 and 100 years, largely due to body composition changes of ageing.

- Meeting energy requirements can be challenging for older adults due to reduced food intake and hence a reduction in dietary variety.
- Older adults have higher protein requirements than younger adults due to reduced muscle protein synthesis rates and elevated metabolism from inflammatory conditions. There are inconsistencies in guidelines for protein intake in this population; recent European recommendations promote higher intakes up to 1.5 g protein/kg body weight.
- Fat is an important energy source particularly for older adults whose appetite may be diminished. While the evidence suggests that adults of advanced age eat fat in excess of recommendations, there are no age-specific guidelines to help interpret the implications of this over consumption.
- Healthy older adults who eat well in terms of quality and quantity will generally meet micronutrient recommendations.
- Micronutrient deficiencies tend to arise from reduced food intake occurring as a result of reduced energy requirements with age.
- Absorption and metabolism can be affected by ageing as well as polypharmacy, poor health, and social isolation.
- Micronutrients of concern in older adults are calcium, magnesium, selenium, zinc, iron, vitamin D, vitamin B_{12}, and folate with vitamin D of particular concern, as food sources are limited and exposure to sunlight is often reduced. Routine vitamin D supplementation may be necessary to achieve requirements.

complications, delayed growth, and higher sensitivity to infections including respiratory infections, diarrhea, and measles.

Previous studies have shown that the concentration of vitamin A, plasma retinol, transthyretin (TTR), and retinol-binding protein (RBP) are low in the adults and children with type 1 diabetes mellitus (T1DM). Beside the role of VAD in the pathology of T1DM due to its effects on the immune system, VAD plays a role in type 2 diabetes mellitus (T2DM) through its effects on antioxidants and lipid metabolism. So, the possible mechanisms of the effect of vitamin A on the pathology of T2DM are categorized as oxidant radicals chelation, increased insulin sensitivity, and obesity and adipose biology.

VAD has shown to have a critical role in pathology of diabetes. VAD affects the pathology of T1DM and T2DM through several different mechanisms. VAD should be considered to be corrected, specifically in high-risk regions. Therefore, VAD should be surveyed and monitored in these regions. If VAD is epidemic in one region, deficiency correction policies should be implemented.

Introduction

Diabetes

The prevalence of chronic diseases is increasing around the world, and diabetes is the one with a significant prevalence. According to studies, the worldwide prevalence of diabetes in 2013 was 8.3%, i.e., 381.3 million persons, and based on estimations, this figure will increase to 8.8%, i.e., 591 million persons, in 2035 (Guariguata et al. 2014). A noticeable percentage is originating from developing countries. In fact, urbanization and lifestyle changes in developing countries have increased the prevalence of noncommunicable diseases (Forouhi and Wareham 2014). Diabetes mellitus has two types: type 1(T1DM) and type 2 (T2DM). T1DM, which is more prevalent in younger people, is caused by lack of insulin secretion and considered an autoimmune disease (Szablewski 2014). T2DM results from decreased insulin sensitivity in older individuals. T2DM accounts for more than 90% of cases and is more common in obese people with low physical activity. Both types of diabetes have many complications and affect the patient's life. Visual problems, heart and kidney disease, and diabetic ketoacidosis are common problems in diabetes (Chiang et al. 2014). In T2DM, eye complications, amputation, cardiovascular problems, and kidney complications are common (Althouse et al. 2014).

Environmental and genetic factors have been proposed in the pathophysiology of diabetes. Genetic factors have a more prominent role in T1DM. Immune cells attack beta cells in the pancreas (Zaccardi et al. 2015). In the past, it was believed that insulin resistance is the cause of T2DM and lack of insulin secretion from β cells is a secondary complication. However, recent studies indicate that glucose hemostasis as well as other regulatory mechanisms are adjusted by various factors, and regulation of the blood sugar level in a proper range is not only affected by glucose uptaking cells but is also affected by insulin secretion by beta cells (Kahn et al. 2014).

Genetic factors can affect insulin secretion from pancreatic β cells and insulin resistance in insulin receptor cells. Environmental factors, among which diet is the most important one, may also affect insulin secretion and insulin resistance. Diet and diet-related factors have the greatest impact on the prevalence of diabetes, especially

T2DM. In addition to the role of diet in the incidence of the disease, it may have a role in the prevention and treatment of diabetes (Korat et al. 2014). Controlling T1DM and T2DM is impossible without controlling food intake and weight loss (Ley et al. 2016). In comparison to other dietary factors which may have a role in the incidence of diabetes, the calorie intake is of importance. Therefore, obese people who have a higher calorie intake are more prone to diabetes. Moreover, macro and micronutrients of the diet have a great role in the incidence, control, and treatment of diabetes (Ley et al. 2014). In recent years, many researchers have considered a special role for micronutrients and conducted many studies in this regard (Pereira 2013). The reason is that many micronutrients are associated with carbohydrate metabolism and insulin. However, without any doubt, there is no consensus on the effect of micronutrients on the prevention and control of T2DM (Neumiller 2012). Among micronutrients, the role of vitamin A in the prevention and control of diabetes will be discussed in this section.

Vitamin A

Vitamin A is a micronutrient that plays a vital role in health. As a fat-soluble vitamin, it plays a significant role in visual health, and it is also important in immunity, epithelial and reproductive tissue health, and gene expression (Iskakova et al. 2015). Vitamin A deficiency causes many health problems among which xerophthalmia is well known. Xerophthalmia's manifestations include eye problems, increased susceptibility to infections, and growth retardation (WHO 2009). Human and animals are unable to produce vitamin A internally, therefore they should receive it from their diet. Vitamin A is available in diet sources as retinol, retinol esters, and previtamins like carotenoids that can convert to the active form in the body. Retinol and retinol esters come from animal foods, but previtamins are available in plant sources. There is debate about the value of these precursors; however, previous studies have shown that every 30 grams of these precursors is converted to 1 gram of vitamin A (Mahan and Raymond 2016). Vitamin A is stored in the liver in the usual form of retinyl ester, but in the circulation, retinol is transferred by a special protein carrier that obtains retinyl ester after its hydrolysis in the liver. Retinol-binding proteins (RBP) are the carrier proteins of vitamin A. They are also bound to transthyretin (TTR).

Vitamin A Deficiency (VAD)

Vitamin A deficiency is very prevalent in low-income countries. Diets poor in vitamin A and its precursors lead to vitamin A deficiency (VAD). Vitamin A deficiency is commonly associated with ocular complications, reduced growth, and higher sensitivity to infections including respiratory infections, diarrhea, and measles. Vitamin A deficiency is one of the important reasons for the increased burden of diseases and reduced growth and is also one of the main causes of blindness in African and South East Asian children (WHO 2009). Severe VAD causes

xerophthalmia, which is initially characterized by night blindness and eye problems followed by Bitot's spots, eventually resulting in corneal ulcers and injuries. According to the WHO, the prevalence of VAD in pregnant women in low-income countries is about 10–20%, and also 250–500 million children have become blind due to secondary effects of VAD, of whom 50% die 1 year after blindness. There is lack of evidence on the prevalence of VAD in adults and other age groups, but there is VAD in other age groups in areas where VAD is common in children and pregnant women. In addition to severe vitamin A deficiency complications, subclinical vitamin A deficiency affects many people in Africa and South East Asia.

Vitamin A Deficiency and Diabetes

Evidence supports declined serum levels of vitamin A in T1DM patients (Yosaee et al. 2016); however, in such patients, the data of the serum levels of vitamin A are mostly vague (Sasaki et al. 1995). In addition, some studies have reported limited changes in the level of vitamin A in the T2DM patients (Sasaki et al. 1995; Lu et al. 2000). Studies indicate that the majority of T1DM patients suffer from low levels of vitamin A. According to many studies, a sort of vitamin A shortage can be seen in the diabetic patients with malnourishment in comparison to malnourished control subjects (Via 2012). We conducted this study to assess the evidence on the effect of vitamin A in T1DM and T2DM.

Cross-sectional studies evaluating the relationship between the metabolomic profile and the risk of diabetes have shown contradictory results. Moreover, limited evidence supports this relationship (Wang et al. 2011). Retinol-binding protein 4 (RBP4), which is a soluble-binding protein, is a vitamin A carrier that may cause insulin resistance. Inflammation and obesity are major causes of diabetes. Several mechanisms are offered to describe the relationship between RBP4 and insulin resistance. There are two receptors in interaction with RBP4; retinoic acid 6 (STRA6) could activate JAK2/STAT5 cascade and pathways of the c-Jun N-terminal protein kinase (JNK) by inducing toll-like receptor 4 (TLR4) and plasma membrane protein, which is involved in insulin receptors components. Insulin resistance can be enhanced by both of these mechanisms (Cione et al. 2016). Therefore, the pathology of diabetes may have a strong relationship with vitamin A. In this regard, there are some reports of the effect of vitamin A deficiency in diabetes patients.

Relationship Between Vitamin A Deficiency and Type 1 Diabetes

One of the common autoimmune diseases is T1DM, which is identified as the condition of absolute or relative destruction of insulin-producing beta cells by T cells (Szablewski 2014; Maahs et al. 2010). Nowadays, the main therapeutic approach to type 1 diabetes is exogenous insulin administration (Hassan et al. 2012; Laing et al. 1999), which could have some side effects. Therefore, there is a

need for substitute methods for insulin therapy to prevent and treat this disease. It has been proven that one of the substitute preventive and treatment methods for insulin is the manipulation of the immune system by changing the course of the disease (Bougnères et al. 1990). Among different nutrients, vitamin A has the greatest effect on the immune system. Evidence suggests that VAD may cause T1DM by its effect on the acquired and innate immune system. Since the early twentieth century, vitamin A has been used to modulate the immune system (Green and Mellanby 1928; Green and Mellanby 1930). Nowadays, to obtain the normal function and regulation of the immune system, vitamin A and its derivatives in the diet are known to be necessary (Ross and Hammerling 1994). It is found that lack of vitamin A could cause insulin secretion failure by glucose simulation (Berdanier 2003). Moreover, cellular retinoic acid (RA), retinol-binding protein (RBP), and transthyretin (TTR) are observed at high levels in the islets of the rat pancreas (Berdanier et al. 2001; Chertow et al. 1987; Driscoll et al. 1997).

Currently, T1DM patients at risk of vitamin A and carotenoids deficiency could benefit from our knowledge of vitamin A metabolism and its role in diabetes (Olmedilla et al. 1997; Granado et al. 2003). Previous studies have shown that the concentration of vitamin A, plasma retinol, TTR, and RBP is low in the adults and children with T1DM (Kobbah et al. 1988; Basu et al. 1989; Nakamura et al. 2010). Lack of vitamin A appears to be a potential cause of type 1 diabetes by modulating the immune system. Research has shown that retinoids are an important factor for regulating the monocytic/macrophage function (Breitman et al. 1980; Geissmann et al. 2003; Jiang et al. 2003). Cytokines like TNF-α and substances like nitric oxide (NO) can be released from macrophages under activated conditions (Sherry and Cerami 1988). The secretion of most of the cytokines produced by macrophages, such as IL-1, IL-6, IL-12, and TNF-α, can be affected by RA (Mohty et al. 2003). A marked reduction in the mRNA level in TNF, regulation of the production of nitric oxide, and increased IL-1 production have been reported as the effects of all-trans-RA supplementation in some studies (Mehta et al. 1994). Therefore, the performance of this pathway can be disturbed by lack of vitamin A. Natural killer cells could also be affected by VAD. The basic role of vitamin A deficiency in NK cell-related activities has been demonstrated in young rodents (Ross 2012). The activity of NK cells and the production of IFN by spleen cells after mitogen stimulation are decreased by lack of vitamin A (Trinchieri 1989; Michael et al. 1989). The activity of NK cells is enhanced at high concentrations of retinoids according to in vitro and in vivo studies (Alter et al. 1978; Micksche et al. 1985; Santoni et al. 1985). However, this simulation process is not quite clear. Moreover, vitamin A insufficiency and the observed immunosuppression have a fascinating dynamic association (Bowman et al. 1990). The activity of the neutrophils is widely affected by VAD. Oxidized retinol and RA are required for differentiation of the neutrophils (Robertson et al. 1992; Tsai and Collins 1993). The genes modulated by RA receptors control the development of neutrophils in the bone marrow, and the RA in cultures speeds up neutrophil maturation (Maun et al. 2004; Ribeiro et al. 2003). The level of neutrophils and the superoxide-production capacity could be significantly recovered by vitamin A or RA treatments in calves and rats (Zhao and Ross 1995; Higuchi and

Nagahata 2000). The level of hyper-segmented neutrophils is significantly higher (67%) in rats with low vitamin A compared to the control group (Twining et al. 1997). Therefore, inconsistent information is available on the association of neutrophilic function and vitamin A in humans.

Evidence also indicates that VAD may cause T1DM by its effects on the acquired and innate immune system. The RA function in T cell biology was explained by Iwata et al. (Iwata et al. 2004) for the first time. Recently, studies have shown the effect of vitamin A deficiency on the immune competence of T cells (Villamor and Fawzi 2005). The results of many studies show the involvement of vitamin A in the modulation of IL-10 production. Th2 cells secrete IL-10 that produces pro-inflammatory cytokines like IFN-g and IL-2 (Leal et al. 2004).

There are a few mechanisms through which vitamin A adjusts the innate and adaptive immune responses, but immune disorders and subsequently T1DM occur following vitamin A deficiency. In addition, vitamin A is very important in the release of glucagon and insulin (Berdanier 2003) and is basically involved in glucose homeostasis in the body. The release of insulin in Langerhans islet cells is associated with activated vitamin A. For a perfect operation of the islets, vitamin A has an important role because of the existing RA-binding proteins in the pancreatic islet cells. The islet cells secrete the hormones which are more than likely regulated by RA. Islet cells act abnormally in secretion of hormone after exposure to graded glucose levels. VAD makes changes in the quality of the pancreatic tissue, possibly through increased digestion of the tissue by collagenase (Berdanier et al. 2001).

Potential Mechanisms of Vitamin A Effects on T2DM

Beside the role of VAD in the pathology of T1DM due to its effects on the immune system, VAD plays a role in T2DM through its effects on antioxidants and lipid metabolism. The possible mechanisms of the effect of vitamin A on the pathology of T2DM are located in three categories: oxidant radicals chelation, increased insulin sensitivity, and obesity and adipose biology.

1- Oxide Radicals Chelation

In diabetic patients suffering from hypoxia, retinol metabolites act as a scavenger of lipoperoxyl radicals at low oxygen pressures (Berry et al. 2012). Self-oxidation reaction uses retinol within lipid oxidation, and retinol is oxidized to 5,6-retinol epoxide as a result of overproduction of free radicals (Regazzetti et al. 2009). To release insulin in pancreatic islet cells, the K/adenosine triphosphate (ATP) channel must be opened as a prerequisite characterized by the ATP/adenosine diphosphate (ADP) ratio. It seems that disorders in the mitochondrial function can change the ratio of ATP/ADP and affect the insulin secretion response stimulated by glucose. ROS not only can nonspecifically damage biomolecules but can also reduce the membrane potential of the mitochondria. Theoretically, the respiratory chain is

irreversibly disconnected by a consequent leakage of superoxide anions and hydrogen peroxide from the electron transport chain amplifying the redox stress until damage (Roehrs et al. 2009).

Mitochondrial DNA is exceedingly near the production site of the ROS; therefore, its performance can be reduced. The radical superoxide activates the UCP-2 (uncoupling protein 2) which can lead to reduction in the ATP/ADP ratio, and consequently insulin secretory response is also decreased. Insulin secretion could be influenced by mitochondrial regulation caused by chelation of ROS that can also prevent cellular damage and adjust the endogenous activities of the scavenging enzymes, which are increased by oxidative stress (Korichneva et al. 2003). Retinol is considered a part of general cellular defense due to its capability to protect (even partly) the mitochondria against the oxidative damage (Robertson et al. 2003).

2-Insulin Sensitivity

Vitamin A could increase insulin signaling or stimulate the insulin release, which both affect insulin sensitivity. Activation of PI3K (phosphatidylinositol 3-kinase) stimulated by RA has a new mechanism in which RA-RAR-binding mediated conjunction is created between p110 (which is a catalytic subunit of PI3K) and a compound containing the regulatory subunits of p85 and PI3K, RAR, and some other unknown proteins. RA appears to have a role in the activation of PI3K by involving in regulation of the intracellular site of the signaling compound. According to the results obtained from binding experiments and analysis of the crystal structure, it has been shown that all-trans RA (ATRA) could conjunct to the PKC isozymes, resulting in reduced activity of protein kinase C (PKC) (Masiá et al. 2007; Finel et al. 2005). It has been shown that this effect is beneficial in diabetes and is involved in decreased insulin-signaling power through affecting insulin signaling and PKC. Protein kinase C also intensifies oxidative stress by activating NADH. Vitamin A could modulate the PKC activity and consequently increase insulin sensitivity through increasing insulin signaling and decreasing oxidative stress (Rolo and Palmeira 2006, Draznin 2006). A lipophilic ligand of the nuclear hormone receptor superfamily which can be associated with the regulation of the transcription, ATRA, and pancreatic glucokinase activity could cause a retinol-meditated release of insulin (Cabrera-Valladares et al. 1999).

3-Obesity and Adipose Biology

Of the potential action sites targeted for retinoids are the retinoic acid receptor (RAR) and retinoid X receptor (RXR) expressed in the adipose tissue (Jeyakumar et al. 2007). It has been shown that retinol levels are low in the human fat tissue (Hong et al. 2004). Numerous studies have demonstrated that differentiation of adipocytes, possible effect of vitamin A on the adipogenic, and thermogenic capacity of rodents could be prevented by RA at high concentrations in vitro and expression

of brown adipose tissue (BAT)-uncoupling protein 1 (UCP-1) gene in vivo (Jeyakumar et al. 2006). It has been reported that secretion of leptin could be inhibited by 9-cis-RA (9cRA), while it can increase glucose uptake and adipogenesis in mature fat cells (Hong et al. 2004). Differentiation of fat cells can be prevented by binding of 9cRA to RAR which halts the transcriptional role of CCAAT/ C/EBPb (enhancer-binding protein beta) (Regazzetti et al. 2009; D'Ambrosio et al. 2011). Increased intracellular retinal levels caused by lack of retinal dehydrogenase 1 (RALDH 1) is associated with decreased adiposity. Retinol is converted to RA by an enzyme. The retinol ability to bind could be predicted at least in part. Retinol disrupts the activity of PPARg due to suppressing receptor activation by binding RXR and PPARg, which emphasizes the main role of retinol as a transcriptional regulator (Frey and Vogel 2011). UCP-1 gene can be positively regulated by vitamin A and one of its famous metabolites, RA. Despite reduced ATP levels, glucose transportation in the skeletal muscle can be enhanced because of overexpression of murine UCP-1. Insulin resistance in diabetes caused by high-fat regimens could be improved by the expression of hepatic UCP-1 (Rolo and Palmeira 2006); moreover, increased expression of UCP-1 results in thermogenesis. It is possible to control obesity through a regulatory function, so that vitamin A supplements contribute to reduced adiposity and increased thermogenic activity through removal of adipose storage and enhancement of BAT-UCP-1 gene expression, for example, in WNIN/ Ob strain (Jeyakumar et al. 2007). One of the inhibitory ways for adipogenesis is probably the use of retinoic acid, so that the master regulator of PPARg can control retinoid metabolism, according to new investigations (Frey and Vogel 2011).

Conclusion

VAD clearly demonstrates having a critical role in pathology of diabetes. VAD affects the pathology of type 1 and type 2 diabetes through several different mechanisms. VAD should be certainly considered an important factor and addressed, specifically in high-risk regions. Therefore, VAD should be extensively surveyed and monitored in affected regions. If VAD is proven to be an epidemic in any one region, deficiency correction policies and procedures should be implemented. In high-risk regions which more than likely happen to be low-income regions as well, prevention is a much more viable and cost effective option.

Policies and Protocols

- Megadose vitamin A capsules (200,000 IU) prescribed 6-monthly have been given to exactly 80% of 1–5-year-old children in developing countries up to now and are accounted for the decrease in the 1–5-year-old mortality.
- However, the adequacy trials on which this is based were directed more than 20 years ago. A single program assessment that has been completed in 2004 (DEVTA in India, 1999–2004) demonstrated no effect on mortality. Vitamin A

capsules decrease the mortality of diarrhea and measles, which have forcefully dropped as the result of implementation of comprehensive inoculatious and oral rehydration programs. Therefore, this regimen does not probably have any significant effect.

- The 6-month course of vitamin A capsules does not reduce vitamin A deficiency. VAD can be decreased by higher intake of vitamin A at physiological levels, by dietary modification, enrichment, and repeated (daily or weekly) supplements. Unlike high-dose vitamin A capsules, good responses have been observed following these methods in reproductive-age women (Mason et al. 2014).

Dictionary of Terms

- **Diabetes** – A Metabolic disease which characterized by high blood sugar, dyslipidemia, and insulin resistance.
- **Vitamin A** – One of the essential fat-soluble vitamins that have several roles in body like vision, immune system modulation, and epithelial tissue function.
- **Vitamin A deficiency** – Lack of vitamin A in diet that cause several damage to body function, like ocular problems and immune system dysfunction.
- **Xerophthalmia** – A severe vitamin A deficiency that characterized by sever visual problems and increased sensibility to infections.
- **Insulin Resistance** – Decrease sensibility of body cells to insulin that make them to need more insulin to response.

Summary Points

- This chapter is about the effect of vitamin A in pathology of diabetes.
- Vitamin A deficiency causes several metabolic problems including an increased risk of diabetes.
- Vitamin A deficiency can cause type 1 diabetes through its effect on immune system function.
- Because of vitamin A role in protection of body from oxidative stress and inflammation, vitamin A deficiency can cause type 2 diabetes because of oxidative stress and inflammation.
- Vitamin A supplementation has been effective in preventing diabetes in vitamin A-deficient societies.

Contents

Abstract

The fact that the world population could reach 8.5 billion by 2030 indicates the challenges of maintaining global food and nutrition securities, especially in low-income countries worldwide. The functions of nutrients to support human health and prevent diseases have been gradually recognized through the survival process of humankind. Micronutrients such as vitamin A are essential

for a variety of biochemical processes. The deficiency of a particular micronutrient is associated with certain symptoms. Depending on the length of time without food intake, humans and animals may experience fasting, starvation, and famine. This is accompanied by reduction of both macronutrients and micronutrients. This chapter is to summarize the role of vitamin A in the regulation of glucose and lipid metabolism and VA metabolism in the cycle of fasting and refeeding. We also would like to offer some future perspectives for vitamin A study.

Keywords

Fasting · Gene expression · Glucose · Lipid · Liver · Macronutrients · Metabolism · Micronutrients · Nutrition security · Refeeding · Retinoic acid · Vitamin A

List of Abbreviations

ALDH	Aldehyde dehydrogenase
CBP	Cellular retinol-binding protein
Gck	Glucokinase gene
Pck1	Cytosolic form of phosphoenolpyruvate carboxykinase gene
RA	Retinoic acid
RALDH	Retinaldehyde dehydrogenase
RAR	Retinoic acid receptor
RARE	Retinoic acid-responsive element
RBP	Retinol-binding protein
RDH	Retinol dehydrogenase
RXR	Retinoid X receptor
Srebp-1c	Sterol regulatory element-binding protein 1c
VA	Vitamin A
VAD	VA deficient
VAS	VA sufficient
ZL	Zucker lean
ZF	Zucker fatty

Introduction

Nutrition is the sum of processes of nourishing or being nourished in an organism. As an essential micronutrient, vitamin A (VA, retinol) is critical for the general health of the human body. The lack of VA leads to the development of diseases such as night blindness in humans. From a public health point of view, it is important to maintain the availability of VA to prevent the development of diseases in a population and an individual.

The Concept of Vitamin, the Discovery of Vitamin A, and Its Role in Public Health

The essentiality of VA to the health of an animal was not discovered due to its role in the treatment or prevention of night blindness. It was recognized by its activity to support animal growth. To discover the essential components in foods, synthetic diets made of purified ingredients were used to test their capability to support the growth or healthy status of animals for the goal of identification of hypothetical "vital amines" (Carpenter 2003). VA was found as a fat-derived factor supporting rat growth (Ross et al. 2012). When weaning rats (3 weeks of age) were fed a purified diet with fat extracted by ether, they only grew normally for about 40 days before the body weight gain stopped. The growth returned when VA-containing foods such as butter and egg yolk were included in the diet (McCollum and Davis 1913; Osborne and Mendel 1913).

As retinal, an oxidized product of retinol, takes part in the vision cycle, VA deficiency will lead to eye problems such as night blindness. In addition, VA deficiency may also increase mortality in children due to its role in immunity (Semba 2012). The lack of dietary VA intake is the major reason for the development of its deficiency. VA deficiency could also be observed in subjects with malfunctions of digestion and absorption in regions that have plenty of dietary VA sources (Hajar Al Binali 2014).

Due to the gradual growth of human population on this planet, food security and health problems have become challenges of human society for a while. Both Millennium Development Goals of United Nations Millennium Declaration in 2000 (Waage et al. 2010) and Sustainable Development Goals by United Nations General Assembly in 2015 (Lim et al. 2008) had pointed out these challenges. Hunger and malnutrition are major global health problems. For example, micronutrient deficiencies affect two billion population globally (Bhutta et al. 2013). According to the data collected in 1995–2005, 5.2 and 190 million preschool-age children might be affected with night blindness and at risk of VA deficiency (serum retinol concentrations <0.70 μmol/l), respectively (WHO 2009). It has been thought that 0.6 million deaths for children under 5 years old were due to VA deficiency (Black et al. 2008). A meta-analysis has indicated that significant reductions in mortality of children aged under 5 in VA deficiency regions were observed after its supplementation (Mayo-Wilson et al. 2011).

Molecular Pathways of Vitamin A Absorption and Signal Transduction

VA plays crucial roles in a variety of physiological functions ranging from vision to cell differentiation. Dietary molecules with VA activity are in two forms, preformed VA mainly as retinyl esters from animals and provitamin A as carotenoids from

plants (Ross et al. 2012). In the digestive tract, retinyl esters are hydrolyzed into retinol and fatty acids by lipases before they are absorbed into enterocytes (Harrison 2005). Provitamin A carotenoids such as β-carotene are absorbed into enterocytes without any modification. After absorption, β-carotene is converted into retinol eventually in both small intestine and liver cells (Lakshman 2004; Wyss 2004). Inside enterocytes, retinol is re-esterified with fatty acids to form retinyl esters again through the actions of lecithin-retinol acyltransferase and acyl-CoA-retinol acyltransferase. Retinyl esters and other dietary lipids are assembled into chylomicrons and delivered to other parts of the body. Retinyl esters in the chylomicron remnants are eventually taken up into hepatocytes for their uses or storage in the hepatic stellate cells (Blomhoff and Blomhoff 2006).

VA's metabolites, retinal and retinoic acid (RA), are the main mediators of its functions. Several enzymes and proteins are involved in the transport, production, and catabolism of retinoids. Retinol is oxidized to retinal (retinaldehyde). Then, retinal is further oxidized to RA (Blomhoff et al. 2006). These are processes catalyzed by enzymes (Duester 2000). RA mainly regulates gene expression in its targeted tissues and cells. This is achieved through the activation of retinoic acid receptors (RARs) and retinoid X receptors (RXRs)(Napoli 2011). These two members of nuclear receptor superfamily bind to retinoic acid-responsive element (RARE) and activate the transcription of RA-responsive genes (Evans 2005). Additional nuclear receptors have been suggested to mediate RA signals as well (Zhang et al. 2015a). One is hepatocyte nuclear factor 4α (Sladek et al. 1990). Another one is chicken ovalbumin upstream promoter-transcription factor II (Li et al. 2009), which interacts with RXRα to form heterodimer (Kliewer et al. 1992).

The Metabolic Changes During the Transition of Fasting and Refeeding

Depending on the length of time between two food ingestions, the subjects could be in the postabsorptive or fasting period that lasts several hours to a day or the starvation period that could last for days. Dramatic metabolic changes occur with the food ingestion in the body of the subjects. These include the switch of primary substrates for energy production and the changes of plasma levels of hormones responsible for the regulation of anabolic and catabolic states (McGarry et al. 1987).

The liver plays an essential role in the regulation of metabolic homeostasis. This is achieved, at least partially, through the regulation of expression levels of hepatic genes for glucose and lipid metabolism (Brown and Goldstein 2008). The transition of fasting to refeeding state is accompanied by the changes of the expression levels of genes, which are responsive to the stimuli of hormones such as insulin and glucagon. For instance, insulin increases the expression of genes involved in hepatic glycolysis, glycogenesis, and lipogenesis, and suppresses the expression of genes involved in gluconeogenesis, which correspond to the fed and fasted states, respectively. To facilitate the glucose usage in the fed state, insulin induces the expression of hepatic glucokinase gene (*Gck*), the first enzyme of hepatic glycolysis. At the

same time, insulin suppresses the expression levels of cytosolic form of phosphoenolpyruvate carboxykinase gene (*Pck1*) and glucose 6-phosphatase catalytic subunit, the enzymes involved in the early and late steps of gluconeogenesis, respectively (Hanson and Reshef 1997). To facilitate the hepatic lipogenesis in the fed state, insulin induces the expression level of sterol regulatory element-binding protein 1c (*Srebp-1c*), a master transcription factor that stimulates the expression of genes for the hepatic fatty acid biosynthesis (Horton et al. 2002). These genes are also regulated by glucagon, which activates protein kinase A pathway (Hardie and Carling 1997).

The Current Understanding of Roles of Vitamin A in Glucose and Lipid Metabolism

As early as 1937, the elevation of the hepatic VA content was observed in the liver samples of patients who died of diabetes, suggesting the role of VA in glucose metabolism (Moore 1937). Early studies had shown that the hepatic glycogen content was depleted in rats with VA deficient (VAD) status (Wolf et al. 1957). This depletion was not due to the reduction of food intake associated with the development of VA deficiency as rats in the pair-feeding group still had hepatic glycogen content. Our lab also reported the depletion of hepatic glycogen content in the liver of VAD rats recently (Zhang et al. 2012). Interestingly, rats fed a diet with excessive amount of VA had an increase of hepatic glycogen content (Singh et al. 1968).

VA status also affects the mRNA and protein expression levels of the hepatic glucokinase, the first enzyme for hepatic glycolysis (Li et al. 2016). In the liver, the *Gck* expression is reduced in fasting and increased upon refeeding. The induction and suppression of *Gck* mRNA level are attributed to the actions of insulin and glucagon, respectively (Iynedjian et al. 1989). In an attempt to identify lipophilic molecules with abilities to modulate the insulin-regulated gene expressions in hepatocytes, we have found that retinoids in the liver lipophilic extract synergized with insulin to induce *Gck* expression in primary rat hepatocytes (Chen et al. 2009). Retinoids synergized with insulin to induce the hepatic *Gck* expression through the activation of RAR/RXR (Chen et al. 2009). The levels of the hepatic *Gck* mRNA (Zhang et al. 2012) and glucokinase activity (Chen et al. 2009) in VAD rats were lower than that in VA-sufficient (VAS) animals.

Gluconeogenesis from endogenous noncarbohydrate sources is critical for the maintenance of plasma glucose level during fasting state. In the liver, the cytosolic form of phosphoenolpyruvate carboxykinase has been considered the first rate-limiting enzyme for gluconeogenesis (Hanson and Garber 1972). The hepatic *Pck1* expression is increased by fasting and diabetes and decreased by refeeding and insulin treatment. Glucagon, glucocorticoids, thyroid hormone, and RA induce hepatic *Pck1* expression, while insulin inhibits it (O'Brien and Granner 1996). Two RAREs have been identified in the hepatic *Pck1* promoter and have been shown to bind to several transcription factors (Scribner et al. 2007). We have shown that retinoids affect insulin-suppressed

Table 1 Comparisons of body and plasma parameters in fasting and VA deficiency

Parameters	Fasting	VA deficiency
Body weight	Reduced	Reduced
Fat mass	Reduced	Depleted
Liver mass (net)	Reduced	Reduced
Liver glycogen	Low	Low
Glucose	Low	Low
TAG levels	Low	Low
Insulin	Low	Low
Glucagon	High	Low
Leptin	Reduced	Low

Pck1 expression (Zhang et al. 2011). Interestingly, the hepatic *Pck1* mRNA level in Zucker lean (ZL) rats with VAD status is not reduced in comparison with that in VAS ZL rats (Zhang et al. 2012). However, VA deficiency reduced the hepatic *Pck1* mRNA in Zucker fatty (ZF) rats (Zhang et al. 2012).

VA status and retinoids also regulate lipid metabolism in animals. In rats, VA deficiency led to the loss of the carcass fat, but not cholesterol, with the reduction of body mass (Brown and Morgan 1948). RA such as isotretinoin (13-*cis* RA) has been used to treat patients with acne. Interestingly, significant portion of those patients developed hypertriglyceridemia (Bershad et al. 1985). In addition, RA-treated patients with acute promyelocytic leukemia gained body weight (Tallman and Kwaan 1992). The treatments of RA (Gerber and Erdman 1981)- and RXR-specific agonist (LG100268) (Davies et al. 2001) induced hypertriglyceridemia in rats. We have shown that retinoids synergized with insulin to induce the expression of *Srebp-1c* in primary rat hepatocytes (Li et al. 2011). The two liver X receptor binding sites (Chen et al. 2004) that mediate the insulin-induced *Srebp-1c* expression are also RAREs in the *Srebp-1c* promoter (Li et al. 2011).

In addition to the hepatic gene expressions, the VA status has been shown to affect insulin and glucagon secretions in pancreatic islets (Chertow et al. 1987, 1994). The glucose-stimulated insulin secretion is impaired in islets or the pancreas isolated from VAD rats, which can be restored after the replenishment of VA status in those animals. Table 1 shows the comparison of changes of body weight, fat mass, liver mass (net), liver glycogen, and plasma levels of glucose, plasma triacylglycerols, insulin, glucagon, and leptin in fasting and VA deficiency conditions.

VA Use and Metabolism in Different Cells

For their use and storage, retinoids and carotenoids are delivered to cells and tissues via multiple ways (O'Byrne and Blaner 2013). Retinol esters and carotenoids can be circulated in lipoproteins. In the postprandial state, retinyl esters in chylomicrons and their remnants are taken up by most cells and tissues. Retinyl esters and carotenoids may also associate with very-low-density lipoprotein, low-density lipoprotein, and high-

density lipoprotein. In the absence of food intake, retinol is mainly circulated in a complex containing retinol-binding protein 4 (RBP4), transthyretin and thyroid hormone. As the VA metabolite-regulating gene expression, RA is also present in circulation.

Retinoids and carotenoids are metabolized in a variety of cells (Ross et al. 2012). In enterocytes, retinol can be re-esterified into retinyl esters. Upon the entry, β-carotene is hydrolyzed into retinal, which is reduced by NADH-dependent retinal/retinaldehyde reductase to retinol. Retinol is then esterified by lecithin retinol acyltransferase to form retinyl esters, which are packed in chylomicrons for the transport to the lymph system and ultimately the circulation.

The liver is a significant site of VA storage and metabolism (Ross et al. 2012). Within hepatocytes, retinyl esters are hydrolyzed by retinyl ester hydrolase to retinol, which is then either esterified by acyl-CoA retinol acyltransferase as a free retinol or esterified via lecithin retinol acyltransferase if retinol is bound to cellular retinol-binding protein (CRBP). CRBP-bound retinol can be oxidized to retinal by NAD(P)H-dependent retinol dehydrogenases (RDHs) and then to RA by retinaldehyde dehydrogenases (RALDHs). RA binds to cellular RA-binding protein and then enters the nucleus to regulate gene expression. Further metabolism of RA occurs through the cytochrome P-450 enzyme system CYP26 in the liver and brain. In the liver, carotenoids undergo cleavage, incorporation into and release as part of very-low-density lipoprotein or other lipoproteins for storage or transport to other tissues. Locally, retinol can be transferred to the hepatic stellate cells for storage as retinyl esters in lipid droplets.

The adipose tissues also play a role in retinoid storage and metabolism (Bonet et al. 2012). Adipocytes take up circulating retinoid in the forms of chylomicron retinyl esters and retinol-RBP complexes, store it as retinyl esters with fatty acids, and convert retinol into RA for the regulation of adipogenesis. All adipocytes can account for 15–20% of the whole body retinoid stores in rats.

Early studies had shown that the secretion of insulin and glucagon was impaired in the pancreas isolated from VAD rats as reviewed in (Chen and Chen 2014). 9-cis RA has been observed in pancreatic β-cells and insulin secretion cells (Kane et al. 2010). We have shown that RA, but not retinal, induced *Srebp-1c* expression in INS-1 insulinoma cells (Chen et al. 2009; Li et al. 2011). Retinal can only induce *Srebp-1c* expression in INS-1 cells when RALDH1 was overexpressed, suggesting that pancreatic β-cells lack the enzymes oxidizing retinal to RA, such as RALDH1 (Li et al. 2012). The role of VA in the function of pancreatic β-cells needs further attention.

Current Understanding of Changes of the Enzymes Involved in VA Metabolism in the Development of Metabolic Diseases

To date, multiple RDHs and RALDHs (also known as aldehyde dehydrogenases, ALDHs) have been thought to be responsible for RA biosynthesis (Blomhoff et al. 2006). The alterations of VA metabolism have been associated with the metabolic diseases such as diabetes and obesity.

In the blood of patients with diabetes, the activity of ALDH1, an important enzyme to clear lipid peroxidation-derived aldehydes in red blood cells, was increased in comparison with that of the control subjects (Giebultowicz et al. 2014). The increase of ALDH1 activity seems to be associated with the severity of the disease and may be a compensatory effect against oxidative stress. In addition, the upregulation of RALDH1 (ALDH1A1) expression level has been observed in the kidney of *db/db* mice with decrease of RA level in the tissue, demonstrating the alteration of RA production in the diabetic state (Starkey et al. 2010). The increase of 13-*cis* RA has been considered as a consequence of increased *Raldh3* expression in pancreatic islets of high-fat diet-induced diabetic mice (Shimamura et al. 2010). Overexpression of *Raldh3* reduced insulin secretion but increased glucagon secretion in vitro, indicating that RALDH3 disrupts the balance between insulin and glucagon, and may induce β-cell dysfunction leading to the development of type 2 diabetes mellitus. These results indicate that RALDH3 is also associated with metabolic disease.

RALDH1 has been associated with obesity development and energy balance (Ziouzenkova et al. 2007). We have shown that both *Raldh1* mRNA and RALDH1 protein levels were elevated in the liver of ZF rats, which may cause the excessive RA production and result in higher *Srebp-1c* expression (Li et al. 2012). This may attribute to the elevated lipogenesis in ZF rats. Mice with deletion of *raldh1* gene (*raldh1*−/− mice) are resistant to high-fat diet-induced obesity and insulin resistance (Ziouzenkova et al. 2007). Originally, this was attributed to the reduction of peroxisomal proliferator-activated receptor γ activation in the presence of retinal in adipocytes. Alternatively, it was thought that the deficiency of *Raldh1* gene leads to an elevation of thermogenic program in white adipose tissue, a process that may promote energy dissipation (Kiefer et al. 2012). This may explain that *Raldh1*−/− mice display reductions of gluconeogenesis and hepatic lipogenesis (Kiefer et al. 2012). Later, it was suggested that RALDH1-derived RA promotes adipogenesis and RALDH1 deficiency impairs all-*trans* RA production, therefore decreasing adipogenesis (Reichert et al. 2011). The role of VA in the adipose tissues deserves further investigation.

It has been shown that rats fed a high-fat diet had an elevation of the hepatic RALDH activity and *Raldh1* mRNA expression, which are associated with downregulations of hepatic *Adh1* and *Rdh10* mRNA expression levels (Zhang et al. 2015b). This was attributed to the cholesterol intake accompanied by the feeding of the high-fat diet (Zhang et al. 2015b). Interestingly, the mouse *Raldh2* gene promoter contains a binding site for SREBPs (Wang et al. 2001). In addition, oxysterol induced *Raldh1* and *Raldh2* expression levels in the mouse liver and hepatoma cells via the possible activation of liver X receptors, which leads to the upregulation of SREBP-1c (Huq et al. 2006). There seems to be a link between cholesterol metabolism and RA production, a topic that remains to be determined.

Current Understanding of the Regulation of the Enzymes Involved in VA Metabolism in the Response to Physiological Changes

Theoretically, the rise and fall of the dietary amount of micronutrients should also send a signal to the body regarding the nutritional statuses. This signal should be integrated with the signals of macronutrients and hormones to contribute to the dynamic changes of the metabolism of the host.

As shown in Fig. 1, both insulin (a hormone) and RA (a metabolite of VA) can regulate the expression of genes critical for the hepatic glucose and lipid metabolism. We have shown that insulin synergizes with RA to induce *Gck* gene expression in primary hepatocytes (Chen et al. 2009). The RARE in the hepatic *Gck* promoter has been identified as a site interacting with multiple nuclear receptors (Li et al. 2014). We have also shown that insulin synergizes with RA to induce the *Srebp-1c* gene expression in primary hepatocytes, which is mediated by the two liver X receptor elements identified previously (Li et al. 2011). In addition, RA has been shown to attenuate the insulin-suppressed *Pck1* gene expression in primary hepatocytes (Zhang et al. 2011).

The cycle of fasting and refeeding is associated with the changes of expression levels of hepatic genes. These changes include the reduced expression levels of *Gck*, *Srebp-1c*, and *Fas*, and increased expression level of *Pck1* in the fasting state, which were reversed after refeeding as indicated in Table 2. Interestingly, the expression

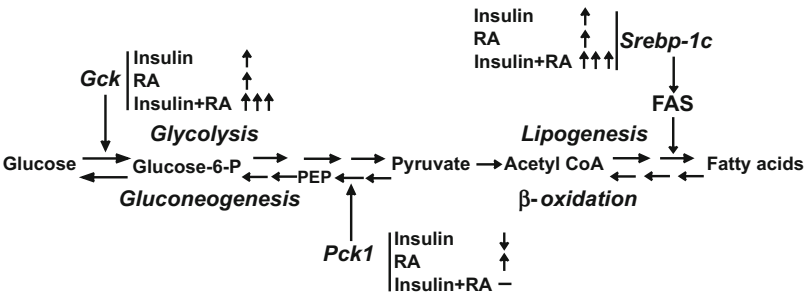

Fig. 1 Interactions of insulin and retinoic acid (RA) signaling in the regulation of critical genes for the hepatic glucose and fatty acid metabolism. Glucose is phosphorylated into glucose 6-phosphate by glucokinase (gene, *Gck*). Glucose 6-phosphate is converted into pyruvate via glycolysis. Pyruvate can be indirectly converted into phosphoenolpyruvate (PEP), a process that is mediated by phosphoenolpyruvate carboxykinase (gene, *Pck1*) in gluconeogenesis. Pyruvate is converted into acetyl CoA, which can be used for the synthesis of fatty acid via lipogenesis, a process mediated by fatty acid synthase (FAS). Acetyl CoA can also be derived from fatty acid through β-oxidation. FAS is induced by the activation of sterol regulatory element-binding protein 1c (gene, *Srebp-1c*), a gene that can be induced by insulin stimulation. RA synergizes with insulin to induce the expression levels of *Gck* and *Srebp-1c* genes. On the other hand, RA induces, and insulin reduces the expression level of *Pck1* gene. The presence of RA attenuated the insulin-reduced *Pck1* gene expression

Table 2 Comparisons of the changes of key representative hepatic genes of glucose and lipid in the cycle of fasting and refeeding

Genes	Fasting	Refeeding	VAS vs. VAD
Gck	Reduced	Increased	Higher
Pck1	Increased	Reduced	No change
Srebp-1c	Reduced	Increased	Higher
Fas	Reduced	Increased	Higher

levels of *Gck*, *Srebp-1c*, and *Fas*, but not *Pck1*, in the liver of VAD ZL rats experiencing the cycles of fasting and refeeding (Li et al. 2016) or fasted for 6 h (Zhang et al. 2012) were lower than that that of VAS ZL rats. This shows some similarities between VA deficiency and fasting as shown in Table 1. Indeed, the development of VA deficiency is associated with reduction of food intake (Chen et al. 2014; Zhang et al. 2012). It becomes reasonable when we observed that VA metabolism contributes to the regulation of the hepatic gene expression during the cycle of fasting and refeeding (Li et al. 2016).

It has been reported that refeeding after a 16 h fasting in mice resulted in the reduction of hepatic *Rdh1* and *Rdh10* mRNA levels and the reduction of hepatic RA content (Obrochta et al. 2015). This reduction of the gene expression can be observed in mice receiving the gavage of glucose or insulin injection after the fasting. The mechanism was attributed to the insulin-regulated activity of forkhead box protein O1 transcription factor, which regulated the hepatic *Pck1* gene expression (Obrochta et al. 2015). This insulin-reduced *Rdhs* expression can also be observed in cultured HepG2 cells (Obrochta et al. 2015). Unfortunately, when we analyzed the liver samples in VAS rats experiencing the cycle of fasting (48 h) and refeeding (for 6 h) (Li et al. 2016), no change of *Rdh2*, *Raldh1*, and *Raldh4* mRNA expression levels was detected (data not shown). Whether the refeeding time was not enough or too long for mRNA sample analysis or whether there is any change of the activities or protein levels of those enzymes remains to be determined.

Recently, we have observed changes of VA metabolic enzymes in another experimental setting related to fasting. VA deficiency leads to the reduction of food intake, which is similar to fasting state. Therefore, we have performed pair-feeding studies, in which ZL and ZF rats with VAS status consumed the same amount of the VAS diet in weight as the VAD diet consumed by VAD rats over an 8-week period of time (Chen et al. 2014). This caused a scenario, in which the VAS-pair-fed (VAS-PF) rats were in a fasted situation before they received their ration for the last day of the experiment. This was due to the reduced food intake of VAD rats in ad libitum state, which resulted in the lack of enough food for the VAS rats to consume over a 24-h period of time. Therefore, we created two groups of VAS-PF rats. The first group VAS-PF rats were allowed to consume as much VAS diet as they could (VAS-PF-AD group). The second group VAS-PF rats were fed the same amount of VAS diet in weight as that of VAD diet consumed by the VAD rats. To prevent the creation of a prolonged fasting state

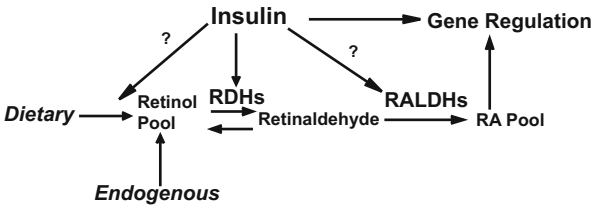

Fig. 2 Effects of insulin on retinol and retinoic acid (RA) pools for gene expression in hepatocytes. Retinol pool is derived from both dietary and endogenous sources. Retinol is reversibly oxidized into retinaldehyde by retinol dehydrogenases (RDHs), and retinal is irreversibly oxidized by retinaldehyde dehydrogenase (RALDHs) into RA. It has been shown that insulin can affect the expression levels of RDHs genes, which has the potential to regulate the sizes of retinol and RA pools. Whether insulin can regulate the entry of dietary retinol into cellular retinol pool and the activities or expression of RALDHs remains to be determined. RA and insulin work cooperatively to regulate gene expression in hepatocytes.

in VAS-PF rats, the VAS diet was divided into four equal portions and fed to them every 6 h (VAS-PF-AM). The VAS-PF-AD consumed more diet than the VAS-PF-4M rats during the 24-h period of time (Chen et al. 2014). The VAS-PF-AD ZL, but not ZF rats, had higher *Rhd2* and *Cyp26a1* mRNA levels than the VAS-PF-4M rats did. The VAS-PF-AD ZL and ZF rats had lower *Raldh1* mRNA level than the VAS-PF-4M rats did. The elevation of *Rhd2* and *Cyp26a1* expression levels suggests an increase of RA production as *Cyp26a1* is a very sensitive RA-responsive gene (Wang et al. 2002). As VAS-PF-AD rats consumed more VAS diet than VAS-PF-4M rats did, these changes of genes for VA metabolism and RA responses probably can be attributed to the effects of overfeeding on the VA metabolism in the liver.

We also have tested whether RA production is needed for the insulin-regulated hepatic gene expression (Li et al. 2017). We used streptozotocin to generate ZL diabetic rats with both VAD and VAS statuses and treated with vehicle control, insulin, RA, and RA + insulin for 3 h. The results show that insulin regulates the hepatic genes for glucose and lipid metabolism in VAD-diabetic rats, indicating that insulin functions in the absence of RA. However, RA still can modulate insulin-regulated gene expression in the liver of VAD-diabetic rats (Li et al. 2017).

As shown in Fig. 2, VA (retinol) in a hepatocyte can come from an endogenous pool or from a dietary source in a feeding status. During fasting, the VA from dietary source diminishes, which may change size of VA pool in hepatocytes. On the other hand, after feeding, the dietary VA enters the VA pool and contributes to the increase of the intracellular VA pool size. After a refeeding process, the dietary VA may be able to contribute to the cellular VA pool significantly. If insulin regulates the expression levels of genes involved in RA production, then these changes may indicate that there is a coordinative interaction between RA production and refeeding process. Theoretically, RA is dynamically produced and rapidly turned over inside a cell. At any moment, the cellular RA pool can be

from VA that derives from the dietary source or endogenously stored one. Since the plasma VA level is always maintained in a normal range for well-nourished individuals, the participation of dietary VA in the regulation of a hepatic gene expression can occur without any dramatic change of plasma VA levels.

Perspectives

VA was identified due to its ability to support the animal growth, an anabolic response. Famine, starvation, or any condition associated with reduction of food intake trigger catabolic states. The switch from fasting to feeding is accompanied by the changes of the expression levels of hepatic genes involved in glucose and lipid metabolism. The reduction of dietary VA as well as other macro- and micronutrients during the fasting should send the body signals to face the incoming catabolic changes. We have now begun to observe alterations of VA metabolism and its downstream RA signaling in response to the changes of feeding behavior. More studies are needed to define the role of VA in the fasting and starvation phase. This may help us to combat the food security and nutrient deficiency problems that may challenge human society when its population becomes larger and larger on this planet.

Policies and Protocols

The knowledge presented here has not been taken into policy considerations. However, the knowledge included here should be considered when policies are to be developed to deal with food or nutrition security. Many previous and current studies have demonstrated that vitamin A contributes to the glucose and lipid metabolism. Therefore, the ideal amount of micronutrients needed for the metabolism of macronutrients is something deserved to be considered. This will not only maximize the use of micronutrients in the prevention of nutrient deficiencies but also reduce the potential detrimental effects associated with overnutrition.

Dictionary of Terms

- **Glycolysis** – Glycolysis is the enzymatic pathway for the production of pyruvate from glucose.
- **Glucagon** – Glucagon is a catabolic hormone secreted from pancreatic α-cells to regulate metabolism.
- **Gluconeogenesis** – Gluconeogenesis refers to the enzymatic pathways for the production of glucose from noncarbohydrate precursors.

- **Insulin** – Insulin is an anabolic hormone secreted from pancreatic β-cells to regulate metabolism.
- **Lipogenesis** – Lipogenesis refers to the enzymatic pathways for the generation of lipids.
- **Nutrition** – Nutrition is the combined processes of nourishing an organism for the proliferation, growth, and aging across its life span.
- **Preformed vitamin A** – Preformed vitamin A refers to dietary molecules derived from animal products containing vitamin A activity such as retinol and retinyl esters.
- **Provitamin A** – Provitamin A refers to dietary molecules derived from plant products that can be used to generate retinol such as carotenoids.
- **Retinyl ester** – Retinyl ester is the retinol linked to a fatty acid through an ester bond.
- **Vitamin A** – Vitamin A is a micronutrient with activities derived from retinol or molecules leading to its production.

Summary Points

- Potential challenges of food security and nutrition due to the rise of human population on this planet require further understanding of the roles of nutrients in the control of human health.
- Diets provide both micronutrients with regulatory roles and macronutrients with energy for the body.
- The cycle of fasting and refeeding in the feeding behavior is associated variations of entries of micronutrients and macronutrients into the body.
- The liver is critical for the switch of fasting (a catabolic state) to refeeding (an anabolic state) in the metabolic homeostasis.
- The changes of hepatic gene expression levels are at least partially responsible for the switch of metabolic states.
- As an essential micronutrient, vitamin A was first discovered due to its role in the support of animal growth, an anabolic process.
- Recently, we have found that vitamin A status plays a role in the regulation of the hepatic glucose and lipid metabolism and body weight.
- The development of vitamin A deficiency in animals is associated reduction of body weight and expression levels of genes for glucose and lipid metabolism, very similar to the fasting or starvation.
- Vitamin A is oxidized into retinal and then to retinoic acid, which is the primary metabolite to regulate gene expression in cells.
- Insulin and retinoic acid work cooperatively to regulate expressions of genes involved in the hepatic glucose and lipid metabolism.
- Insulin may regulate the production of retinoic acid in hepatocytes.
- Vitamin A metabolism or retinoic acid production in hepatocytes may contribute the gene expression changes during the cycle of fasting and refeeding in the liver.

Abstract

Thiamine is a water-soluble vitamin, essential for normal cellular functions and energy production. As it is not synthesized by the human organism, it must be obtained by exogenous sources. A reduction in thiamine tissue concentration may interfere with numerous cellular mechanisms triggering off neurodegenerative processes with consequent changes in brain functions. Thiamine deficiency is common in certain groups like alcohol chronic users, pregnant woman, and people living in food insecurity situation. The low offer of thiamine for newborn and infants can compromise the correct maturation of the central nervous system and development of the cognition as explained by animal models studies. Thiamine deficiency during pregnancy and breastfeeding induces dysfunctions in the learning and consolidation of spatial abilities of offspring that can compromise the access of children living in food insecurity situations to formal job and education. Observed from this perspective, thiamine deficiency in vulnerable populations plays a more important role than the manifestation of clinical syndromes: the thiamine deficiency can be understood as a mechanism for perpetuating the poverty condition. Based on favorable risk/benefit profile, we recommend the fortification of easily accessible foods (such as wheat flour) with thiamine and oral replacement for alcohol dependent people, pregnant women, and infants living in situations of food insecurity.

Introduction

Vitamin B1, thiamine, reveals various biological functions and its deficiency can cause significant physical damage not only to the individual but also to the community. As the deficiency is related to social vulnerability situations, understanding the relation of thiamine deficiency with poverty may have repercussions on interventions with a high potential for changing the situation of the vulnerability of specific communities. Thus, this chapter seeks to show the biological functions of thiamine; to discuss the relationship of the deficiency in special situations, for instance, in the use of alcohol, during gestation, and breast-feeding; and to list these conditions with poverty and show health interventions.

Biological and Nutritional Aspects

Thiamine is a water-soluble vitamin, essential for normal cellular functions and energy production. Its chemical structure consists of a pyrimidine linked to thiazole by a methyl bridge; both fractions (pyrimidine and thiazole) are necessary for its biological activity. It is stable in pH acid, but becomes unstable in alkaline solutions, high temperatures, or when exposed to ultra violet light (Sardesai 2003; Bémeur and Butterworth 2014).

As it is not synthesized by the human organism, it must be obtained by exogenous sources through food and food supplements (Bettendorff 2012). It can also be produced by microbiota bacteria normal bowel, possibly by local nutrition of the colonocytes, as until now the contribution of this by human metabolism has not been proven.

It is found in the organism mainly in its phosphorylated forms: thiamine monophosphate, thiamine diphosphate, and thiamine triphosphate. About 80% of thiamine found in the body corresponds to thiamine diphosphate, its main active form; 10% is found in the form of thiamine triphosphate and the rest corresponds to free thiamine and monophosphate (Fig. 1) (Sardesai 2003).

Therefore, its presence is essential for the production of energy by the Krebs Cycle, lipid metabolism and glucose, the production of amino acids of the branch chain, and the production and maintenance of the myelin sheath. As well as this, it is necessary for the synthesis of the acetylcholine neurotransmitters, the acid aminobutryic gamma, and glutamate (Monograph, 2003). Its action on the pathways of glucose utilization has great importance on the central nervous system, which needs continuous supply of this nutrient. Thus, the neurobiological repercussions of thiamine deficiency have great clinical importance and will be prioritized in this chapter.

Food Sources

Thiamine is present in various food sources vegetable and animal. However, in larger quantities, it is found only in periocarp and cereal germ. Therefore, as a great amount is lost during its refinement process, many industrialized food stuffs are enriched with this nutrient (Sardesai 2003).

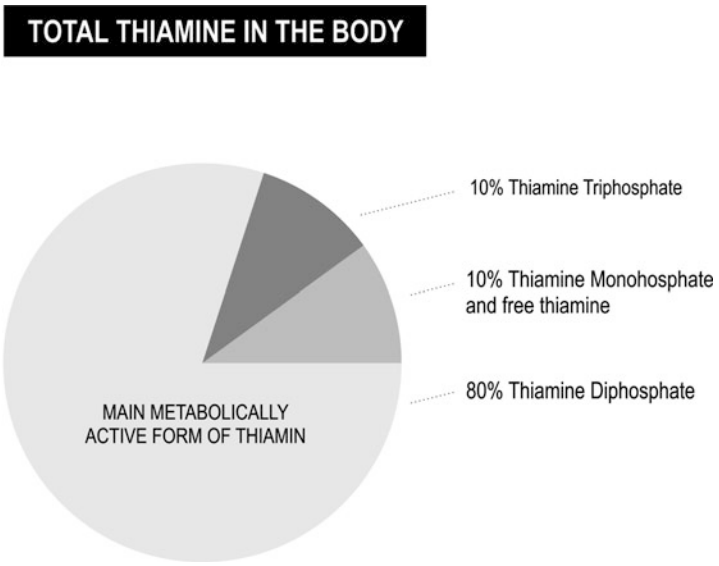

Fig. 1 Thiamine forms in human body. Approximate distribution of thiamine in human body (Source: Sardesai 2003)

Its natural sources include yeast, whole grains like wheat, oats and rice, meat (especially pork), green vegetables, fruit, roots, and legumes. It is not found in fat, oils, or sugar, and milk and derivatives are not considered good sources (Bettendorf 2012).

The breast milk of a well nourished mother supplies adequate quantities of thiamine. However, as the maternal diet is the main determinant of babies nutrition, those breast fed by mothers with lack of thiamine are at risk of developing the deficiency (Who 1999). Thiamine is stable for storage, but the way of preparing the food can change the final content.

Procedures that involve heating up, like prolonged boiling and milk pasteurization, can result in a considerable loss of vitamins, which are sensitive to high temperatures. There are also important losses in the discarded boiling water, since it is a water-soluble vitamin. That is why re-use of the water is recommended for the preparation of other food.

Dietary Recommendations

The recommended daily ingestion (RDA) is shown in Fig. 2 (IOM 2006).

Generally oral ingestion of high doses does not present adverse effects (Sardesai 2003). However, its intravenous administration may lead to respiratory depression and neuromuscular block. In human beings, the anaphylactic reactions are a rare complication of intravenous administration of thiamine (Bettendorff 2012).

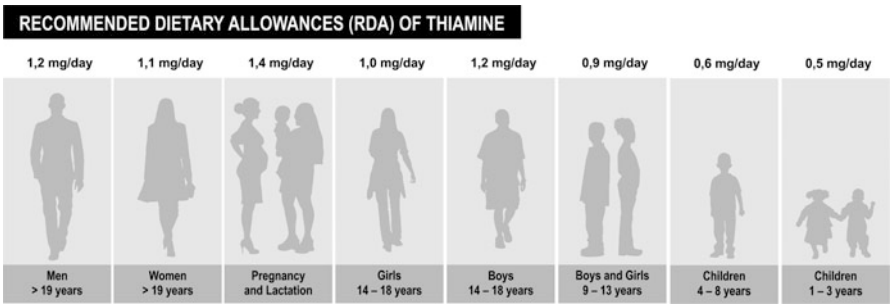

Fig. 2 Recommended Dietary Allowances (RDA) of thiamine by age range. Recommended dietary allowances represent the minimum amount of thiamine ingestion for a healthy person. These values may be insufficient in presence of some diseases (Source: IOM 2006)

Absorption and Metabolism

Adequate ingestion and intestinal absorption determine the availability of thiamine for the biological functions. Its absorption is measured by specific carriers, in a process regulated by innumerable factors and conditions, as what happens in relation to other water-soluble vitamins.

In foods of plant origin, most of the vitamins are found in a nonphosphorylated form. The opposite happens with vitamins of animal origin, in which the predominance of thiamine is in phosphorylated form (Sardesai 2003). To be absorbed, the phosphorylated forms are hydrolyzed by phosphatases in the intestinal lumen and converted into free thiamine, capable of penetrating the cell membrane from two mechanisms depending on the concentration.

1. In concentrations superior to 2 μm, thiamine is absorbed by passive diffusion.
2. In concentrations lower then 2 μm, it is absorbed by an active process depending on sodium and ATP, with the involvement of a specific carrier.

The carriers involved are THTR-1 and THTR-2 expressed in the small and large intestines expressed more significantly in the small intestine (Subramanya et al. 2010).

Following the intestinal absorption, the thiamine is carried in the blood to the liver, both to the erythrocytes and the plasma which are linked to proteins.

It is stored in low quantities, around 25–30mg, above all in the organs with high metabolic need, like the skeletal muscle, the heart, the brain, the liver, and kidneys. Figure 3 shows a simplified schematic of the process described above.

As thiamine is not stored in significant quantities, a continuous supplement of this vitamin is through food consumption, as in a state of insufficient intake, signs of deficiency may appear within 2–3 months (Who 1999) and in the case of absence, body reserves can run out in 2–3 weeks (Sechi et al. 2016).

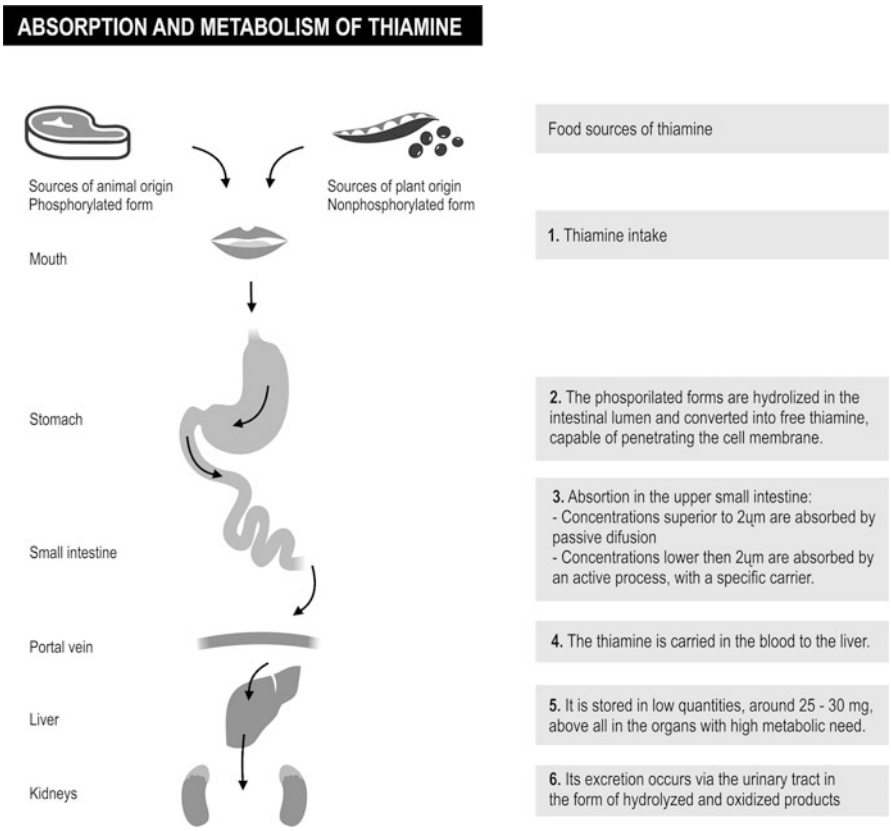

Fig. 3 Absorption and metabolism of thiamine. Simplified absorption and metabolism of thiamine in the human body (Source: Unpublished personal figure)

The main conditions of imbalance which can provoke its deficiency include: chronic use of alcohol, bad nutrition, loss of thiamine due to recurrent vomiting or bad absorption, an increase in the necessity for thiamine due to pregnancy or chronic illnesses, prolonged consumption in excess of carbohydrates, and gastrointestinal surgical procedures including gastrectomy and bariatric surgery (Sechi et al. 2016).

Clinical Thiamine Deficiency

Initial deficiency of thiamine can generate subjective complaints such as drowsiness, stomachache, constipation, weakness of the limbs, fatigue, postprandial plentitude, irritation, paresthesias, edema, palpitations, and lack of memory (Who 1999).

The symptoms can persist in this chronic state or as the deficiency progresses, more specific symptoms may appear, characterized by an acute condition with cardiac involvement and edema or peripheral neuropathy, due to the inhibition of a

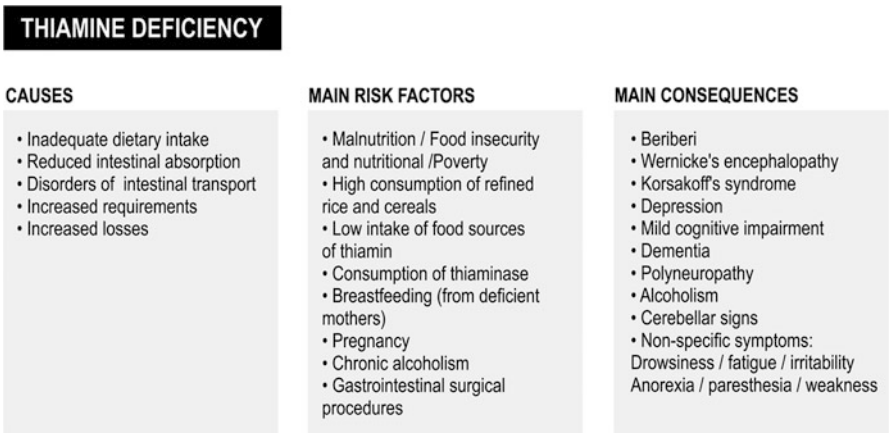

Fig. 4 Main causes, risk factors, and consequences of thiamine deficiency. The squares represent (from left to right) the main causes of thiamine deficiency, risk factors associated with this form of subnutrition, and the possible clinical outcomes (Source: Unpublished personal figure)

series of reactions in which thiamine dyphosphate acts as a coenzyme, thus, establishing Beriberi, one of the main diseases related to the major deficiencies of thiamine.

The World Health Organization (WHO) advises against using the term Beriberi substituting it for the term “thiamine deficiency with peripheral neuropathy” in cases of manifestations related to dry Beriberi, “thiamine deficiency with cardiopathy” referring to wet Beriberi and "thiamine deficiency with lactic acidosis” referring to Beriberi Shoshin (Who 1999).

Another related form of thiamine deficiency affects infants, breastfed by mothers with thiamine deficiency, usually asymptomatic. As the developing brain is more sensitive, symptoms appear acutely and mortality rates are high, with death occurring within a few days. The initial aspect is characterized by restlessness, crying, constipation and occasional vomiting, progressing with generalized edema, dyspnea, cardiac disturbance, gastrointestinal disorders, and oliguria (Who 1999).

Figure 4 summarizes the main causes, risk factors, and consequences of thiamine deficiency.

Poverty, Chronic Use of Alcohol, and Thiamine Deficiency

The Use of Alcohol and Thiamine

Among the biological consequences of the harmful use of alcohol, there is a high prevalence of the deficiency of complex B vitamins (Cook et al. 1998), of which thiamine is prominent. The chronic use of alcohol provokes a reduction in the absorption of thiamine, impaired use, increased metabolic demand, reduced hepatic stock, increase of urinary loss, as well as the usual inadequate global nutritional

intake (malnutrition) of these individuals. In relation to intestinal absorption, chronic alcohol consumption exerts a specific tissue effect, causing a significant inhibition of the absorption of thiamine through the brush and basolateral border membranes, associated to a decrease in the expression of the THRT-1 carrier in both membranes, apparently without affecting the carrier THTR-2 (Subramanya et al. 2010). It can be concluded that people who have problems with the use of alcohol present more health problems caused by the lack of thiamine.

The classification system of mental disorders "International Classification of Diseases" (ICD-10) categorizes the problems related to the chronic use of alcohol in abuse and dependence (ICD-10 2016). In general, abuse is characterized by the recurrent use of the substance leading to possible loss of capacity to deal with daily obligations, legal, social interpersonal and risk exposure, within a period of twelve months. Dependence is defined by the continued use of the substance, with a set of cognitive, behavioral symptoms characterized mainly by tolerance, withdrawal symptoms, and compulsion.

Screening individuals who make bad use of alcohol is justified by the increased risk of harmful consequences for their physical and mental health, as well as the problems caused to their families and society, since the patterns of dangerous consumption are of great importance for public health. Hence, diagnostic instruments that allow the health team to stratify the use are fundamental (Babor et al. 2001).

For the screening and detection of people with alcohol use, two instruments will be shown which have easy application and are extremely valid: CAGE (Fig. 5) and AUDIT (Fig. 6).

In the case of using CAGE, a result is considered positive when an affirmative answer is obtained for two or more questions. It is important to emphasize that the questionnaire does not diagnose dependence but rather demonstrates the high probability of the presence of the disorder, which should alert the interviewer to continue the approach, as these people would benefit from reducing or stopping consumption of alcoholic beverages (Ewing 1984). Recommendation of the use of CAGE lies in its high sensitivity and the possibility of any professional in the health area to apply it and start a closer relationship with the patient.

As thiamine plays a key role in the central nervous system, alcohol-induced deficiency can lead to a severe neurodegenerative process, culminating in neuronal death. In addition to thiamine deficiency, the direct neurotoxic effect of alcohol acts

Fig. 5 CAGE Questionnaire: questions and interpretation. Questionnaire for screening problems with alcohol use. Positive screening in CAGE questionnaire demands further diagnostic evaluation (Source: Ewing 1984, p. 1907)

AUDIT QUESTIONNAIRE

Question domain	Question	Content
Hazardous alcohol use	1	Frequency of drinking
	2	Typical quantity
	3	Frequency of heavy drinking
Dependence symptoms	4	Impaired control over drinking
	5	Increased salience of drinking
	6	Morning drinking
Harmful alcohol use	7	Guilt after drinking
	8	Blackouts
	9	Alcohol-related injuries
	10	Others concerned about Drinking
Result	**Score**	**Recommended course of action**
Questions have a score range of 0 – 4 points	0 - 8	Advice focused on the reduction of hazardous drinking.
	16 - 19	Brief counseling and continued monitoring
	20 or more	Further diagnostic evaluation for alcohol dependence

Fig. 6 AUDIT Questionnaire: questions, scores, and interpretation. Audit table contents are adapted from *World Health Organization – the alcohol use disorders identification test*. Full explanation and printable version of the test can be found at: http://www.who.int/substance_abuse/publications/audit/en/

in conjunction, revealing a higher prevalence of neuropsychiatric conditions in these patients (Bettendorff 2012). Thus, the neurodegenerative processes caused by alcohol use may provoke mild clinical cognitive, impairment, dementia, Wernicke's encephalopathy, or polyneuropathy (Zimatkin and Zimatkina 1996).

Approximately 50–80% of individuals in chronic use of harmful alcohol have, to some extent, cognitive functions impaired, which is sometimes not diagnosed (mild cognitive impairment that does not bring about functional problems, only diagnosed by neuropsychological tests; or dementia, with impact on the functional life of the patient). In these patients, diffuse atrophy of the central nervous system (enlargement of the ventricles and cortical reduction) and significant hippocampal atrophy can be observed. The clinical characteristics of impairment include limited learning capacity, coding, and

memory recall deficiency and altered visuospatial and executive functions (Bernardin et al. 2014). Patients who have cognitive alterations due to the use of alcohol seek treatment the least, making their condition worse. Therefore, a cognitive approach is an important health practice for the treatment of people with alcohol problems.

Polyneuropathy caused by chronic thiamine deficiency is characterized by being distal, sensorimotor, with greater involvement of the lower limbs in comparison to the superiors. Its onset is usually slow, with bilateral paresthesia, distal and painful. Distal motor weakness can lead to the illness known as "fallen foot" which is relatively common with variable muscle weakness in the lower limbs (Sechi et al. 2016).

Wernicke's encephalopathy occurs acutely and is characterized as triad: mental confusion, ophthalmoplegy, and ataxia, but not all elements are present at diagnosis (Bettendorff 2012). Its manifestation is commonly associated with alcohol abstinence, but it can also occur with people who are nonconsumers, for example with patients with gastric carcinoma (Zimatkin and Zimatkina 1996).

In these people, a significant reduction in the activity of thiamine-dependent brain enzymes is observed. Its neuropathology characteristic involves neuronal loss, microhemorrhages, and gliosis in the mammillary region and in the paraventricular periaqueductal (Thomson et al. 2009). Although this is common, it is often undiagnosed (Thomson et al. 2009).

Early treatment with high doses of thiamine permits a quick reserve of some cognitive and neurological deficiencies as well as preventing the development of structural lesions. To avoid further complications, thiamine must be administered prior to glucose replacement (Galvin et al. 2010).

If left untreated, Wernicke's encephalopathy may lead to death (20% mortality) or Korsakoff syndrome can develop which can be understood as chronicity, which is irreversible even with the use of thiamine (Sechi et al. 2016). Patients that develop Wernicke's encephalopathy because of other conditions not associated with the use of alcohol rarely evolve Korsakoff syndrome, indicating the synergistic effect of thiamine deficiency and alcohol neurotoxicity (Thomson et al. 2009).

Clinically, Korsakoff syndrome is characterized by recent memory impairment and affected individuals tend to repeat the same questions and fail to recognize people they know after the onset of the illness. In spite of mainly affecting the consolidation of recent memory, there may be an effect on past memory too. The individuals become disorientated and tend to invent situations and fill in memory gaps with false facts (Thomson et al. 2009).

The structural brain lesions found in Korsakoff's psychosis affect mainly the mammillary region, the mammillothalamic tract, and the anterior thalamus (Sechi et al. 2016), and the amnesia is probably due to the interruption of the diencephalic-hippocampal circuits (Thomson et al. 2009). That is, it is an extremely severe, dysfunctional condition that must be prevented with the replacement of thiamine for patients who develop Wernicke's encephalopathy.

In view of this, it is understood that for this group that consumes alcohol in a chronic and harmful way and that have an insecure food diet, the prophylactic use of thiamine must be considered, seeking to prevent all of the mentioned clinical disorders. In spite of the replacement of thiamine orally showing some controversy

concerning its effectiveness, such as the inhibition of intestinal absorption of thiamine by alcohol, a recommended practice for harm reduction (Galvin et al. 2010). In the case of prophylactic administration via parental, there are no studies evaluating its benefits nor evidence of effective dosing, but the biggest difficulty of administration, cost, and human resources may hinder its use.

Also, once people with alcohol problems present increased risk for other vitamins of B Complex, replacement of thiamine together with the other complex B vitamins necessary is recommended (Sechi et al. 2016).

In addition, knowing that the metabolism of thiamine and of magnesium are interdependent, it is fundamental that the levels of this micronutrient are monitored; this is because deficiency can cause thiamine tissue loss and reduction of enzymatic activity, as well as impairing the response to the administration of thiamine (Zieve 1969).

We suggest a simple and low cost approach to be applied in chronic alcohol users (Fig. 7), which could signal early the need for thiamine replacement, in order to prevent further harm to the health of these individuals.

The Use of Alcohol and Poverty

Although alcohol is a common denominator in the lives of many poor families, there are few strategies for addressing poverty in relation to its use (Samarasinghe 2014).

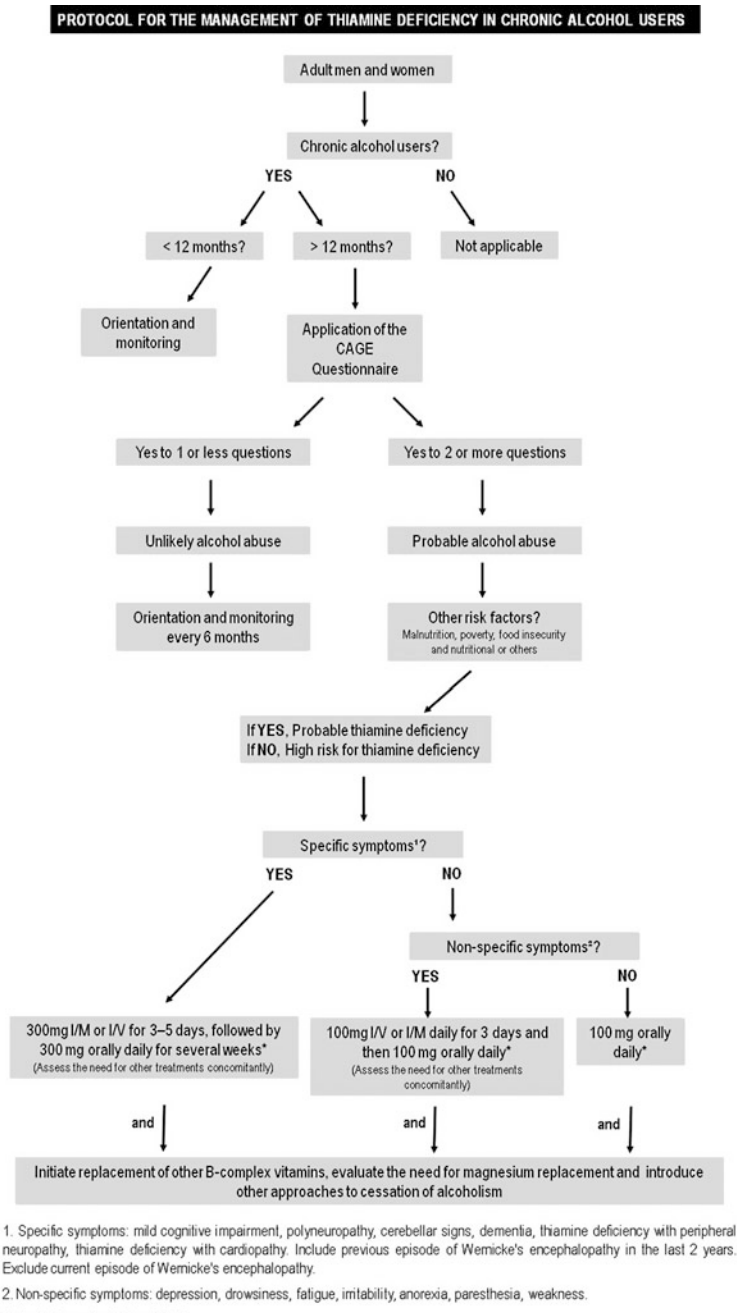
Alcohol can influence people's economic status, just as economic status can determine the use of alcohol. In the case of poor families, its use can have a great negative influence, since they are economically vulnerable and small changes can destabilize their daily economy, reducing their disposable income for basic necessities, such as food, being significantly responsible for poverty, and precarious health (Samarasinghe 2014).

Excessive use of alcohol contributes to prolonged social economic problems, interfering with education, health, and nutrition. It contributes to an increase in criminality, of domestic violence, overloads the health system, and is one of the main causes of incapacity.

It is therefore extremely important to investigate how poverty and chronic consumption of alcohol are interlinked, in order to take a new look at public policies, due to the fact that the reduction of poverty should not only focus on the increase of family income but in the way these families use the money available, as little as it may be (Samarasinghe 2014).

Even though of a lower socioeconomic level this does not mean that these people drink more than others, they seem to be more vulnerable to the consequences of alcohol consumption, due to lack of resources. They have less ability to avoid the adverse consequences of this behavior, making access to support health services difficult (Who 2014). The cause of thiamine deficiency, like poor alimentation (food), also neurobiological and behavioral can be explained, at least partially, the main deleterious impact is that the use of alcohol causes social vulnerability.

Approximately 30–80% of alcohol dependents have thiamine vitamin deficiency (Cook et al. 1998). This deficiency can make socioeconomic conditions worse for those who live in poverty. For example, the initial manifestations of deficiency can



1. Specific symptoms: mild cognitive impairment, polyneuropathy, cerebellar signs, dementia, thiamine deficiency with peripheral neuropathy, thiamine deficiency with cardiopathy. Include previous episode of Wernicke's encephalopathy in the last 2 years. Exclude current episode of Wernicke's encephalopathy.

2. Non-specific symptoms: depression, drowsiness, fatigue, irritability, anorexia, paresthesia, weakness.

* Adapted from: Latt, Dore, 2014.

Fig. 7 Suggested protocol for the management of thiamine deficiency in alcoholics. Suggested protocol for the management of thiamine deficiency in alcoholics. These individuals should be guided and monitored continuously, as well as the doses of thiamine administered and symptomatology reported individually (Source: Unpublished personal figure)

include irritability, fatigue, queasiness, and depression (Cook et al. 1998). These symptoms may harm the individual's family relationship, leading to a decrease in their productivity at work and an increase in the use of alcohol which, in the long term, can lead to neuropsychiatric impairment and the appearance of irreversible lesions, causing definite incapacitation.

Thus, it can be seen that in the face of a complex association between poverty and alcohol use, evaluation of nutritional aspect, specifically thiamine, becomes a fundamental health measure in vulnerable communities. The replacement of thiamine can represent a reduction in harm caused by the use of alcohol, diminishing the social impact of its use.

Pregnancy, Breastfeeding, and Thiamine

Pregnancy and Social Vulnerability

The state of pregnancy is responsible for the depletion of various metabolites essential for the maintenance of maternal homeostasis and fetal development (Black et al. 2008; Swaminathan et al. 2015).

This occurs due to an increase in metabolic demand for the formation of the fetus. Thiamine deficiency in pregnancy is related to an increase in morbidity and mortality of babies, especially if associated with other risk factors for malnutrition. As thiamine acts in metabolic processes fundamental for the Central Nervous System, its deficiency, from the neurobiological point of view, can cause neurodegenerative processes and consequent impairment in cognitive and emotional functions.

Thiamin deficiency is not a rare phenomenon in pregnancy and can occur in up to 27% of healthy pregnant women in the first 3 months of pregnancy, even as they receive adequate nutritional oral supplementation of this vitamin (Bakker et al. 2000; Baker et al. 2002). In part, this deficiency can be explained by the quick build-up of this vitamin and its metabolites on the fetal tissues (Bakker et al. 2000).

There is a relationship between groups with social vulnerability, that is, people living in extreme conditions and with thiamine deficiency. Groups of prisoners, people in refugee camps, and populations in situations of extreme poverty are more inclined to develop deficiency of this nutrient (Basoglu et al. 2006; Adamolekun 2010).

Thus, in vulnerable populations, thiamine deficiency in pregnancy is even more frequent: research done in a refugee camp showed that 58% of pregnant women had deficiency of this micronutrient, even after oral supplementation. In the population considered in this study, thiamine deficiency was the main cause of infant mortality (Mcgready et al. 2001), a fact that alerts us of the severe effects of malnutrition associated to pregnancy. It is emphasized that the methods of thiamine dosage and its concentration in the blood are difficult to be used in clinical practice, or to show indirect results, such as the evaluation by the activity of transketolase, or for being expensive as is the use of HPLC equipment. Therefore, it is soon realized that the identification of pregnant women in situations of social vulnerability is an important practice in order to diagnose thiamine deficiency in pregnancy.

Poverty and other social conditions of vulnerability are directly linked to food insecurity. The United Nations Food and Agriculture Organization (FAO) defines food security as "A situation that exists when all people, at all times, have physical, social and economic access to sufficient, safe and nutritious food that meets their dietary needs and food preferences for an active and healthy life" (FAO 2002). Thus, in general terms it can be assumed that food insecurity is caused by the absence of consistent, adequate food in sufficient quantity (Wight et al. 2014).

The measurement of food insecurity can be done by various methods, each one associated to specific limitations and advantages. Among these methods are included anthropometric evaluations, of household expenses and of food consumption, and national inquiries about the available caloric per capita. All of these methods, however, are indirect measures of the phenomenon, being done by the use of scales based on a food insecurity experience which is the only one in writing (Pérez-Escamilla et al. 2008). Of the scales available, the US Household Food Security Survey Measure Stands Out (HFSSM), whose development was coordinated by The United States Department of Agriculture (USDA) bringing with it, its main advantage, ample use, and validity in a wide range of languages and for various contexts sociocultural (Table 1) (Pérez-Escamilla et al. 2008; USDA 2012).

Scales such as the HFSSM provide objective parameters for screening at-risk families. The use of these tools may constitute an important health practice for the evaluation of groups in food insecurity situations especially, for pregnant women and children, increasing sensitivity of the screening programs, nutritional evaluation, and prenatal care. Not less important, its use enhances the stratification of necessary risks for the definition of public health policies, as well as allowing early intervention – before they become perceptible clinical manifestations and laboratory tests for malnutrition.

Thiamine Deficiency and Perpetuation of Poverty

Although clinical studies on the effects of maternal thiamine deficiency and their impacts on the cognitive development of a newly born baby are still scarce, there are solid indications that point to this phenomenon (Dias et al. 2013).

Thiamine plays a key role in neuronal physiology (Zhang et al. 2011). In CNS, in addition to the well-described metabolic function of thiamine as a cofactor of enzymes involved in glucose metabolism and in the synthesis of neurotransmitters, various researchers have suggested other roles nonmetabolic for thiamine. Among these functions, stabilization of the structure and function of the plasmatic membrane, participation in phosphorylate signal transduction paths, and action against agents which induce cytotoxicity can be highlighted (Bâ et al. 1996; Bâ 2008). In addition, studies suggest that thiamine may play a role in the modulation of iconic channels and nerve conduction (Ramakrishnan et al. 1999; Oliveira et al. 2007).

A reduction in thiamine tissue concentration may interfere with numerous cellular mechanisms triggering off neurodegenerative processes with consequent

Table 1 HFSSM score interpretation

For households with one or more children

This scale composed by different sections based on the households characteristics: questions for all households, question for households with one or more children, and questions and adult referenced questions. Low and very low food security are positive screening for food insecurity

changes in brain functions (Martin et al. 2003). It is interesting to note that the neurogenerative process does not happen in a generalized way in the CNS, because there are brain regions more sensitive to the deficiency like thalamus, striated, and cerebellum. We infer that the greater sensitivity of neuronal areas reinforces the importance of thiamine in other biological processes in the CNS and not only as a coenzyme of carbohydrate metabolism.

Animal models demonstrate that thiamine deficiency during pregnancy and breastfeeding induces dysfunctions in the learning and consolidation of spatial abilities of offspring. This phenomenon is probably related to deficiencies in systems GABA and glutamate neurotransmitter (Dias et al. 2013). Furthermore, maternal thiamine deficiency is associated to motor development and also to memory formation of the offspring. There were losses in neurobiological processes such as cell proliferation, migration, and differentiation and synaptogenesis, axogenesis, and myelinogenesis (Bâ 2011). Therefore, thiamine deficiency during pregnancy and breastfeeding can cause damage to the formation and structuring of the baby's brain tissue, leading to cognitive impairment.

In this way, children of mothers who live in a situation of social vulnerability are subject to the risks of malnutrition and, consequently, of thiamine deficiency. It should be remembered that these children are exposed to hostile environments, with a low supply of nutrients and lack of psychosocial stimuli fundamental to their development. Born into these conditions, there is a commitment to the full development of their academic abilities being productive in the future. Children coming from this deprived environment can become adults unable to achieve social mobility, that is, to get out of poverty. In this scenario, it is understood that continuing in poverty is not only due to social factors, such as the lack of an educational system of quality, malnutrition, more specifically thiamine deficiency, constituting a determinant factor of poverty in communities with social vulnerability.

The Approach to Thiamine Deficiency During Pregnancy and Breastfeeding

The pharmacokinetics of thiamine and its response-curve to maternal supplementation is still not well established (Coats et al. 2013, Mcgready et al. 2001). The rapid growth of the fetal brain during the third trimester of pregnancy renders it vulnerable to inadequate nutrient supply (Drewett et al. 2001) and the deficiency of thiamine, in this manifestation of clinical and subclinical conditions of this hypovitaminosis. This scenario is aggravated by the maintenance of insufficient intake of this vitamin through breastfeeding, if maternal deficiencies are not corrected.

However, there are challenges to supplementing thiamine, aimed at treating the deficiency. It is proposed that the thiamin concentrated in maternal (human) milk should rise proportionally to the serum increase of the oral supplement. However, plasma levels of thiamine in newborns are not adequately corrected by short-term maternal supplementation even though such supplementation is able to normalize thiamine levels in the milk of these pregnant women (Coats et al. 2013). In this way, new born babies to mothers known to be deficient may need immediate replacement, even if they consume milk containing adequate levels of thiamine. Thus, direct replacement of thiamine for undernourished new born is recommended, considering that the recent neonatal or breastfeeding period is the most vulnerable to thiamine deficiency, in terms of adequate neurodevelopment of the offspring (Bâ 2005).

The current recommendations for nutritional interventions in the prenatal period by WHO are favorable to recommending a balanced diet and exercise during pregnancy for all women, besides the increase in caloric and protein intake in undernourished populations (Who 2016). However, "WHO" does not recommend maternal oral supplementation of thiamine or multivitamins and minerals in communities with social vulnerability (Who 2016). This fact is justified, primarily, by the small number of studies that are based on this replacement practice being safe and recommended. Therefore, there is a need for deeper investigation about the role of thiamine during pregnancy and breastfeeding, as well as the consequences for the woman and the baby, so that clinical replacement protocols are the best recommendation (Ramakrishnan et al. 1999).

(i) To identify the pregnant women in a risk situation by means of questionnaires and food insecurity evaluations, preferably adapted to and valid for the place and its reality.
(ii) To fortify nonperishable foods (such as flour), with thiamine. This is a simple public health measure, which is cheap and safe, for the prevention of the deficiency of vitamin B1, especially in populations where food insecurity exists (Harper 2006).
(iii) To begin oral replacement of thiamine in pregnant women proven to be vulnerable. Extend this supplement to the infants.

It is concluded then that there is a gap in the literature of systematic studies in which (i) the mothers are evaluated in the various stages of pregnancy in relation to thiamine deficiency and (ii) the impact of oral replacement in negative outcomes for

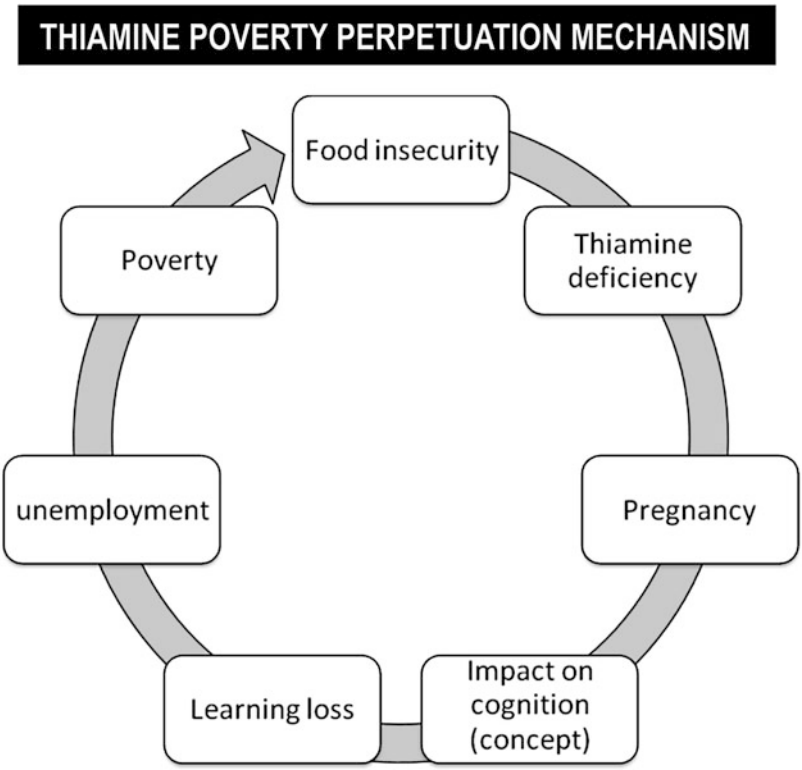

Fig. 8 Thiamine poverty perpetuation mechanism. Mechanism proposal for poverty perpetuation system associated with thiamine deficiency (Source: Unpublished personal figure)

pregnant women and the newly born. This need for studies is more noticeable for samples from populations of a low socioeconomic level, more vulnerable to multidimensional damage caused by malnutrition.

Finally, it is observed that the damage caused by thiamine deficiency goes further than its clinical manifestations they constitute, above all, a vicious cycle of perpetuation of the condition of poverty and vulnerability (Fig. 8).

Policies and Protocols

Public Policies for Prenatal Support and Fight Against Malnutrition and Alcoholism

As a way to minimize the negative impacts of thiamine deficiency in vulnerable populations, we recommend to adopt the following policies:

- Identification of potential vulnerable groups: refugees, people living in extreme poverty, exposed to urban violence, and children and pregnant women from low-income populations.
- Identification of adults, children, and pregnant women at food risk.
- Fortify nonperishable foods (such as wheat flour) with thiamine.
- Create and support programs to combat alcoholism with the support of local groups and initiatives.
- Invest in policies of social and labor reintegration to chronic alcohol dependents.
- Extend coverage of prenatal care programs to vulnerable and impoverished populations.
- Ensure adequate dietary intake for children and pregnant women in food risk.

Protocols for Food Insecurity Screening and Thiamine Supplementation in Children and Pregnant Women

- Identify food insecure situation through the Household Food Security Survey Measure (or adapted version of this questionnaire for local reality). The application of the questionnaire should take into account the presence or absence of children at home and their application instructions followed. Residents of a household should be considered food insecure if the score on the questionnaire is equal to or greater than 3.
- Consider extending thiamine replacement to mothers and infants at nutritional risk.

Protocols for Food Insecurity Screening and Thiamine Supplementation in People with Alcohol-Related Problems

- Screen all adolescents and adults, in all primary care consultations, for problems related to alcohol use through the CAGE or AUDIT questionnaire. Consider as positive screening those who answered yes to two or more questions in the CAGE or who obtained 8 or more points in the AUDIT.
- Include advice on the risks attributed to harmful use of alcohol in any primary care consultation of adolescents and adults positively screened by CAGE or AUDIT, regardless of the source population or other intervention proposals.
- Refer individuals with positive screening to alcohol-related problems for multi-disciplinary evaluation according to the reality of the local Health System.
- Initiate replacement of thiamine and other B-complex vitamins in all people with chronic alcohol-related problems at the doses indicated for the corresponding age group and sex.

Dictionary of Terms

- **Cytotoxicity** – Property of a substance, molecule, or microorganism that leads (by diverse mechanisms) to cellular destruction.
- **Food insecurity** – Inability to obtain adequate food to nourish the caloric, protein, and micronutrient demands needed by an individual.
- **Infant** – Period of life between 29 days and 2 years of age.
- Ionic Channels: Structures present in the wall of cell membranes that allows the passage of ions into or out of a cell.
- **Korsakoff's syndrome** – Disease caused by the evolution of untreated Wernicke's encephalopathy. It is characterized by irreversible structural brain lesions that lead to memory impairment and confabulations.
- **Micronutrient** – Necessary dietary substances in small amounts for the maintenance of homeostasis.
- **Plasma membrane** – Double phospholipid layer responsible for separating the interior from the cellular exterior.
- **Vulnerability** – Situation attributable to an individual, group, or population in which access to essential resources and rights is absent or severely compromised. This concept can be extended to people dependent on others to perform most of their activities or patients with certain physiological or pathological conditions that compromise their judgment or put them in a situation of fragility.
- **Wernicke's encephalopathy** – Neuropsychiatric disease caused by thiamine deficiency, especially in chronic alcoholics. It begins acutely and is characterized by the triad – ophthalmoplegia, ataxia, and mental confusion – and may or may not present itself with all of these.

Summary Points

- In this chapter, we presented the role of thiamine in the development of the central nervous system, its organic functions, and diseases related to its deficiency.
- Thiamine plays an important role in central nervous system maturation and consolidation of cognition, and its deficiency is particularly deleterious to chronic alcoholics, pregnant women, and infants.
- Pregnant women are more likely to develop thiamine deficiency than the general population, and this effect is more pronounced in those living in poverty.
- The role of thiamine deficiency in perpetuation of poverty status in vulnerable groups was observed.
- Despite the importance of this micronutrient, replacement programs are not yet well established in scientific literature.
- Based on favorable risk/benefit profile, we recommend the fortification of easily accessible foods (such as wheat flour) with thiamine and oral replacement for alcohol dependent people, pregnant women, and infants living in situations of food insecurity.

Abstract

The vitamin B_6 vitamers include pyridoxine, pyridoxal, and pyridoxamine, as well as their phosphorylated forms such as pyridoxal phosphate, which is a key coenzyme for a surprising variety of enzymes involved in myriad aspects of metabolism. Vitamin B_6 also contributes to the synthesis of many neurotransmitters. Given this widespread role, it is not surprising that vitamin B_6 deficiency can induce many negative effects including convulsive seizures in infants, developmental delay, hypertension, and susceptibility to atherosclerosis. Conversely, the administration of vitamin B_6 vitamers, or the manipulation of vitamer-bound enzymes, has shown promise against cancer, parasitic diseases such as malaria, and Parkinson's disease. In this chapter, we examine the critical and broad role played by vitamin B_6 vitamers and their coenzymes in metabolism, with a focus on the detrimental effects of deficiency and their therapeutic potential.

Vitamin B6 · Vitamers · Pyridoxal phosphate · Coenzyme · Neurological function · Seizure · Neuroprotection · Immunity · Diabetes

List of Abbreviations

5-HT	Serotonin
AADC	L-Aromatic amino acid decarboxylase
AGE	Advanced glycation end product
CBS	Cystathionine β-synthase
DA	Dopamine
DOPA	Dihydroxyphenylalanine
GABA	ɣ-Aminobutyric acid
GABA-T	GABA transaminase
GAD	Glutamic acid decarboxylase
Gc	Glucocorticoid
NAS	*N*-Acetylserotonin
NE	Norepinephrine
ODC	Ornithine decarboxylase
PL	Pyridoxal
PLP	Pyridoxal phosphate
PM	Pyridoxamine
PN	Pyridoxine

Introduction

The term vitamin B_6 refers to a group of naturally occurring pyridine derivatives including pyridoxine (PN, pyridoxol), pyridoxal (PL), and pyridoxamine (PM). Their phosphorylated derivatives are also included in this group, generically referred to as vitamin B_6 vitamers. PN specifically refers to the alcohol form, PL to the aldehyde form, and PM to the amine form. These forms of the vitamin B_6 vitamers could be converted to the key coenzymatic form pyridoxal phosphate (PLP) through the actions of an oxidase, a kinase, and a phosphatase (Fig. 1). Pyridoxal kinase activity increases during brain maturation. The activity of this enzyme in the red blood cells of African-Americans is approximately 50% lower than that of Caucasian Americans. An inverse relationship between the activity of the kinase and the concentrations of brain PLP and brain monoamines has been reported. Unbound PLP is hydrolyzed by an alkaline phosphatase. Much of the PLP in liver and muscle is protein bound, thus regulating the concentration of active, unbound PLP. There are more than 140 PLP-dependent enzymatic reactions distributed in all organisms comprising diverse groups such as the oxidoreductases, transferases, hydrolases, lyases, and isomerases. About 1.5% of the genes of prokaryotes encode PLP enzymes which participate in the metabolism of amino acids, carbohydrates, and lipids indicating the versatility of PLP-dependent enzymes. A detailed account has been provided (Dakshinamurti 1990) and recently reviewed (Dakshinamurti and Dakshinamurti 2014).
