
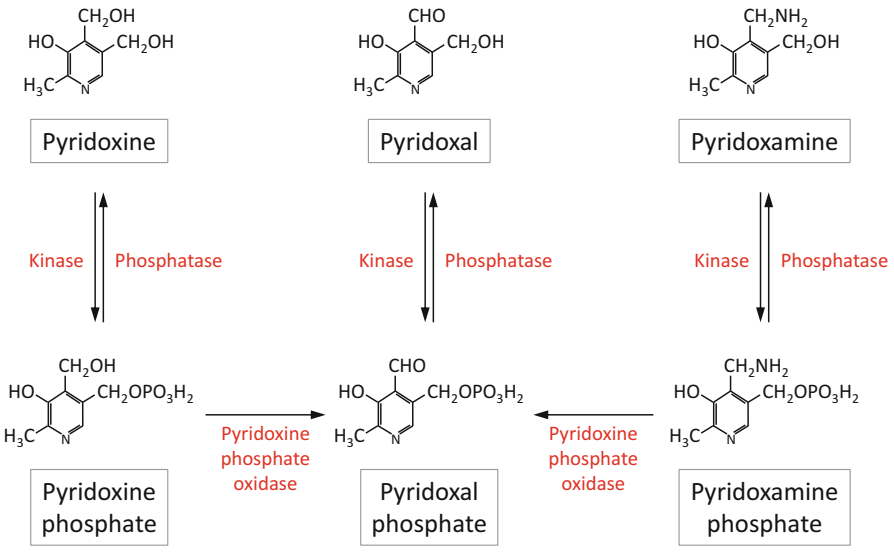

Fig. 1 Interconversion between vitamin B_6 vitamers. Pyridoxine, pyridoxal, and pyridoxamine are phosphorylated by a common pyridoxal kinase. The resulting phosphorylated forms of pyridoxine phosphate and pyridoxamine phosphate can be converted to pyridoxal phosphate by pyridoxine phosphate oxidase

PLP-Dependent Enzymes and Antioxidant Actions of PLP

PLP is the active coenzymatic form of vitamin B_6 and is the most versatile of all the coenzymatic form of vitamins found in all organisms. PLP-dependent enzymes are included in five of the six enzyme classes as defined by the Enzyme Nomenclature Committee of the International Union of Biochemistry and Molecular Biology. They act as coenzymes in enzymatic reactions involved in synthesis, degradation, and interconversion of amino acids, acting as oxidoreductases, transferases, hydrolases, lyases, and isomerases. Based on the fold type of the structural superfamilies, fold type I is the largest group, comprising the aspartate aminotransferase family. Fold type II is the tryptophan synthase family. Alanine racemase is fold type III, whereas the D-amino acid aminotransferase is type IV. PLP-dependent enzymes are classified into three groups depending on the site of elimination and replacement of the substituents. Reactions occurring at the α-carbon atom include transaminase, racemases of α-amino acid, amino acid α-decarboxylases, and enzymes catalyzing the condensation of glycine and the 2-β cleavage of β-hydroxy amino acids such as δ-aminolevulinic acid synthase, serine hydroxyl methylase, and sphingosine synthetase. Reactions occurring at the β-carbon atom of the substrate include serine and threonine dehydratase, cystathionine synthetase, tryptophanase, and kynureninase. Reactions occurring at the γ-carbon include homoserine dehydratase and γ-cystathionase.

Glycogen phosphorylase, another PLP-dependent enzyme, catalyzes the first step in the degradation of glycogen. The physiological role of phosphorylase in skeletal muscle is as an energy source, as approximately 2% of total soluble protein of muscle tissue is the enzyme phosphorylase. This enzyme is under regulatory control with AMP and IMP being activators and ATP and ADP being inhibitors. The involvement of the phosphate group rather than the carbonyl group is a novel feature of the role of PLP in the phosphorylase reaction. The phosphate group of PLP functions in the form of dianion as a proton donor-acceptor. PLP has an important role in maintaining the quaternary structure and conformation of phosphorylase. A reservoir function for PLP in muscle phosphorylase is also indicated.

Hydrogen sulfide (H_2S) is produced endogenously in organs such as the heart and the central nervous system. This endogenous production of H_2S depends upon PLP enzymes such as cystathionine β-synthase (CBS), cystathionine γ-lyase, and 3-mercaptopyruvate sulfotransferase. CBS is highly expressed in the hippocampus and the cerebellum. Along with nitric oxide and carbon monoxide, H_2S forms a triad of gaseous signaling molecules in the body. H_2S is involved in the regulation of intracellular signaling molecules such as protein kinase A, receptor tyrosine kinase, and mitogen kinase and in oxidative stress signaling. The L- and T-type calcium channels as well as potassium and chloride channels are regulated by H_2S. The release and function of neurotransmitters such as γ-aminobutyric acid (GABA), *N*-methyl-D-aspartate, glutamate, and catecholamines require H_2S as a signal. Thus, H_2S has a number of neuronal functions.

Recent evidence attests to the antioxidant properties of vitamin B_6 vitamers, comparing favorably to the well-established antioxidant vitamins such as ascorbic acid and the tocopherols. PN and PM inhibit superoxide radicals and prevent lipid peroxidation, protein glycosylation, and Na^+,K^+-ATPase activity. Hyperglycemia-induced oxidative stress is a significant cause of diabetic complications. PLP inhibits this oxidative stress as well as lipid peroxidation and protein oxidation. PN has a very high level of quenching of hydroxyl radicals.

Assay, Sources, Bioavailability, and Requirement

Much of the data currently available on the total vitamin B_6 content of foods is based on microbiological methods using the growth of *Saccharomyces uvarum* (ATCC 9080). Enzymatic and radioenzymatic methods have been used for the determination of PLP. The most commonly used methods are based on ion exchange or paired ion reverse-phase high-performance liquid chromatography with post-column derivatization (Dakshinamurti and Stephens 1969; Sharma and Dakshinamurti 1992a; Deitrick et al. 2001).

Vitamin B_6 vitamers and their phosphorylated derivatives are present in most foods. Glycosylated forms of PN are present in plant-based foods. PL and PLP are the major forms present in animal-based foods. The vitamin B_6 content of selected foods has been reported (Lecklem 2001). Vitamin B_6 vitamers and their phosphorylated derivatives are photosensitive. There is a loss of vitamin activity due to food processing techniques such as heat sterilization. This loss was responsible for the epidemic of seizures caused by vitamin B_6 deficiency in infants fed such formula diets (Coursin 1954).

The absorption of vitamin B_6 occurs after the hydrolysis of the phosphorylated and glycosylated forms in the lumen of the intestine. There is a specialized Na^+-dependent carrier-mediated system for the absorption of PN (Said 2004). Once absorbed, there is interconversion of the various forms of vitamin B_6 vitamers. The concentrations of PL and PLP in the erythrocyte are 2.6- and 1.8-fold higher than in blood plasma due to the higher affinity of PL to hemoglobin than to albumin. Similarly, PLP synthesized in the erythrocytes is bound with higher affinity to hemoglobin than to albumin. The kinase, oxidase, and transaminase are all present in the erythrocytes. In the muscle, vitamin B_6 is present mostly as PLP bound to glycogen phosphorylase.

The physiological requirement for vitamin B_6 depends on one's age, sex, body size, extent of physical activity, and protein intake in the diet. Oral contraceptive drug use is associated with many clinical side effects that are normally associated with pregnancy. The requirements for vitamin B_6 in women during pregnancy and lactation and of adolescents during the rapid phase of growth are high. The current dietary allowance (RDA) recommendations are set at 2.0 mg for adult males and females, 0.9 mg for children between 4 and 6 years of age, and 1.2 mg for children in the age group 7–10 years (National Research Council, Dietary Reference Intake Tables, The National Academies, Washington, D.C. 2005).

Vitamin B_6 Deficiency: Primary and Secondary

Impairment of somatic growth and a pellagra-like dermatitis are reported in all vitamin B_6-deficient animals. Anemia is reported in most vitamin B_6-deficient species. Ataxia, hyperacusis, hyperirritability, impaired alertness, abnormal head movements, and convulsions are seen in a variety of vitamin B_6-deficient species including humans. The widespread occurrence of vitamin B_6 deficiency-induced convulsive seizures in infants receiving heat-sterilized proprietary milk formulae has been referred to earlier (Coursin 1954). Treatment of these infants with PN resulted in a marked improvement in the wave form and normalization of the amplitude and frequency of their EEG.

Signs of vitamin B_6 deficiency caused by a primary dietary deficiency are rare in the developed world. However, many conditions are recognized in which a deficient condition is caused due to increased requirements or poor availability of the vitamin because of formation of inactive complexes between the vitamin and various drugs.

Vitamin B_6 deficiency has been recognized in pregnant women based on the tryptophan load test, as well as on the determination of vitamin B_6 vitamer levels. When maternal vitamin B_6 levels are low, the PLP levels of cord blood are significantly decreased. Premature infants have very low levels of plasma PLP at birth (Reinken and Mangold 1973). The use of oral contraceptive drugs is associated with clinical side effects that are similar to those associated with pregnancy and are related to hormone-induced changes in tryptophan metabolism.

A functional deficiency of vitamin B_6 has been recognized in uremic patients receiving hemodialysis (Dobbelstein et al. 1974). Resin-based phosphate binders lead to a greater loss of water-soluble vitamins. Isonicotinic acid hydrazide has been used for a long time in the treatment of pulmonary tuberculosis. Its use has been associated with signs of vitamin B_6 deficiency, and supplementation with 50 mg PN reversed this. Another antituberculosis drug, cycloserine, has similar effects on the vitamin B_6 status of patients receiving this drug. Penicillamine is used in the treatment of Wilson's disease and also for cystinuric patients to prevent the formation of urinary cysteine stones. These patients are prone to epileptic seizures which are corrected by the administration of PN (Smith and Gallagher 1970; Cohen 1969).

Neurobiology of Vitamin B_6

The crucial role played by vitamin B_6 in the nervous system arises out of the fact that the putative neurotransmitters dopamine (DA), norepinephrine (NE), serotonin (5-HT), and GABA, as well as taurine, sphingolipids, and polyamines, are synthesized by PLP-dependent enzymes. There is considerable variation in the affinities of the various apoenzymes for the cofactor PLP. In view of this, there is a differential susceptibility of various PLP enzymes to a decrease of PLP during vitamin B_6 depletion in animals and humans. The decarboxylation of glutamic acid, 5-hydroxytryptophan, and ornithine is considerably decreased in all vitamin B_6-deficient species (Fig. 2).

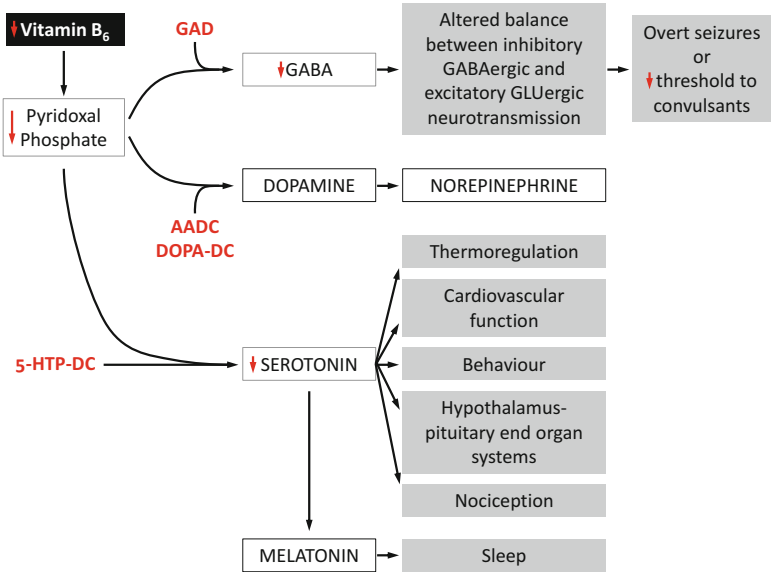

Fig. 2 Physiological consequences of vitamin B_6 depletion. Depletion of vitamin B_6 results in loss of the coenzyme form of pyridoxal phosphate/PLP, in turn decreasing synthesis of GABA and serotonin. These alterations have wide-ranging effects on normal physiology (*gray boxes*). Key enzymes are in *red text*

The enzyme L-aromatic amino acid decarboxylase (AADC) lacks substrate specificity and is considered to be involved in the synthesis of catecholamines and serotonin. There are many differences in the optimal conditions for enzyme activity including kinetics, affinity for PLP, activation and inhibition by specific chemicals, and differences in regional distribution of dihydroxyphenylalanine (DOPA) and 5-hydroxytryptophan decarboxylase activities. Nonparallel changes in brain monoamines in vitamin B_6-deficient rats have been reported (Siow and Dakshinamurti 1986; Dakshinamurti et al. 1976). Brain levels of serotonin were significantly decreased during vitamin B_6 deficiency, whereas DA and NE were not affected.

The neurotransmitter GABA is present almost exclusively in the nervous system of invertebrates and vertebrates. GABA is formed from glutamic acid through the action of glutamic acid decarboxylase (GAD) and is catabolized by GABA transaminase (GABA-T) to yield succinic semialdehyde. Both GAD and GABA-T are PLP enzymes. GABA is an inhibitory neurotransmitter, whereas glutamic acid is excitatory. GABA, GAD, and GABA-T are localized in areas of the brain that are inhibitory in function. In addition to the involvement of GABA in the etiology of convulsive seizures, abnormalities in the GABA-ergic neuronal pathways contribute to other CNS disorders such as depression, anxiety, and panic disorders. During a moderate deficiency of vitamin B_6, there are biologically significant decreases in the activities of the PLP-dependent GAD-65 isoform and AADC (5-HTP-DC) leading to decreases in neurotransmitters GABA and 5-HT. Under these conditions, DOPA

decarboxylase is not affected, resulting in no change or even an increase in catecholamines in the nervous system. Decreases in brain serotonin are implicated in physiological changes such as decreased deep-body temperature and altered sleep pattern with a decrease in deep slow-wave and REM sleep (Dakshinamurti 1982).

Neuroendocrinology of Vitamin B_6

The hypothalamus is one of the areas of the brain of vitamin B_6-deficient rats that exhibits significant decreases in PLP and serotonin compared with vitamin B_6-replete controls. There is no decrease in the content of dopamine and norepinephrine. The concept of the regulatory role of the hypothalamus through the neurotransmitters is generally accepted. The hypothalamus of normal animals has high concentrations of both serotonin and dopamine, which are antagonistic in their effects on pituitary hormone regulation (Dakshinamurti et al. 1988).

In determining the focus of the biochemical lesion leading to the hypothyroid state in the vitamin B_6-deficient animal, various possibilities such as primary with a defective thyroid gland, secondary with a defective pituitary thyrotroph, or tertiary with a defective hypothalamus were considered. The results are consistent with a hypothalamic type of hypothyroidism in the vitamin B_6-deficient animal, caused by a specific decrease in hypothalamic serotonin levels (Dakshinamurti et al. 1986).

The pineal gland transduces photoperiodic information and has a role in the temporal organization of various metabolic, physiological, and behavioral processes. Melatonin is the major secretory product of the pineal gland. In the pinealocyte tryptophan is hydroxylated to 5-hydroxytryptophan and decarboxylated to yield serotonin which is converted to *N*-acetylserotonin (NAS). NAS is converted to melatonin by hydroxyl-indole-*O*-methyltransferase. Melatonin synthesis is stimulated by β-adrenergic postganglionic sympathetic fibers from the superior cervical ganglion, which are stimulated in the dark. Melatonin levels in tissues and body fluids show both circadian and seasonal rhythms. Pineal levels of 5-HT and 5-hydroxyindoleacetic acid are significantly lower in the vitamin B_6-deficient rat, and treatment of the deficient rats with PN restored the levels of 5-HT, NAS, and melatonin to the levels seen in vitamin B_6-replete animals (Viswanathan et al. 1988).

The secretion of prolactin is regulated by both stimulatory and inhibitory factors of hypothalamic origin. Evidence based on the administration of serotonin precursors, agonists or antagonists, intraventricular administration of serotonin, and electrical stimulation of the raphe nucleus indicates that the central serotonergic projections to the hypothalamus are involved in the stimulation of prolactin secretion. Administration of PN to vitamin B_6-deficient rats results in a significant increase in plasma prolactin (Sharma and Dakshinamurti 1994).

The vitamin B_6 status of the individual has significant effects on the central production of serotonin and GABA, neurotransmitters that control pain perception, anxiety, and depression. High-dose PN, through its effects on neurotransmitters, has a favorable impact on dysphoric mental states (McCarty 2000; Russo et al. 2003).

Experimental Vitamin B_6 Deficiency in the Neonatal Rat: Seizures and Vitamin B_6

It was the general belief that if the nutrition of the mother was adequate for conception and maintenance of pregnancy, the intrauterine mechanisms for active transport and concentration would supply the necessary nutrients for the normal development of the unborn child. In view of this, it was of interest to produce and characterize vitamin B_6 deficiency in the very young rat. Sperm-positive female Holtzman rats were maintained on a vitamin B_6-supplemented diet during the first week of gestation and then divided into two groups. One was continued on the B_6-supplemented diet, and the other was fed a vitamin B_6-deficient diet until the delivery of the pups and also during the nursing period. There was a small but significant difference in the body weight of the pups between the two groups. Deficient pups had a significant decrease in brain PLP content. Related to this was the occasional finding, among the vitamin B_6-deficient group, of pups with spontaneous convulsions that became noticeable at about 3–4 days of postnatal age. These fits were characterized by a high-pitched scream followed by generalized convulsions of a few seconds' duration and repeated many times within a 1–3-min time period. The motility, perception, and alertness of the deficient neonates were inferior to those of the control pups. This was the first report of the production of congenital PN deficiency (Dakshinamurti and Stephens 1969). In view of the high mortality of the deficient pups, they could not be used in studies on the development of the central nervous system. In a further study, female rats were fed a vitamin B_6-deficient diet from the first postpartum day and the pups were fed the deficient diet from the day they were weaned until they were 5–6 weeks of age. The effects of deficiency on various electrophysiological parameters were examined. The bursts of high-voltage spikes during spontaneous EEG activity, as well as the spontaneous convulsions observed, reflect the decrease in cerebral GABA concentration in the deficient rats. The more complicated changes in cortical auditory evoked potentials in the vitamin B_6-deficient rats are the result of the retardation of normal ontogenetic development of the central nervous system of these rats (Stephens et al. 1971).

The thalamus acts as a relay station for various peripheral and central inputs to the cerebral cortex. Hence, the electro-responsiveness of thalamic ventroposterior lateral neurons in normal control and vitamin B_6-deficient adult rats in response to local administration of convulsants such as picrotoxin or pentylene tetrazole was studied. The extent of neuronal recovery following intrathalamic administration of either GABA or PN, or systemic administration of PN, was assessed using computerized EEG analysis. The results demonstrated an antiepileptic effect of exogenously applied GABA and PN on the thalamic ventroposterior lateral neuron. Neuronal recovery following PN administration is related to synthesis of GABA through activation of GAD (Sharma and Dakshinamurti 1992b; Sharma et al. 1994).

Pyridoxine: Dependency Seizures

PN dependency has been recognized as an inborn abnormality. Infants, generally soon after birth, have seizures that are resistant to the commonly used antiepileptic drugs and respond only to pharmacological doses of PN. It is a rare autosomal recessive disorder. In view of the prevalence of atypical variants of this disorder, it is generally under-recognized. A PN-dependent condition has to be considered in all children with intractable epilepsy up to 3 years of age (Gospe 2002). The unusual rhythmic in utero movements reported retrospectively by some mothers might represent fetal seizures (Clayton 2006). At present there is no biochemical test to confirm PN-dependent seizures: clinical diagnosis is the only mode of recognition. Response to PN monotherapy and recurrence of seizures upon withdrawal of treatment is the only confirmatory test. Such testing is fraught with difficulty due to ethical considerations. PN dependency is distinct from the PN-deficient state of infants reported earlier (Coursin 1954).

The intravenous administration of 50–100 mg PN results in a dramatic cessation of seizures in affected children. In some cases, the dose might be as high as 500 mg. The pharmacological requirement of PN is for life, and the required dose level can be titrated. An untreated PN-dependent condition results in delay in achieving milestones, developmental defects, as well as permanent brain damage (Alkan et al. 2004).

Recent studies indicate that increasing the dose of PN in PN-dependent children without seizures could improve their IQ, indicating a role for PN in normal brain development (Baxter 2003). Autopsy studies on PN-dependent seizure patients show elevated glutamate and decreased GABA levels in the frontal and occipital cortices (Alkan et al. 2003). Of the two isoforms of GAD, GAD-65 is PLP-dependent, and defective binding of PLP to the apoenzyme is suggested to be the cause of the decreased synthesis of GABA in these patients. There are other seizure conditions in which PN therapy finds a place. Infantile spasm in combination with diffuse electroencephalographic abnormalities is referred to as "West syndrome." Mental retardation is associated with this condition. Following reports of beneficial effects, initial treatment with high doses of PN is the established therapy in some European countries and in Japan (Pietz et al. 1993).

Neuroprotection by Vitamin B_6

Domoic acid, a rigid structural analog of glutamate, is a neuroexcitant. It was identified as the toxic contaminant of cultivated mussels responsible for the outbreak of acute food poisoning characterized by gastrointestinal and neurological symptoms (Teitelbaum et al. 1990). Acute intrahippocampal administration of picomole amounts of domoic acid led to EEG epileptiform seizure discharge activity. Domoic acid was 125 times more potent than kainic acid, a well-known neuroexcitant. Local administration of GABA or PN attenuated the seizure activity (Dakshinamurti et al. 1991). Following domoic acid injection, GABA levels decreased significantly in various brain regions. The direct application of GABA to the hippocampus of rats

exhibiting domoic acid-induced seizure activity resulted in suppression of spike discharges. PN had a similar, but slower effect (Dakshinamurti et al. 1993). It has been reported that serotonin functions in the stabilization of brain regional GABA-ergic neurons and in seizure control. The neuroprotective action of PN flows from its effect on the synthesis of both GABA and serotonin (Dakshinamurti et al. 2003). PN treatment, in association with the histidine deacetylase inhibitor sodium butyrate, significantly restored the age-related reduction in memory function. The restorative potential of PN on ischemic damage in the hippocampal CA1 region of Mongolian gerbils has been established (Yoo et al. 2012).

Vitamin B_6 and Hypertension

Hypertension is one of the major causes of chronic illness in western societies, where about 20–30% of the adult population have some degree of blood pressure elevation. For the majority of patients, the underlying cause has not yet been recognized and the condition is referred to as "essential hypertension." Various animal models have been used to study this hypertensive state. The moderately vitamin B_6-deficient rat has been introduced as an additional animal model to study hypertension (Paulose et al. 1988; Dakshinamurti and Lal 1992; Dakshinamurti and Dakshinamurti 2001). The possibility that the reversible hypertension in these animals was related to sympathetic stimulation was studied. The concentrations of both epinephrine and norepinephrine in plasma were threefold higher compared to controls. The turnover of norepinephrine in the hearts of deficient hypertensive rats was threefold higher as compared to controls. Treatment with PN returned both blood pressure and catecholamine levels to normal within 24 h, indicating that the lesion could be at the level of neurotransmitter regulation. Serotonergic neurotransmission in the central nervous system controls a wide variety of functions such as blood pressure, emotional behavior, endocrine secretion, and perception of pain and sleep. It is possible that the decrease in neuronal serotonin and the consequent changes in its receptors, particularly 5-HT_A, may cause hypertension in B_6 deficiency. The 5-HT_{1A} receptor agonists all have acute hypotensive effects in this rat model.

Pyridoxal Phosphate, Calcium Channels, and Cardiovascular Function

The end result of centrally mediated sympathetic stimulation is an increase in peripheral resistance which is reflected in elevation of both resting and stimulated vascular tone in the resistance arteries of the moderately vitamin B_6-deficient hypertensive rat. Elevated peripheral resistance is the hallmark of hypertension as seen in all models of hypertension. The increase in the tone of caudal artery segments from the hypertensive rat is calcium-dependent. The decrease in the tone following the addition to the medium of the calcium channel antagonist, nifedipine, indicates that increased peripheral resistance resulting from increased permeability of smooth

muscle plasma membrane to Ca^{2+} might be central to the development of hypertension in the vitamin B_6-deficient rat. Calcium influx occurs through plasma membrane Ca^{2+} channels that are voltage-operated or receptor-mediated. Voltage-sensitive Ca^{2+} channels open upon depolarization of the cell membrane, resulting in an inward movement of calcium ions. ATP is an extracellular nucleotide that mediates its effect via plasma membrane-bound P2 receptors. The slow L-type channel is the major pathway by which Ca^{2+} enters the cell during excitation for initiation and regulation of the force of contraction of cardiac and skeletal muscle. Vascular smooth muscle also contains L-type channels.

The possibility that in the vitamin B_6-deficient rat a higher concentration of cytosolic-free Ca^{2+} might be responsible for the higher tension in the vascular smooth muscle was studied. In the vitamin B_6-deficient hypertensive rat, radiolabeled $^{45}Ca^{2+}$ influx into the vascular smooth muscle was increased to twice that of the controls. The KCl-induced [Ca^{2+}] increase was significant in cardiomyocytes isolated from vitamin B_6-deficient hypertensive rats. A single injection of vitamin B_6 (10 mg/kg body weight) to the deficient animal completely reversed the KCl-induced changes in [Ca^{2+}] due to vitamin B_6 deficiency. Similar results were obtained in other diet-induced hypertensive animal models, as well as in genetically hypertensive animal models such as the Zucker obese rat (Lal and Dakshinamurti 1993, 1995). In further studies, the possibility that PN or more particularly PLP could directly modulate the cellular calcium uptake process was studied. Bay K8644, a dihydropyridine-sensitive calcium channel agonist, stimulated calcium entry into artery segments from control rats. PLP dose-dependently reduced the Bay K8644-stimulated calcium uptake by control artery segments (Lal et al. 1993; Dakshinamurti et al. 1998). The basal uptake of $^{45}Ca^{2+}$ by caudal artery segments from vitamin B_6-deficient hypertensive rats was at least twice the uptake by caudal artery segments from normal rats. The in vitro direct antagonism indicates the possibility that the calcium channel agonist Bay K8644, the calcium channel antagonist nifedipine, and PLP might all act at the same site on the calcium channel.

In a further study, the effect of PLP on the ATP-induced contractile activity of the isolated rat heart and the ATP-mediated increase in intracellular [Ca^{2+}] in freshly isolated adult rat cardiomyocytes, as well as on the specific binding of ATP to the cardiac sarcolemmal membrane, were examined to determine if PLP is an effective antagonist of ATP receptors in the myocardium. The infusion of ATP caused an immediate increase (within seconds) in LVDP, +dP/dt and –dP/dt. This effect was completely blocked in hearts pretreated with PLP for 10 min. The specificity of the effect of PLP was established (Wang et al. 1999).

Studies in humans have identified an independent association between low plasma vitamin B_6 concentration and a higher risk of coronary artery disease (Chang et al. 1999). In addition to the role of vitamin B_6 in atherosclerosis, other potential explanations include the role of PLP in platelet aggregation and the association between low PLP and inflammatory markers (Friso et al. 2005). Low plasma PLP concentration was inversely associated with major markers of inflammation and independently associated with cardiovascular disease risk (Friso et al. 2004). Our observations on the role of PLP in both major calcium channels for the

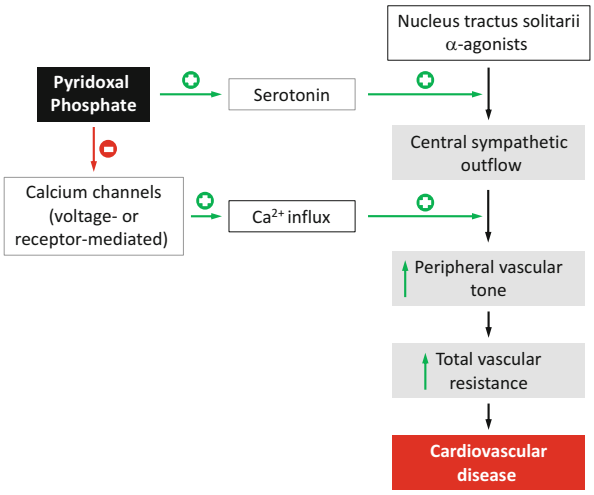

Fig. 3 PLP-mediated mechanisms leading to attenuation of hypertension. Adrenergic stimulation leads to increased peripheral vascular tone, increased total vascular resistance, and an increase in susceptibility to cardiovascular disease such as hypertension. Pyridoxal phosphate induces serotonin-mediated central sympathetic outflow, but also inhibits both voltage- and receptor-mediated calcium channels, reducing calcium influx and attenuating the increase in vascular tone, which may provide the mechanism for PLP-mediated cardioprotection

influx of extracellular calcium might proffer a viable biochemical explanation for the association between low PLP concentration and the risk for cardiovascular disease (Fig. 3). The increase in $[Ca^{2+}]$ in cardiomyocytes might contribute to heart dysfunction and increased myocardial infarction and explain the beneficial effect of vitamin B_6 in patients with hypertension and myocardial infarction (Dakshinamurti et al. 2000; Dhalla et al. 2000).

Cardiovascular Complications of Diabetes Mellitus: Inhibition of Advanced Glycation End Product Formation by Pyridoxamine

The reducing sugar glucose, which is elevated in the diabetic condition, can modify proteins through condensation of its aldehyde group with the ε-amino group of lysine residues, forming a Schiff base. This is referred to as the Maillard reaction and is dependent on the concentration of glucose, being exacerbated in the diabetic condition. The Schiff bases isomerize to intermediate ketosamine Amadori products including glycated hemoglobin (HbA_{1c}). Over a period of weeks and months, glucose-independent reactions including rearrangement, condensation, dehydration, polymerization, and fragmentation lead to a host of metabolites referred to as advanced glycation end products (AGEs). Lipid peroxidation of polyunsaturated fatty acids similarly produces advanced lipoxidation end products.

Histopathological evidence attests to the accumulation of AGEs in a variety of tissues such as the renal cortex, glomerular mesangium, and basement membrane. Evidence for the role of AGEs in vascular complications has been presented (Ahmed and Thornalley 2007). Experimentally, the injection of AGE precursors or AGE-modified proteins induces vascular damage similar to that seen in the diabetic condition. Various studies indicate that hyperglycemia is the most significant factor in the onset and development of vascular complications of diabetes, of which chronic kidney disease is a major component. Inhibition of the renin-angiotensin system with angiotensin-converting enzyme inhibitors and/or angiotensin II receptor blockers is the main pharmacotherapy for chronic kidney disease. In addition, they also block the formation of reactive carbonyl precursors of AGE as well as induced reactive oxygen species generation (Thomas et al. 2005). Of the various compounds that inhibit or correct individual steps in the pathophysiological sequence leading to vascular complications of diabetes, two stand out: PM and benfotiamine. PM is a member of the vitamin B_6 vitamer group. Benfotiamine is a lipid-soluble vitamin B_1 analog. Treatment with high-dose PM improved the urinary albumin/creatine ratios and fasting serum triglyceride and 3-deoxyglucosone. PM also prevents the accumulation of Nε-(carboxymethyl) lysine, nitrotyrosine, TGF-β1, and laminin-β1 in the kidney. The therapeutic potential of ACE inhibitors has been tested in clinical trials (Brenner et al. 2001). Studies using various animal models indicate that PM is effective in the treatment of diabetic nephropathy, retinopathy, and neuropathy (Chang et al. 2009; Chen and Francis 2012). The function of PM is not related to its role as a member of the vitamin B_6 vitamers. PM, in combination therapy, might find a use in the treatment of a wide range of chronic diseases in which oxidative stress, inflammation, and tissue damage lead to a chemical modification of proteins (Metz et al. 2003).

Vitamin B_6: Gene Expression and Anticancer Effect

In rats fed a diet adequate in vitamin B_6, the fraction of total PLP found in the nuclei of liver cells was 21%, and this increased to 39% in rats fed a vitamin B_6-deficient diet indicating a conservation of the vitamin in the nuclear compartment during deficiency, a situation analogous to the distribution of biotin in biotin-replete and biotin-deficient animals (Dakshinamurti 1997). PLP in the cell nucleus is protein bound. Cells grown in the presence of 5 mM PN have a decreased glucocorticoid-dependent induction of enzymes. Vitamin B_6 regulates the transcriptional activation of human glucocorticoid receptors in HeLa cells. This modulatory role on transcription is not restricted to the glucocorticoid receptor, but extends to all members of the steroid hormone receptorsuper family, leading to a decreased transcriptional response to various steroid hormones (Oka et al. 1995). PLP modulates gene expression through its influence on the functional interaction between the steroid hormone receptors and transcription factor NFI (Davis and Cowing 2000).

The growth of B16 melanoma in vitro was inhibited by 5 mM PN or PL. Treatment of mice with PL (0.5 g/kg body weight) reduced the growth of both

new and established B16 melanoma. PL supplementation was shown to reduce cell proliferation and DNA synthesis in both estrogen-dependent and estrogen-independent mammary carcinoma cell lines (Komatsu et al. 2003). The growth of MH-134 hepatoma cells transplanted into C3H/He mice was significantly reduced by the administration of large amounts of PN to mice. High dietary intake of vitamin B_6 has been shown to suppress herpes simplex virus type 2-tranformed cell-induced tumor growth in BALB/c mice (Jansen et al. 1999). Epidemiological studies indicate a reduced risk of lung and colorectal cancer in older men ingesting high doses of vitamin B_6 (Hartman et al. 2001; Larsson et al. 2010).

PLP was reported to be a strong inhibitor of DNA polymerases α and ε from a phylogenetically wide range of organisms, from protists, plants, insects, and fish to mammals. These polymerase classes are related to DNA replication. Treatment with pharmacological doses of vitamin B_6 suppressed the expression of the cell proliferation-related genes c-myc and c-fos in colon epithelium of mice treated with azomethane. PLP has been shown to inhibit DNA topoisomerases I and II, which are needed for strand separation, replication, and recombination. Inhibition of DNA topoisomerase arrests the cell cycle and induces apoptosis. PLP has been shown to be an effective inhibitor of many enzymes that have binding sites for phosphate-containing substrates of effectors, including RNA polymerase, reverse transcriptase, and DNA polymerase (Matsubara et al. 2003). Based on a meta-analysis of prospective studies, an inverse association between blood PLP levels and the risk of colorectal cancer has been reported (Larsson et al. 2010).

Oxaliplatin in combination with 5-fluorouracil is standard treatment for metastatic colorectal carcinoma. Peripheral sensory neuropathy is the dose-limiting side effect of this treatment. PN administration reduces oxaliplatin-induced neurotoxicity, thus allowing for more effective and less toxic treatment of such cancers. The preventive effect of vitamin B_6 on tumorigenesis might also derive from its strong antioxidant action (Garg and Ackland 2011; Jain and Lim 2001). These observations highlight the potential use of pharmacological doses of vitamin B_6 in cancer therapy.

Vitamin B_6 and Immunity

There is overwhelming evidence for the requirement of vitamin B_6 in antibody production. The thymus of vitamin B_6-deficient rats is depleted of lymphocytes, and deficient animals had impaired antibody formation following exposure to various antigens. Cell-mediated immunity is also impaired in vitamin B_6-deficient rats. A decline in immune response is a concomitant of the aging process in animals and humans with the most significant effect on cell-mediated immunity. PN supplementation led to lymphocyte proliferative response to both T- and B-cell antigens (Kwak et al. 2002). Diseases such as uremia and arthritis are associated with immunological abnormalities. Treatment of uremic patients with pharmacological doses of PN results in a significant increase in lymphocyte reactivity. Plasma PLP is significantly lower in patients with rheumatoid arthritis compared to controls matched for age, gender, race, and weight (Roubenoff et al. 1995). The plasma

levels of PLP inversely correlated with production of tumor necrosis factor by unstimulated peripheral blood mononuclear cells.

Glucocorticoids (Gc) are widely used in the treatment of inflammatory and autoimmune states. Long-term Gc use is associated with severe side effects. Vitamin B_6 does not interfere with Gc action in immune cells while selectively inhibiting the unwanted side effects of Gc receptor-dependent transactivation in nonimmune cells (Bamberger et al. 2004). PL and PLP suppress the expression of cytokine genes in macrophages, indicating the anti-inflammatory activity (Zhang et al. 2016).

Vitamin B_6 deficiency is widely prevalent among HIV-infected persons (Baum et al. 1991). The relationship of PLP to the activation of CD4 T cells by antigen-presenting cells has been studied. CD4 T cells are the mediators in the initiation and continuation of the immune response causing autoimmune diseases and allogenic transplant rejection. The CD4 glycoprotein is the characteristic surface receptor of all helper T cells. The extracellular part of the CD4 molecule is comprised of four domains, D1 to D4. CD4 binds to major histocompatibility complex MHC class II through the D1 and D2 domains. PLP binds very tightly to the D1 domain of CD4 and thus interferes with the CD4-MHC II interaction. Non-incorporation of CD4 into the activation complex could lead to T-cell apoptosis. The tight association of D1 and PLP would prevent protein-protein interaction of CD4 itself, its dimerization, and the interaction of the dimer with other molecules on the T-cell surface leading to apoptosis.

PLP has been shown to be an anion channel blocker in a variety of cells (Korchak et al. 1980). It has been suggested that PLP might have a role in the treatment of autoimmunity and in transplant rejection (Namazi 2003). As the interaction of HIV gp120 and CD4 occurs through the D1 domain, PLP may have an anti-HIV effect as well. High concentrations of PLP inhibit viral coat protein envelope glycoprotein binding and infection of CD4 T cells by isolates of HIV-1 in vitro (Guo et al. 1994). Thus, PLP might function as an immune stimulator, not only by increasing CD4 T-cell count but also by protecting uninfected CD4 T cells from infection by HIV-1 (Salhany and Stevenson 1996). These effects of PLP are seen at concentrations in the range 50–70 mM. The rapid hydrolysis of PLP by tissue nonspecific alkaline phosphatase is a problem in maintaining such high concentrations of PLP. Levamisole, an antihelminthic drug, is an inhibitor of alkaline phosphatase. Thus a combination of high PLP dose along with this inhibitor might maintain the required tissue concentration of PLP to afford protection of uninfected CD4 T cells against HIV-1.

Toxicity of Pyridoxine

Concern about the toxicity of PN was associated with the use of Bendectin (doxylamine plus PN) by pregnant women and the subsequent occurrence of birth defects in the offspring. Later studies have ruled out any teratogenic effect of PN (Check 1979). Concern about its toxicity resurfaced after reports of reversible sensory neuropathy in persons ingesting gram quantities of PN for long periods

extending to years. It is significant to note that the reported sensory neuropathy was reversible after stopping of the ingestion of these large amounts. This indicates no permanent structural damage to the nervous system. High-dose PN ingestion over several years has been in vogue for the treatment of various clinical conditions such as homocysteinemia, PN-dependent seizures, autism, and Down syndrome (Rimland et al. 1978). There have been no adverse effects associated with these treatments. A dose of 500 mg/day PN for up to 2 years was not associated with neuropathy (Bendich and Cohen 1990).

Pyridoxal Phosphate Enzymes as Drug Targets

PLP enzymes have been targets of therapeutic intervention. In Parkinson's disease, abnormal pulsatile stimulation of the striatal dopamine receptors leads to dysregulation of genes and proteins in the downstream neurons and, consequently, alterations in the neuronal firing patterns. This results in the motor complication associated with Parkinson's disease, and the treatment aim is to restore normal dopaminergic transmission of striatal synapse. Levodopa slows the progression of Parkinson's disease.

The PLP-binding enzyme ornithine decarboxylase (ODC) is the rate-limiting step in polyamine biosynthesis. Polyamines are DNA-binding agents regulating its conformation. Mammalian ODC is a downstream mediator of myc-regulated reactions and is upregulated in proliferating cells. It is implicated as an oncogene in multiple types of tumors. Inhibition of ODC suppresses tumor development. Hence, ODC is a promising anticancer target. Inhibitors of ODC such as difluoromethylornithine are being tested as anticancer agents (Wu et al. 2011; Seiler 2003).

PLP-dependent enzymes are potential targets for developing antiparasitic drugs. There are several PLP enzymes with high prevalence among the protozoan species. Enzymes of the sulfur-containing amino acid metabolic pathway are significant in terms of their distribution between hosts and their disease-causing parasites. The enzymes of the forward transsulfuration pathway are present in protozoan parasites, but lacking in their host. Another PLP enzyme, methionine ɣ-lyase, is important to the parasite for the production of propionic acid for energy metabolism and for the degradation of sulfur-containing amino acids. Host mammalian cells lack this enzyme, and hence it is a target for drug development against infection by protozoans such as *Trichomonas vulgaris* and *Entamoeba histolytica*. The halogenated methionine analog S-trifluoromethyl-L-homocysteine and its amide derivative are toxic to the parasite and have potential as antiparasitic drugs (Sato et al. 2010).

Of the parasitic diseases, the most devastating is malaria, with a worldwide annual death toll of more than a million people. It is transmitted by the mosquito. Xanthurenic acid is required for gametogenesis and fertility of the parasite *Plasmodium falciparum*. It is synthesized in the tryptophan degradative pathway through the PLP-dependent enzyme kynurenine aminotransferase. Hence, this enzyme is a target for the development of antimalarial drugs (Muller et al. 2009). African sleeping sickness is another widespread epidemic caused by *Trypanosoma*

brucei, which is transmitted by flies. ODC, a key enzyme in the pathway for the synthesis of polyamines, is a target enzyme for drug development. Alpha-difluoromethylornithine, an irreversible inhibitor of ODC, has been developed for the treatment of sleeping sickness (Krauth-Siegel et al. 2007).

Policies and Protocols

The prevalence of frank clinical symptoms of vitamin B_6 deficiency is rare in advanced countries. However, a relative deficiency is present in pregnant women and women on oral contraceptive steroids. Vitamin B_6-dependent seizures in infants and children, and the use of pyridoxine for their treatment, are well-recognized. However, newer information on the protective role of pharmacological doses of vitamin B_6 in the treatment and amelioration of a variety of chronic conditions needs to be disseminated, and policies in this regard are useful. RDA levels do not have any relevance to the protective role of vitamin B_6 in hypertension, cardiovascular diseases, nephropathy, retinopathy, neuropathy, and dysfunction of the immune system and as an adjuvant in cancer treatment. The required therapeutic doses are much higher. There is no toxicity associated with these dose levels. Given these considerations, hospital-level policies to consider vitamin B_6-based treatment as frontline or adjuvant treatment for such conditions should be evaluated.

Dictionary of Terms

- **Primary vitamin B_6 deficiency** – A deficiency in vitamin B_6 that is due to a lack of availability in the diet. Primary vitamin B_6 deficiency is relatively rare in the developed world.
- **Pyridoxal phosphate-dependent enzymes** – An enzyme whose activity depends upon the presence of pyridoxal phosphate as a coenzyme. Over 140 pyridoxal phosphate-dependent enzymes are known, and they play critical roles in the metabolism of amino acids, carbohydrates, and lipids.
- **Pyridoxine dependency** – A condition characterized by a requirement, typically lifelong, for administration of high levels of pyridoxine far in excess of normal daily requirements. Pyridoxine dependency can result in epileptic seizures that can only be alleviated by the provision of pyridoxine.
- **Secondary vitamin B_6 deficiency** – A deficiency in vitamin B_6 that occurs despite an adequate dietary supply. A secondary vitamin B_6 deficiency can occur in specific situations of vitamin B_6 loss, such as uremic dialysis patients, in whom water-soluble vitamin loss can be significant.
- **Vitamer** – Chemical compounds that exhibit the activity of a particular vitamin. These compounds typically have a similar chemical structure and can be used in vitamin-deficient individuals to provide vitamin activity.

Summary Points

- Pyridoxine, pyridoxal, and pyridoxamine and their phosphorylated derivatives are vitamers of the vitamin B_6 group. Pyridoxal phosphate is the most versatile of all coenzymatic forms of vitamins.
- There are over 140 PLP-dependent enzymes and they are present in all organisms. PLP enzymes participate in the metabolism of amino acids, carbohydrates, and lipids.
- Primary deficiency of vitamin B_6 is rare in developed countries. However, pregnant women and women on oral contraceptive steroids have a relative vitamin deficiency even on a normal intake of vitamin B_6. A functional deficiency of vitamin B_6 is also recognized in uremic patients and patients treated with drugs such as isonicotinic acid hydrazide, cycloserine, and penicillamine.
- Vitamin B_6 has a crucial role in neurobiology as the putative neurotransmitters, GABA, catecholamines, and serotonin are products of PLP-dependent decarboxylases. There are nonparallel changes in the catecholamines and serotonin in vitamin B_6 deficiency leading to a significant neurotransmitter imbalance.
- Maternal vitamin B_6 deficiency has a significant impact on neuronal development of the offspring. Congenital deficiency leads to seizures in the neonate and impaired neuronal development.
- Pyridoxine dependency is recognized as an inborn abnormality in children having intractable epilepsy which is not responsive to anticonvulsant therapy and responds only to pharmacological doses of pyridoxine.
- Pyridoxine affords neuroprotection against neuroexcitants such as domoic acid. This neuroprotection flows from its effect on the syntheses of GABA and serotonin.
- Vitamin B_6 deficiency is also associated with hypertension. Various animal models of hypertension respond to pharmacological doses of pyridoxine. In addition to its effect on serotonergic neurotransmission, PLP is a regulator of cellular calcium channels affecting both the voltage-mediated and the ATP-mediated Ca^{2+} channel transporters. High-dose pyridoxine is effective in the treatment of hypertension and cardiovascular diseases.
- Hyperglycemia is the most significant factor in the onset and development of vascular complications of diabetes leading to chronic kidney disease. Treatment with high-dose pyridoxine is effective in the treatment of nephropathy, retinopathy, and neuropathy.
- Vitamin B_6 regulates the transcriptional activation induced by steroid hormone receptors. Large doses of pyridoxine have an effect on tumorigenesis. PLP functions as an immune stimulator and protects uninfected CD4 T cells from infection by HIV-1.
- High doses of pyridoxine up to 500 mg/day over years have been used in the treatment of several chronic human conditions with no adverse effects.
- Pyridoxal phosphate-dependent enzymes such as ornithine decarboxylase are potential targets for developing antiparasitic drugs.

Abstract

A number of key carboxylase enzymes involved in metabolism depend upon the vitamin biotin for their structure and function. Humans and animals require biotin to be supplied in the diet. Biotin deficiency is relatively rare in the developed world and typically reflects consumption of egg white-enriched or ketogenic diets, whereas deficiency in underdeveloped countries is more likely to be due to biotin-poor diets. The effects of biotin deficiency are not typically life-threatening, but can lead to developmental delays in children, or hair and skin abnormalities in affected individuals. In contrast, biotin supplementation has been shown to provide salutary benefit in some individuals, such as diabetics. Here we examine the biochemistry of biotin, as well as the effects of biotin deficiency and supplementation, with a focus on human health.

Keywords

Biotin · Prosthetic group · Carboxylases · Multiple carboxylase deficiency · Glucose metabolism · Cell differentiation and proliferation · Pancreatic inflammatory proteins · Pharmacological effects

List of Abbreviations

ACC	Acetyl-CoA carboxylase
ATP	Adenosine triphosphate
HCS	Holocarboxylase synthetase
MCC	β-methylcrotonyl-CoA carboxylase
MCD	Multiple carboxylase deficiency
PAP	Pancreatitis-associated protein
PC	Pyruvate carboxylase
PCC	Propionyl-CoA carboxylase
PEPCK	Phosphoenolpyruvate carboxykinase
SMVT	Sodium-dependent multivitamin transporter

Introduction

Biotin is a water-soluble vitamin. Its discovery, elucidation of its structure, and delineation of its role in metabolism involved diverse investigations spanning several decades. Biotin was shown to be cis-hexahydro-2-oxo-1H-thieno [3,4] imidazole-4-valeric acid. The best known and understood role of biotin is as the prosthetic group of the biotin-containing enzymes – propionyl-CoA carboxylase (PCC), pyruvate carboxylase (PC), β-methylcrotonyl-CoA carboxylase (MCC), and acetyl-CoA carboxylase (ACC). The biotin-dependent carboxylase catalyzes an adenosine triphosphate (ATP)-dependent CO_2 fixation reaction in which biotin functions as a CO_2 carrier on the surface of the enzyme. These enzymes catalyze key reactions in gluconeogenesis, fatty acid biosynthesis, and amino acid catabolism. In addition, biotin has been shown to participate in other cellular events such as transcriptional and translational regulation. This review examines the role of biotin in metabolism, biotin deficiency, biotin dependency, as well as the non-prosthetic group functions of biotin.

Structure and Biosynthesis

du Vigneaud showed that the previously known requirement of various bacteria for pimelic acid was satisfied by biotin. Later studies provided direct evidence for the incorporation of pimelic acid as a unit in the biosynthesis of biotin, indicating a two-stage biosynthetic pathway involving the synthesis of pimelate and its incorporation in the biotin bicyclic ring structure (Lin and Cronan 2011). Dethiobiotin, a sulfur-free analog of biotin, is the direct precursor of biotin during its biosynthesis in microorganisms. Most microbes, plants, and fungi synthesize biotin, whereas for animals and humans, it is a required growth factor. The last four steps in the biosynthesis of biotin are conserved in biotin-producing microorganisms. Of these, two enzymes – 8-amino oxononanoate synthase and 7,8-diaminopelargonic acid aminotransferase – are pyridoxal-5-phosphate-dependent enzymes (Mann and Ploux 2011). Several inhibitors of these two enzymes have been used for the design of herbicides and antibiotics. The addition of biotin to food, feed, and cosmetic products creates a large demand which is met by chemical synthesis. In view of the high environmental burden of these processes, current efforts are directed toward the improvement of microbial biotin production. The major portion of biotin in animal and plant sources is protein bound. Biocytin (biotinyl lysine) is released upon the enzymatic digestion of biotin-containing proteins. It is cleaved by the enzyme biotinidase into biotin and lysine (Fig. 1).

Absorption and Transport

Biotin is widely distributed in foodstuffs, although in low concentrations. Egg yolk, liver, nuts, and legumes are rich in biotin. Most of the biotin in foods such as meat and cereals is protein bound. Enzymatic hydrolysis in the gastrointestinal

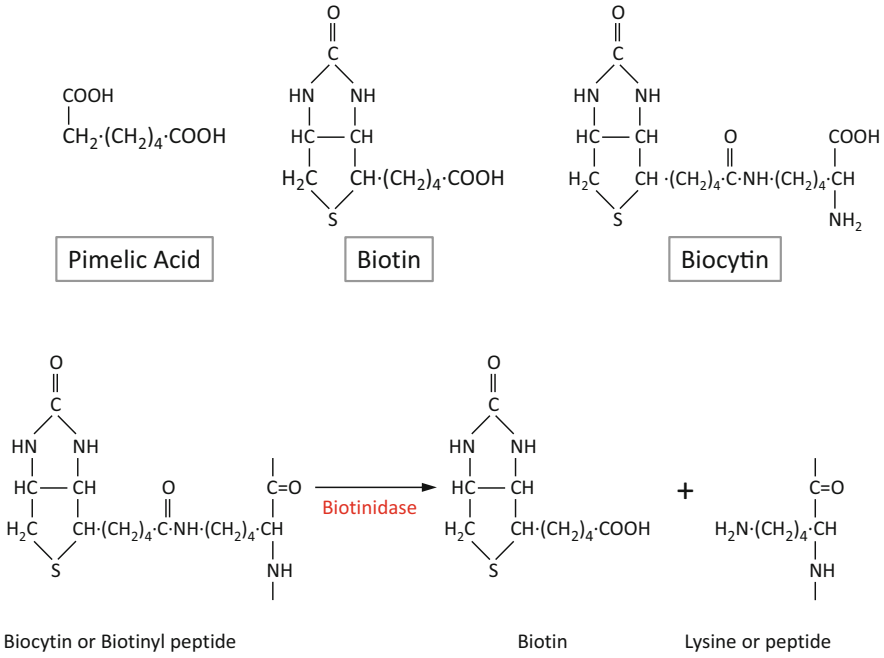

Fig. 1 Structure relationship of biotin and congeners

tract releases biocytin (or biotinyl peptides) rather than free biotin. Biotinidase activity is present in pancreatic and intestinal secretions as well as in brush border membranes. The uptake of biotin by human cell lines is saturable (Dakshinamurti and Chalifour 1981; Chalifour and Dakshinamurti 1982). The uptake of biotin and biocytin in rat jejunal segments is biphasic (Dakshinamurti et al. 1987). At concentrations below 50 nM, the saturable uptake mechanism would make enough biotin available to the animal. This saturable component uses a sodium-dependent multivitamin transporter (SMVT) having affinity for pantothenic acid, lipoic acid, as well as biotin. The rarity of primary biotin deficiency in humans is consistent with this. The late-onset type of multiple carboxylase deficiency (MCD) was shown to be due to the lack of a system for absorbing biotin in the nanomolar range, and in turn due to the lack of biotinidase. Biotinidase is the only protein in brush border membranes and the only protein in human serum that binds to biotin (Chauhan and Dakshinamurti 1986, 1988). Based on the above studies, it was suggested that biotinidase in vivo functions in the transport of biotin (Dakshinamurti and Chauhan 1989). It has been shown that in cases of late-onset MCD, patients lack the system for absorbing nanomolar biotin and respond only to pharmacological biotin doses, indicating that only the saturable portion of the biotin transport system is defective (Roth et al. 1982; Roth 1985).

Biotin Assay

Microbial growth assays using microorganisms such as *Lactobacillus plantarum*, *Lactobacillus casei*, *Ochromonas danica*, or *Saccharomyces cerevisiae* have traditionally been used to measure biotin content. Avidin-binding assays measure the ability of biotin to compete with radiolabeled (^{3}H or ^{14}C) biotin for binding to avidin (Dakshinamurti et al. 1974; Dakshinamurti and Allan 1979). Avidin-binding assays using electrochemical or bioluminescence detection or a double-antibody technique have been published (Terouanne et al. 1989; Thuy et al. 1991).

Biotin Requirement

There is no reliable estimate of the biotin requirement of various human groups. The Food and Nutrition Board of the National Research Council has prescribed adequate intakes for various age groups (National Research Council, Dietary Reference Intakes Tables, The National Academies, Washington, D.C., 2005).

Biotin as Prosthetic Group of Biotin Enzymes: Role in Metabolism

The best known and understood role of biotin is as the prosthetic group of biotin-containing enzymes, the carboxylases. Biotin acts as a vector for the transfer of the carboxyl group by biotin enzymes which include PCC, PC, MCC, and two isoforms of acetyl-CoA carboxylase (ACC1 and ACC2) in mammals. Biotin enzymes are present in prokaryotes and eukaryotes, with phylogenetic analysis indicating an ancient evolutionary origin. Although the enzymes catalyze very different reactions, they share common active site features and mechanisms of action. These enzymes control key steps in gluconeogenesis, branched-chain amino acid catabolism, fatty acid synthesis, and fatty acid oxidation in specific tissues, thus underscoring their key roles in intermediary metabolism (Fig. 2).

Biotin-dependent carboxylases function in two steps – biotin carboxylase and carboxyl transferase. The biotin carboxylase component catalyzes the MgATP-dependent carboxylation of the N1 of the biotin cofactor using bicarbonate as the CO_2 donor. Biotin is linked covalently through an amide linkage to the ε amino group of a specific lysine in the biotin carboxyl carrier protein by a protein ligase. In the second step, the carboxyl transferase catalyzes CO_2 transfer from carboxybiotin to the carboxyl group acceptor. The substrates are coenzyme A esters such as acetyl-CoA, propionyl-CoA, and 3-methylcrotonyl-CoA. Pyruvate serves directly as a substrate (Tong 2013).

As most food sources are low in their biotin content, which is usually protein bound, higher organisms have developed an efficient biotin recycling mechanism to ensure adequate supply of biotin for normal metabolism. Biotin taken up by the cell is covalently attached to various apocarboxylases by holocarboxylase synthetase

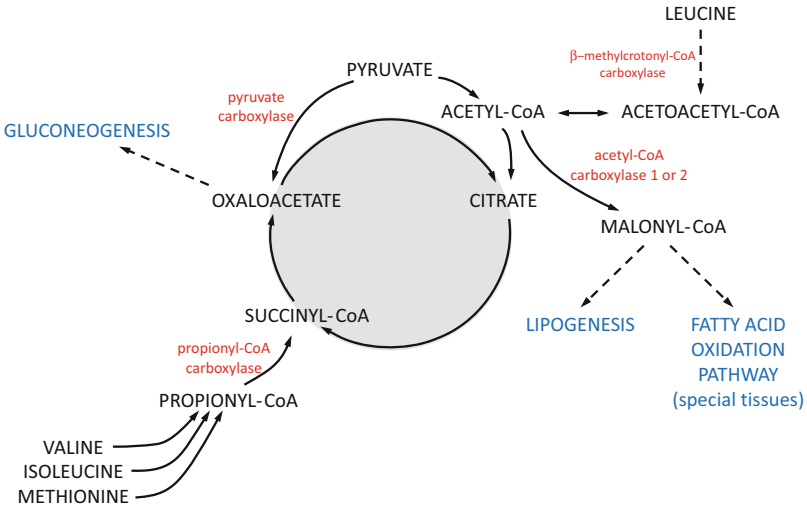

Fig. 2 Role of biotin enzymes in intermediary metabolism

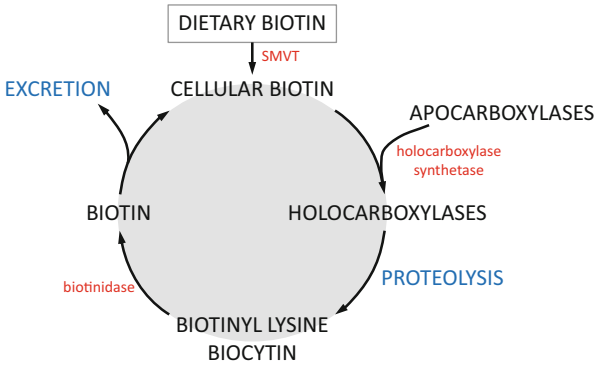
Fig. 3 The biotin cycle



(HCS). During the turnover of biotin enzymes, the biotin peptide or its further degradation product biocytin is cleaved by intracellular or plasma biotinidase, thus regenerating biotin which is recycled for the synthesis of the new biotin holocarboxylase (Fig. 3). Given this efficient recycling mechanism, the biotin requirement of the organism is low. However, mutations in either biotinidase or HCS are lethal as they lead to MCD.

Acetyl-CoA Carboxylase

ACC catalyzes the ATP-dependent carboxylation of acetyl CoA, leading to the formation of malonyl-CoA. In mammals, there are two isoforms of ACC: ACC1 is expressed in lipogenic tissues such as liver, adipose tissue, and lactating mammary

gland. The product malonyl-CoA is the building block to extend the chain length of fatty acids by two carbon increments, catalyzed by fatty acid synthase. Long-chain fatty acids are incorporated into complex lipids such as triglyceride and phospholipid. ACC1 is regulated by hormones and dietary and nutritional state. ACC1 is stimulated by citrate and inhibited by long-chain acyl-CoA and by phosphorylation of the enzyme. Mammals have another isoform – ACC2 – which is associated with the outer mitochondrial membrane and is expressed in the heart, skeletal muscle, and liver. The product of ACC2, malonyl-CoA, is an inhibitor of carnitine palmitoyltransferase-1, involved in the transport of long-chain fatty acyl-CoAs into the mitochondria for β-oxidation. ACC2 knockout mice show elevated fatty acid oxidation and increased energy expenditure (Abu-Elheiga et al. 2001).

Propionyl-CoA Carboxylase

In the catabolic pathways of odd-chain fatty acids, PCC is crucial for the catabolism of branched-chain amino acids isoleucine, threonine, and valine as well as methionine. PCC catalyzes the conversion of propionyl-CoA to methylmalonyl-CoA which in turn enters the tricarboxylic acid cycle via succinyl-CoA. Mammalian PCC is a mitochondrial enzyme which is activated by monovalent cations (K^+, NH_4^+). Inherited deficiency of PCC leads to propionic acidemia (Dakshinamurti and Chauhan 1988).

3-Methylcrotonyl-CoA Carboxylase

MCC catalyzes the conversion of 3-methylcrotonyl-CoA to 3-methylglutaconyl-CoA and is involved in the catabolism of leucine and isovalerate. Deficiency in the activity of this enzyme results in 3-methylcrotonyl-glycinuria, an inborn error of metabolism.

Pyruvate Carboxylase

PC catalyzes pyruvate conversion to oxaloacetate, with a crucial role in gluconeogenesis in the liver and the kidney where it catalyzes the first step in the synthesis of glucose from pyruvate. It is also present in lipogenic tissues and participates in fatty acid synthesis by transporting acetyl groups via citrate and reducing groups via malate, from the mitochondria to the cytosol. It has an anaplerotic role in the formation of oxaloacetate, replenishing intermediates of the tricarboxylic acid cycle that have been used up for the synthesis of glucose, fatty acids, and amino acids. A rare autosomal recessive metabolic disorder resulting in deficient PC activity has been reported with multiple clinical manifestations.

With the exception of ACC1, the biotin carboxylases are mitochondrial enzymes. Biotin deficiency affects mitochondrial metabolism and function significantly.

Oxidative phosphorylation is impaired in biotin-deficient rat liver mitochondria (Dakshinamurti et al. 1970). A role for biotin in maintaining mitochondrial complex IV and heme metabolism has been reported (Atamna et al. 2007).

Biotin deficiency affects the level of tricarboxylic acid cycle intermediates. PC has an anaplerotic role, and its deficiency decreases the production of succinyl-CoA. MCC deficiency leads to methylcrotonyl-CoA accumulation in the mitochondria where it reacts with glycine, depleting its content in the mitochondrial matrix. Succinyl-CoA and glycine are the precursors of heme synthesis. Thus, biotin deficiency, through depletion of these intermediates, leads to a decrease of mitochondrial complex IV, a functional indicator of heme deficiency, decreasing ATP production (Atamna et al. 2007). The significant role of biotin in energy metabolism is indicated by the sparing of the brain and the heart from the effects of general biotin deficiency, thus protecting these organs at the expense of organs such as the liver and kidney (Pacheco-Alvarez et al. 2004; Velazquez-Arellano et al. 2008). Because of the relative insensitivity to biotin deficiency, cardiac tissue is able to maintain ATP synthesis.

Biotin Deficiency

Hair thinning with loss of color, periorificial skin rash, hypotonia, lethargy, and developmental delay are the clinical sequelae of pronounced biotin deficiency in human adults and infants. Early reports of these clinical findings were the result of feeding individuals an egg white diet. The egg white protein avidin binds to free biotin, rendering it unavailable for absorption. Diet-induced biotin deficiency, with its unique clinical signs, is rare; however, milder conditions of deficiency can occur.

Measurement of serum biotin and the urinary excretion of biotin and its metabolite bisnorbiotin have been used as measures of the biotin status of individuals, but they are fraught with uncertainty. Indices based on the metabolic function of biotin have been found to be more reliable as indicators of biotin status. Among these are the urinary excretion of metabolites in biotin-mediated steps in metabolism and the activation index of biotin enzymes. Urinary excretion of 3-hydroxyisovaleryl carnitine and 3-hydroxyisovaleric acid is increased in early biotin deficiency due to a decrease in activity of the biotin enzyme MCC (Stratton et al. 2011). PCC activity in peripheral blood lymphocytes has been shown to be an early and more sensitive indicator of marginal biotin deficiency than urinary excretion of 3-hydroxyisovaleric acid. Malnutrition in developing countries is a major cause of multiple vitamin deficiencies. In the developed world, biotin deficiency is related to genetic factors leading to biotin dependency. However, conditions of prolonged parenteral nutrition lacking biotin supplementation, or the use of infant formulas lacking biotin, have been shown to result in biotin deficiency (Sato et al. 2016; Wakabayashi et al. 2016). Long-term treatments with a heterogeneous group of anticonvulsants have been shown to result in biotin deficiency due to impaired biotin absorption and salvage

by the kidney (Mock and Dyken 1997). A low-carbohydrate, high-fat "ketogenic" diet is used to treat drug-resistant epilepsy and has been shown to induce a relative biotin deficiency (Yuasa et al. 2013). A marginal deficiency of biotin is common in normal human pregnancy. The frequency of such deficiency during the first trimester is of concern due to the teratogenicity of biotin deficiency.

Biotin Dependency

Single Carboxylase Deficiency

The incidence in infants of organic acidemia has been investigated and characterized as due to the lack of one or more of the biotin carboxylases (Sweetman and Nyhan 1986). Inherited disorders of individual biotin carboxylases have been reported. These patients do not respond to pharmacological biotin doses. PCC deficiency causes elevated concentrations of propionic and lactic acids in blood and increased levels of their secondary metabolites such as 3-hydroxypropionic acid, 2-methylcitrate, and propionyl glycine excreted in the urine.

Multiple Carboxylase Deficiency

In MCD, the patient exhibits deficiencies of all three mitochondrial carboxylases – PC, PCC, and MCC. Two distinct types of MCD are recognized based on the age of onset and the nature of clinical presentation (Sweetman and Nyhan 1986). A deficiency of HCS is generally regarded to be the prime biochemical lesion in the neonatal type of MCD. The beneficial response of the affected infant to large doses of biotin administered prenatally to the mother suggests a defective HCS with a high K_m for biotin (Roth et al. 1982). Incidentally, this was the first instance of successful prenatal treatment of this condition. The prenatal treatment followed by postnatal biotin supplementation of the child resulted in the total avoidance of any effects of biotin deficiency in the child.

The late-onset (or juvenile) form of MCD is associated with low serum biotin values and is associated with defective biotin absorption due to biotinidase deficiency. Biotinidase, along with HCS, participates in the cellular biotin cycle (Fig. 3). Biotinidase deficiency is an autosomal recessive inherited metabolic disorder. Untreated individuals develop neurological and cutaneous symptoms as well as myelopathy. These symptoms can be prevented if the biotin treatment is started at birth or before symptoms develop. Newborn biotinidase screening has been instituted in many countries worldwide (Wolf 2011, 2015). A case of biotin dependency due to a defect in biotin transport was reported. In this child, biotin dependency was not the result of biotinidase, holocarboxylase, or biotin deficiency but the result of a genetic defect in a biotin transport protein distinct from the SMVT.

Biotin-Binding Proteins

Besides the carboxylases in which biotin is attached covalently to the apocarboxylase, there are a group of proteins which bind biotin non-covalently. Both avidin, the biotin-binding protein of raw hen egg white, and streptavidin, a bacterial protein, have exceedingly high affinities for biotin (K_m of 10^{-15} M). This is the strongest known non-covalent binding between a protein and a small molecular weight ligand. Other biotin-binding proteins include biotinidase, biotin HCS, biotin antibodies, and nuclear biotin-binding protein, with progressively lower affinities for biotin.

Monoclonal antibodies to biotin have been prepared using keyhole limpet hemocyanin (Dakshinamurti et al. 1986; Dakshinamurti and Rector 1990). One of the four clones isolated produced antibody of high affinity that bound both free and haptenic biotin antigen as well as biocytin. The high affinity between biotin and avidin has been utilized in various areas of biological research. Of much significance is the use of avidin-biotin complex for the localization and evaluation of cell surface receptors. The use of monoclonal biotin antibodies facilitates these studies.

Avidin-biotin technology, based upon the strong interaction between avidin or streptavidin and biotin, has been applied in biology, medicine, and technology. Even biotin covalently bound to a protein is available for binding by avidin or streptavidin. The various chemical and enzymatic biotinylation procedures have contributed to the extensive use of the avidin (streptavidin)-biotin technology (Dundas et al. 2013). The monoclonal anti-biotin antibody has been shown to be an excellent substitute for streptavidin-based immunoassay systems.

Non-prosthetic Group Functions

Biotin Requirement for Cultured Cells and for Cell Differentiation

A requirement for biotin was demonstrated for HeLa cells, human fibroblasts, and Rous sarcoma virus-transformed baby hamster kidney cells (Chalifour and Dakshinamurti 1982; Bowers-Komro and McCormick 1985). Mammalian cultured cells under conditions such as serine starvation, when they do not get growth signals, come to a halt in the quiescent, non-growing G0 state. Normal cells in G1 arrest due to serine starvation do not incorporate [^{3}H]-thymidine into DNA, but do so as soon as serine is restored. However, biotin-deficient cells, under similar conditions, do not incorporate [^{3}H]-thymidine even when serine is restored. When biotin is restored to the medium, the biotin-deficient cells, after a lag, start incorporating thymidine into DNA, with a stimulation of protein synthesis during this lag.

The 3T3-L1 mouse fibroblast cell line can differentiate into an adipose cell type. When the cells reach confluence and start to differentiate, they greatly increase the rate of triglyceride synthesis. This parallels the coordinate increase in the activities of the key enzymes of lipogenesis and correlates with the rise in the nuclear run-off transcription rates for the mRNA during differentiation. This process of

differentiation can be accelerated by increasing the amount of serum in the culture medium, or by adding insulin or biotin to the culture medium.

Biotin deficiency in mice changes the subpopulation of spleen lymphocytes and decreases their proliferative response to concanavalin A. Under conditions of biotin deficiency, the involution of the thymus is accelerated and thymocyte maturation is arrested, indicating that a specific stage in T cell maturation is sensitive to biotin deficiency.

Development of the Palatal Process

Congenital malformations occur in domestic fowl maintained on a biotin-deficient diet. At mid-gestation, biotin-deficient embryos weighed less than normal embryos and had external malformations such as micrognathia and micromelia. There was a marked decrease in the size of the palatal process due to altered proliferation of the mesenchyme. The development of the palatal process in culture was investigated (Watanabe et al. 1995). After 72 h of organ culture, more than 40% of the explants from normal (biotin-repleted) mouse embryos were in stage 6 of development, which dropped to only 6.5% for embryos cultured in biotin-deficient medium. Administration of biotin to biotin-deficient dams 24 h prior to removal of the embryo resulted in over 50% of explants at stage 6 of development when cultured in a medium containing 10^{-7} M biotin. There was no detrimental effect on any of the organic acid intermediates or their secondary metabolites on palatal closure of the explants when these compounds were added to the organ culture medium, indicating the continuous requirement for biotin during proliferation of the mesenchyme, perhaps for the synthesis of growth factors during organogenesis. As a marginal deficiency of biotin in normal human pregnancy is quite common, the teratogenic effects of such deficiency are a matter of concern.

Biotin and the Reproductive System

In mammals, spermatogenesis is dependent primarily on testosterone, which is produced in the Leydig cells and acts on the tubular cells of the seminiferous tubules to drive spermatogenesis. Testicular and serum levels of testosterone are decreased in the biotin-deficient rat (Paulose et al. 1989). Biotin deficiency was accompanied by a significant sloughing of the seminiferous tubule epithelium in these rats. Treatment of biotin-deficient rats with gonadotropins or biotin increases the levels of serum testosterone. Even when the testosterone levels are maintained high in biotin-deficient rats by testosterone implants, the increase in serum testosterone does not result in normal spermatogenesis. In contrast, the administration of biotin alone or with testosterone to biotin-deficient rats leads to normal spermatogenesis. This suggests that biotin is involved in the formation of local testicular factors that are required in addition to testosterone and follicle-stimulating hormone, for the normal interaction among Leydig, Sertoli, and peritubular cells.

The effects of diets with varying biotin contents on the estrus cycle, estradiol and progesterone serum levels, ovarian morphology, uterine mRNA abundance of estradiol and progesterone nuclear receptors, as well as estradiol-degrading enzymes in the liver of BALB/cAnNHsd female mice were studied (Baez-Saldana et al. 2009). Biotin deficiency was associated with reduction in ovary weight, arrested estrous cycle, and significant changes in ovarian morphology. Biotin deficiency decreases serum insulin growth factor-1 concentration, which might account for the effects observed in ovarian follicles in biotin-deficient mice.

Immunological and Inflammatory Functions

Cytokines, secreted by immune cells in response to antigen stimulation, bind to target cell receptors to activate intracellular signaling cascades controlling cellular processes such as growth, proliferation, and apoptosis. The expression of genes encoding the cytokine interleukin-2 and its receptor correlates with the biotin status of human lymphoid cells (Wiedmann et al. 2003). The effect of biotin on the metabolism of cytokines might underlie its role in immune function. The activities of various cell signals such as biotinyl-AMP, SP1 and SP3, nuclear factor NF-κB, and receptor tyrosine kinase are biotin dependent. Biotin deficiency upregulates tumor necrosis factor-α production, and biotin excess downregulates it (Kuroishi 2015). As this factor has an important role in the pathogenesis of inflammatory disease, the possibility of treating inflammatory diseases with biotin would be a fruitful area of investigation.

Biotin and Glucose Metabolism

The initial and rate-limiting step in the metabolic utilization of glucose is its phosphorylation by glucokinase, whose activity is influenced by dietary, nutritional, and hormonal states of the animal. Hepatic glucokinase is decreased in biotin-deficient rats fed with either high or low carbohydrate diets, and administration of insulin or biotin restored glucokinase activity to normal levels (Dakshinamurti and Cheah-Tan 1968a, b). Biotin also played a role in the precocious development of glucokinase in young rats (Dakshinamurti and Ho Chong 1970). In all these studies, enzyme activity correlated with protein synthesis. Pharmacologic levels of biotin increased glucokinase activity levels in biotin-repleted animals (Dakshinamurti 2005). Hepatic glucokinase activity in biotin-injected starved rats increased threefold compared with starved rats. The relative amount of glucokinase mRNA in the liver of biotin-injected starved rats increased fourfold over the levels seen in normal-fed rats and about 20-fold of that seen in starved rats not receiving biotin injection. Glucokinase induction was marked and rapid and correlated with increased glucokinase enzyme activity. In “run-on” transcription assays using isolated liver nuclei, biotin administration to the whole animal increased glucokinase gene transcription sevenfold, an effect that was not due to an increase in overall transcription efficiency

as the transcription of the β-actin gene was unaffected (Chauhan and Dakshinamurti 1991).

In both fasted and diabetic rats, hepatic phosphoenolpyruvate carboxykinase (PEPCK) activities are markedly increased. Refeeding a high-carbohydrate diet to fasted rats decreased PEPCK mRNA due to repression of PEPCK gene transcription by insulin. Three hours after biotin administration to starved rats, hepatic PEPCK mRNA levels decreased to 15% of the levels seen in non-biotin-injected starved rats. The effect of biotin paralleled the effect of insulin in these animals. In "run-on" transcription experiments using isolated liver nuclei, biotin suppressed hepatic PEPCK mRNA by 55% at 30 min after biotin administration. The inhibition is dominant over other stimulatory effects (Dakshinamurti and Li 1994). There are many similarities between biotin and insulin in their actions on enzymes of glucose metabolism. Both induce a key glycolytic enzyme and repress PEPCK, the key gluconeogenic enzyme. Further experiments indicate that biotin repressed the gluconeogenic genes through a pathway independent of insulin signaling (Sugita et al. 2008).

Biotin stimulated glucokinase activity and mRNA expression after a short-term treatment in cultured pancreatic β cells. Biotin also stimulated glucokinase activity and insulin secretion in rat islets in culture. Islet glucokinase activity and mRNA are reduced by 50% in the biotin-deficient rat. Insulin secretion in response to glucose was also impaired in islets isolated from biotin-deficient rats (Romero-Navarro et al. 1999). Biotin deficiency also affects pancreatic islet morphology. Besides defects in insulin sensitivity, there was disruption of islet architecture with an increase in the number of α cells in the islet core. Biotin deficiency promoted hyperglycemic mechanisms (Larrieta et al. 2012). Administration of pharmacological concentrations of biotin to normal rodents enhanced insulin secretion and the expression of genes and signaling pathways that favor islet function and augmented the proportion of β cells by enlarging islet size (Lazo de la Vega-Monroy et al. 2013).

Biotin starvation reduces glucose consumption and energy production in three different eukaryotes, despite the fact their phylogenetic lines diverged more than a billion years ago. In these biotin-starved organisms – yeast, nematode, and rat – the genomic expression corresponded to scant glucose conditions, pointing to a strongly selected role of biotin in the control of carbon metabolism (Ortega-Cuellar et al. 2010; Velazquez-Arellano et al. 2011). This concept is strengthened by the similarities between biotin and insulin across species. In genetically diabetic kk mice and rats, biotin improved glucose tolerance. Similar results were also observed in humans with type I or type II diabetes (Singer and Geohas 2006). A combination of biotin and chromium picolinate improved glycemic control in poorly controlled diabetics receiving standard antidiabetic therapy (Albarracin et al. 2008).

A significant proportion of radioactive biotin injected into chicks or rats localized to the nuclear fraction of cells (Dakshinamurti and Mistry 1963b). During progressive biotin deficiency, the nuclear biotin content was relatively conserved, whereas there was a marked depletion of cytoplasmic and mitochondrial biotin content. A biotin-binding protein from rat liver nuclei has been isolated (Dakshinamurti and Chauhan 1990). This, along with other evidence on the incorporation of amino acids

into protein, indicated that biotin was involved in genetic regulation of protein synthesis (Dakshinamurti and Mistry 1963a). Later it was shown that all five histone classes extracted from human lymphocytes contained biotin (Stanley et al. 2001). HCS was distributed primarily in the nucleus of HeLa, Hep2, and fibroblasts with only a minor component in the cytoplasm (Narang et al. 2004; Gravel and Narang 2005). Thus, a dual role for HCS was established: its traditional role in the biotinylation of apocarboxylases and a novel role in the attachment of biotin to histones. HCS appears to interact with the methyl-CpG-binding domain protein 2 and also histone methyl transferase, thus creating epigenetic synergies between biotinylation and methylation events (Gravel and Narang 2005).

Biotin Induction of Pancreatitis-Associated Proteins

Recently, the effect of biotin repletion on the pancreas using a rat model of chronic biotin depletion was studied (Dakshinamurti et al. 2015). Animals fed with egg white-supplemented chow for 6 weeks were subsequently returned to a normal chow diet and given a single dose of biotin, or remained on the egg white diet for 1 week. Pancreatic gene expression was then analyzed by microarray.

Gene ontology analysis of the results revealed global gene expression changes in the pancreas of biotin-repleted rats compared to those with biotin depletion that, collectively, indicated a rapid induction of reparatory mechanisms upon restoration of biotin (Fig. 4) (Dakshinamurti et al. 2015). Notably, transcripts related to inflammation and fibrosis, such as mast cell protease 1 precursor, mast cell chymase 1, collagen Iα1, and collagen Vα1, were elevated by two- to threefold in the biotin-depleted pancreas. In contrast, transcripts associated with pancreatic endocrine/exocrine function were significantly increased by biotin repletion, including glucagon, islet amyloid polypeptide, and α-amylase 1A, as well as regulatory transcription factors including hepatocyte nuclear factor 6, hepatocyte nuclear factor 3β, and pancreas-specific transcription factor 1a. Further, evidence of the induction of a pancreas repair program following biotin repletion was noted. Pancreatitis-associated proteins 1 (PapI/Reg3b) and 2 (PapII/

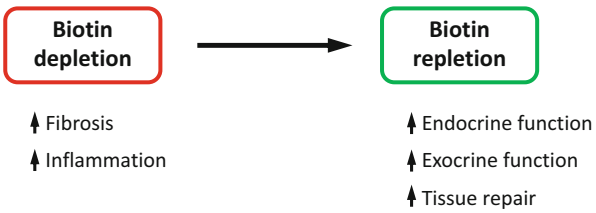


Fig. 4 Biotin repletion induces pancreatic repair. Following 6 weeks of biotin depletion, rats were maintained on a biotin-deficient diet, or were switched to a standard chow diet for 1 week and provided with a single injection of biotin (10 mg/kg IP). DNA microarray and quantitative PCR analysis of pancreas mRNA transcripts revealed gene expression changes indicative of tissue damage, inflammation, and fibrosis in biotin-deficient rats, compared to upregulation of endocrine and exocrine function and evidence of tissue repair following biotin repletion

Table 1 Expression of pancreatic repair transcripts following biotin depletion and repletion (Reproduced with permission from Dakshinamurti et al. 2015. Expression levels noted for acute pancreatitis are derived from Dusetti et al. 2000)

AffyID	Gene name	Gene symbol	BR/BD (fold)	Acute pancreatitis
1368238_at	Pancreatitis-associated protein 1 (PapI)/ regenerating islet-derived 3 beta	Reg3b	+34.3	+13.3
1387930_at	Pancreatitis-associated protein 2 (PapII)/ regenerating islet-derived 3 alpha	Reg3a	+14.9	+8.5
1367581_a_at	Osteopontin/secreted phosphoprotein 1	Spp1	+2.5	+3.6

Reg3a) are C-type lectins implicated in repair processes in numerous tissues; notably, they are induced by inflammation, and the loss of PapI, PapII, and the related PapIII by gene knockdown results in exacerbation of induced acute pancreatitis, with increased inflammatory cell infiltration (Closa et al. 2007; Vasseur et al. 2004; Zhang et al. 2004). A dramatic increase in PapI and PapII expression by 34- and 15-fold, respectively (Table 1), was noted similar to reports of Pap upregulation in acute pancreatitis (Dusetti et al. 2000); quantitative PCR analysis of pancreatic total RNA confirmed the microarray data, showing both transcripts increased in expression by 200-fold in response to biotin repletion. Given this robust response, biotin was assessed for the ability to independently alter Pap gene expression. Treatment of AR42J pancreatic acinar cells with biotin for 48 h induced significant five- to sevenfold increases in PapI and PapII expression (Dakshinamurti et al. 2015). Another transcript implicated in tissue repair, osteopontin/secreted phosphoprotein 1/Spp1, was also induced in the pancreas following biotin repletion, as well as in AR42J cells in response to biotin, but exhibited much lower levels of induction.

Such changes in Pap expression clearly reflect a potent induction; however, it pales compared to the changes observed in the biotin-repleted pancreas. This may simply reflect in vitro versus in vivo differences, however, as others noted that inflammation itself induces Pap gene expression (Closa et al. 2007). Given the microarray evidence of inflammation in the biotin-depleted pancreas, it is possible that restoration of biotin synergistically activates a Pap-mediated repair program in conjunction with the inflammation-driven mechanism.

Collectively, this data suggests that biotin deficiency results in pancreatic inflammation and fibrosis, possibly impairing its normal endocrine and exocrine functions. These results correlate with earlier reports of low biotin levels in diabetic patients and improved blood sugar control by biotin plus chromium picolinate. Biotin therefore appears to play an important role in normal pancreatic health and function. This data also suggests that much of the damage caused by biotin loss can be relatively rapidly reversed, concomitant with the activation of damage repair pathways, at least during the time period tested in this study (6 weeks). This is encouraging for individuals who may suffer acute or chronic biotin deficiency and furthermore suggests that biotin may be of benefit to diabetics in general, an avenue for further research.

Pharmacologic Effects: Biotin and Biotin-Binding Proteins

Animal studies have shown that biotin deficiency results in impaired glucose tolerance and decreased glucose utilization. Various clinical studies have indicated an inverse correlation between serum biotin levels and fasting blood glucose. The hypoglycemic effect of pharmacological doses of biotin has been reported in both type 1 and type 2 diabetic patients (Albarracin et al. 2008).

A common feature of metabolic syndrome is insulin resistance. It is also associated with hypertension. The pharmacological effect of biotin on hypertension was studied in the stroke-prone spontaneously hypertensive rat strain (Watanabe-Kamiyama et al. 2008). Biotin was beneficial: even a single dose decreased systolic blood pressure, an action that might be related to the effect of biotin as a soluble guanylate cyclase activator (Spence and Koudelka 1984; Singh and Dakshinamurti 1988). Biotin regulates the expression of several genes through activation of this cyclase (De La Vega and Stockert 2000).

ACC1 is a key lipogenic enzyme. In mammalian lipogenic tissues, this enzyme is regulated by dietary, nutritional, and hormonal conditions. Allosteric activation by citrate, feedback inhibition by long-chain fatty acids, reversible phosphorylation, and gene regulation of enzyme synthesis are the mechanisms regulating enzyme activity of ACC1. ACC1 is a cytosolic enzyme. In contrast, ACC2 is expressed mostly in the heart and skeletal muscle mitochondria where its product, malonyl-CoA, potently inhibits fatty acid oxidation. Long-chain fatty acids are converted by carnitine palmitoyltransferase into acyl carnitines for transport into the mitochondria, a process inhibited by ACC2-produced malonyl-CoA (Tong 2005; Tong and Harwood 2006). ACC2 knockout mice showed decreased malonyl-CoA content in skeletal and cardiac muscle, with increased fatty acid oxidation and reductions in total body fat, plasma free fatty acids and glucose, and tissue glycogen. These animals are protected from diet-induced diabetes and obesity (Oh et al. 2005). Because of its unique position in metabolism, the inhibition of ACC1 would inhibit de novo fatty acid production in lipogenic tissues and inhibition of ACC2 would inhibit fatty acid oxidation in the skeletal muscle and heart. This would have a favorable effect on cardiovascular risk factors associated with diabetes, insulin resistance, obesity, and the cluster of conditions referred to as the metabolic syndrome. A specific inhibitor of ACC2 would have therapeutic implications and is an area of intense current research.

One of the most devastating rice pathogens in the world is the fungus *Magnaporthe oryzae*, which depends on biotin for its growth (Skamnioti and Gurr 2009). Tamavidin1, an avidin-like biotin-binding protein from the mushroom *Pleurotus cornucopiae*, restricts the growth of *M. oryzae*. The possibility of reducing the availability of biotin to *M. oryzae* in rice by expression of the gene that encodes for tamavidin1 was investigated (Takakura et al. 2012). The positive results indicated a role for this strategy to engineer disease-resistant plants through the pathogen's auxotrophy. Biotin-binding proteins expressed in transgenic plants are

insecticidal to a wide variety of insects and, thus, useful in transgenic crop protection. Although their role in the protection of food crops such as rice has been established with some caveats, their use in protection of non-food crops such as fiber, forestry, and biofuel crops is boundless (Christeller et al. 2010).

Policies and Protocols

To our knowledge, policies on the provision of biotin in the diet, either for deficient individuals or as an adjunct to treatment of disease, are currently lacking. Biotin deficiency is not associated with short- or long-term threats to human life and furthermore is relatively rare, although occurrence is more likely in underdeveloped nations. A strong regulatory policy framework is thus unlikely to be needed, such as daily dietary requirements, particularly since such requirements remain poorly defined. Instead, it may be better to promote education of the benefit of biotin. Pregnant women may be biotin deficient and risk developmental delays in their children. In this case, government policies to promote monitoring of biotin status during pregnancy may be warranted. Government policies to promote education of pregnant women on the risks of biotin deficiency may also be useful. Likewise, those on long-term anticonvulsant therapy are likely to be biotin deficient, requiring supplementation.

Emerging evidence that biotin supplementation is beneficial in certain diseases such as diabetes suggests that it may be prudent to consider the development of policies at the point of care establishing the parameters of such supplementation. Further study in this area is strongly recommended, since biotin supplementation may provide a very cost-effective approach to helping manage diabetes and related conditions.

Dictionary of Terms

- **Avidin –** A protein found at high concentration in egg white, as well as other sources, which binds to biotin with high affinity.
- **Biotin** – A water-soluble vitamin that serves as a prosthetic group for multiple carboxylase enzymes. An alternate name for biotin is vitamin H.
- **Biotinidase** – An enzyme that cleaves covalently bound biotin from biotin-containing molecules. Biotinidase is the only known biotin-binding protein in human plasma.
- **Carboxylase** – An enzyme for transferring carboxyl moieties from a donor to an acceptor molecule.
- **Sodium-dependent multivitamin transporter (SMVT)** – A saturable transporter responsible for biotin uptake at the nanomolar level in the gut. SMVT is also able to bind to and transport pantothenic acid and lipoic acid.

Summary Points

- Biotin, a water-soluble vitamin, has a crucial role in the metabolism of carbohydrates and amino acids as well as in the synthesis and oxidative metabolism of lipids.
- Biotin acts as a prosthetic group for a number of key metabolic carboxylases.
- Humans and other animals obtain biotin from the diet, whereas many other organisms are capable of synthesizing biotin endogenously.
- While dietary guidelines for biotin in humans have been published, the precise requirement for biotin in the diet remains poorly defined.
- Biotin deficiency can cause alopecia, skin rash, lethargy, hypotonia, and, in biotin-deficient infants or children, developmental delays.
- Diet-induced biotin deficiency is rare, but can occur in response to excessive consumption of egg whites due to the biotin-binding capacity of avidin, due to chronic consumption of biotin-poor diets, or following long-term consumption of a ketogenic diet.
- Normal human pregnancy is associated with a biotin-deficient state; patients who have been on long-term anticonvulsant therapy are also biotin deficient.
- In addition to its role as the prosthetic group of the carboxylases, biotin has significant non-prosthetic group functions affecting cell proliferation, differentiation, glucose metabolism, and the inflammatory state.
- Pharmacological doses of biotin have profound ameliorative effects on conditions such as diabetes and inflammation.
- Biotin repletion studies in biotin-deficient rats suggest that biotin is capable of inducing the expression of reparative factors such as the pancreatitis-associated proteins.

Abstract

Vitamin B12 deficiency has been associated with various neuropsychiatric symptoms, and it has also been reported to be a reversible cause of dementia. In addition to myelopathy and hematological changes, increasing evidence suggests an association between low vitamin B12 status and cognitive impairment. The negative impacts of low vitamin B12 status on cerebrum range from subclinical microstructural changes to an overt debilitating state associated with permanent cerebral volume reduction. Therefore, prompt diagnosis of cognitive syndromes related to vitamin B12 deficiency is of paramount clinical importance, since this can significantly alter the prognosis and treatment approach. In addition, the impact of low vitamin B12 status can vary in terms of clinical phenotype and disease severity, resulting in further challenges in clinical practice. This raises the urgent need for other objective tools with sufficient reliability and reproducibility in addition to the existing serology profile survey. By incorporating structuralized cognitive and magnetic resonance imaging evaluations, the cognitive profiles and neuronal substrates vulnerable to vitamin B12 deficiency in the context of neurobiochemistry basis can be further explored. This chapter will provide an overview of the current knowledge from studies aiming on cognitive and magnetic resonance imaging evaluations, and discuss supportive evidence in related fields.

VBDNS	Vitamin B12 deficiency neuropsychological syndromes
Vit.B12	Vitamin B12

Introduction

Vitamin B12 (Vit.B12) is regarded to be a vitally important nutrient that has a significant impact on human health. In humans, vitamin B12 is required for two enzymatic reactions: the conversion of methylmalonyl-coenzyme A to succinyl

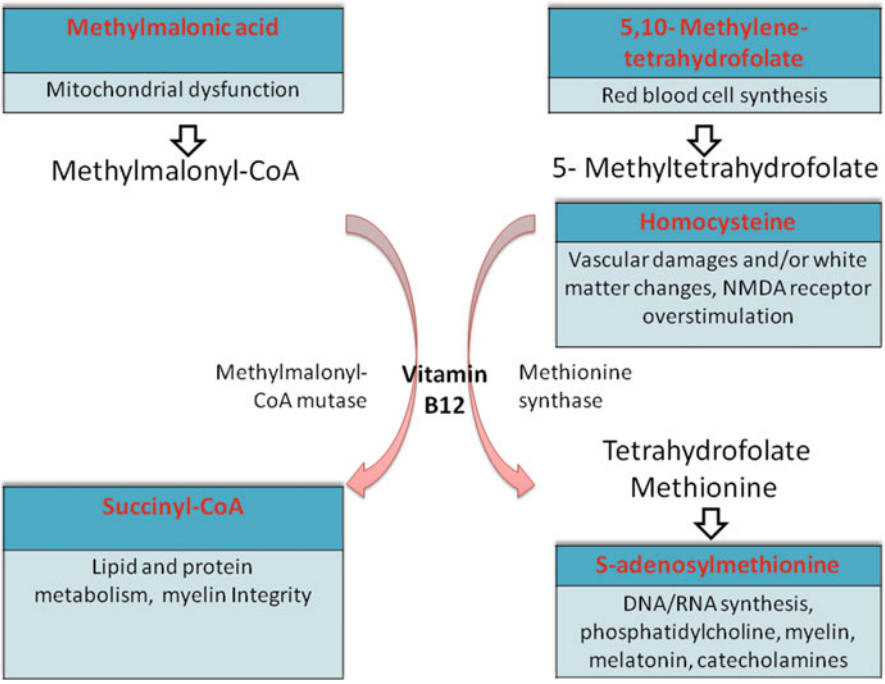

Fig. 1 Biochemistry pathway and cellular impact of vitamin B12 deficiency. In human, two typified major coenzyme B12-dependent enzyme are identified. Methylmalonyl-CoA mutase (the *left half* pathway) is regarded to be necessary for proper myelin synthesis and is not affected by folate supplementation. Contrarily, methionine synthase (the *right half* pathway) transfers a methyl group from 5-methyltetrahydrofolate to homocysteine, thereby generating tetrahydrofolate and methionine. In vitamin B12 deficiency, an increased homocysteine level and the trapping of folate as 5-methyl-tetrahydrofolate, from which tetrahydrofolate (the active form of folate) cannot be recovered, are expected. Current opinion suggests that vitamin B12 deficiency to be defined in terms of the serum concentration of vitamin B12, and of homocysteine and methylmalonic acid, two components of the vitamin B12 biochemistry pathways. *NMDA* N-methyl-D-aspartate, *DNA* deoxyribonucleic acid, *RNA* ribonucleic acid

coenzyme A, and the conversion of homocysteine (Hcy) to methionine. Through its unique biological properties, it is involved in several steps critical for hematopoiesis and myelination (Fig. 1). The clinical presentations related to Vit.B12 deficiency are polymorphic and of varying severity. Hematoneurological dissociations are common (Lindenbaum et al. 1988; Stabler et al. 1990; Tu et al. 2017). In the hematological system, Vit.B12 deficiency has been associated with megaloblastic anemia and dysplastic bone marrow (Stabler 2013). From a neurological aspect, except for subacute combined degeneration, low Vit.B12 status has been associated with various neuropsychiatric symptoms, and it is regarded to be a reversible cause of dementia (Stabler 2013). Cognitive impairment appears to be one of the most common Vit.B12 deficiency neuropsychological syndromes (VBDNS) (Table 1; Tu et al. 2017). As the negative impacts of low Vit.B12 status on cognition can

range from subclinical neuronal metabolic derangement to an overt debilitating state associated with permanent cerebral structural changes, prompt recognition of Vit. B12 deficiency is of paramount clinical importance. Although increasing evidence supports that a low Vit.B12 status contributes to cognitive impairment, it remains frequently overlooked in clinical practice due to its diverse clinical presentations. On the basis of bioabsorption, several etiologies have been identified (Lachner et al. 2012):

1. Food-cobalamin malabsorption (e.g., atrophic gastritis and chronic metformin/antacids users)
2. Autoimmune (e.g., pernicious anemia and Sjögren's syndrome)
3. Surgical (e.g., gastrectomy and ileal resection)
4. Decreased intake or malnutrition (e.g., a vegetarian diet and alcoholism)
5. Intestinal malabsorption (e.g., chronic pancreatitis and inflammatory bowel disease)
6. Increased demand (e.g., pregnancy and lactation)
7. Genetic (e.g., transcobalamin II deficiency)
8. Food-cobalamin malabsorption is likely to be the leading cause of Vit.B12 deficiency, especially in elderly patients (Andrès et al. 2008).

With increasing research related to the biochemical pathway of Vit.B12 deficiency, several biochemical indicators reflecting Vit.B12 status have been identified. Elevated Hcy and methylmalonic acid (MMA) are generally regarded to be more sensitive metabolic indicators of Vit.B12 deficiency than total plasma Vit.B12 (Hvas and Nexo 2005). However, both measurements can be influenced by renal insufficiency, and elevated Hcy may also reflect a lack of folate as well as vitamin B6 (Joosten et al. 1993), thereby limiting their specificity. Another candidate marker, holotranscobalamin (holo-TC), represents the biologically active fraction of Vit.B12 (~20% of total Vit.B12) that can be delivered to all cells of the body and is as a more specific and sensitive marker for functional Vit.B12 status (Hvas and Nexo 2005). Likewise, transcobalamin (TC) saturation (the ratio of holo-TC over total TC) also represents another index that can be used to quantify the biologically active level of Vit.B12. These aforementioned indicators can be used as tools in diagnosis, evaluation, and follow-up, especially for those with hematological presentations. However, a considerable number of patients still have preferential neurological system involvement and/or discordant recovery between neurological and hematological

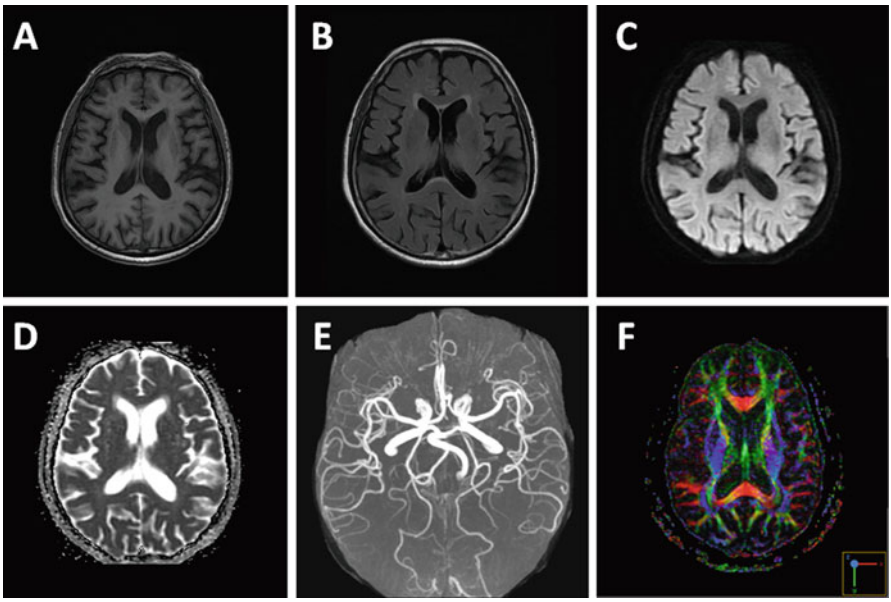

Fig. 2 Clinical and research applications of brain magnetic resonance imaging. There has been increased use of several sequences and protocols of brain magnetic resonance imaging in clinical practice. (**a**) Gradient echo T1-weighted imaging (3D fast-spoiled gradient): A sequence for visualizing detailed brain structure and volumetric assessment. (**b**) T2 FLAIR: A sequence commonly used for detecting structural damages, such as white-matter hyperintensities. A sequence for FLAIR is a special inversion recovery sequence with long inversion time, which results in removing signal from cerebrospinal fluid from the resulting images. (**c**) Diffusion-weighted imaging: A sequence sensitive in detecting highly cellular tissue and ischemic changes by measuring the random Brownian motion of water molecules within a voxel of tissue. (**d**) Apparent diffusion coefficient: A tool enabling quantification of the degree of diffusion of water molecules through different tissues. (**e**) Magnetic resonance angiography: A tool for visualization of intracranial artery pathology by creating an image of blood flow in the vessels. (**f**) Diffusion tensor imaging (displayed in color coding): A novel tool for delineating and quantifying cerebral microstructural changes. *FLAIR* Fluid attenuation inversion recovery

systems. Therefore, cognitive and neuroimaging assessments may be more pertinent tools to evaluate relevant neuropsychiatric symptoms related to Vit.B12 deficiency. In general, cognitive tests are used to assess the intelligence performance of subjects in a structuralized and standardized manner. Neuroimaging studies can mirror the degree and extent of brain parenchymal and even microstructural changes through quantification and descriptive methods. For example, there are various sequences in conventional magnetic resonance imaging (MRI) which can provide information related to brain pathology and volume changes (Fig. 2). Additionally, several other novel protocols have also been proven to detect microstructural changes within regions that are of normal appearances in conventional MRI (Fig. 2). The following text will detail evidence and opinions from current research.

Vitamin B12 Deficiency, Cognition, and Magnetic Resonance Imaging Findings

Impact of Vit.B12 Deficiency on Cognition

Associations Between Vit.B12 Dietary Intake and Cognitive Performance

The results of research on the association between Vit.B12 dietary intake and cognitive performance are diverse (Table 2). A meta-analysis (Doets et al. 2013) of three studies (5254 elderly people aged 49–93 years) for the relative risk of Alzheimer's disease (AD) (431 cases) with a duration of 3.9–9.3 years revealed no association between Vit.B12 intake and the incidence of AD (Corrada et al. 2005; Morris et al. 2006; Nelson et al. 2009). The same study (Doets et al. 2013) also found no significant association between Vit.B12 intake and global cognition. However, other studies reported an association between slower global cognitive declines in elderly people with a high Vit.B12 intake (Morris et al. 2005). Associations between total Vit.B12 intake and performance on naming, nonverbal memory recall, and constructional praxis were also observed in patients with AD (Kim et al. 2014). Furthermore, studies on the association between Vit.B12 intake and domain-specific cognition have also reported inconsistent results. Some studies have reported apossible relationship between dietary Vit.B12 intake and constructional praxis (Tucker et al. 2005), while others have reported associations with nonverbal memory and abstract reasoning (La Rue et al. 1997). In a double-blind, randomized placebo-controlled trial which investigated whether daily supplementation with high doses of oral Vit.B12 alone or in combination with folic acid had any beneficial effects on cognitive function in the elderly with mild Vit.B12 deficiency (a serum Vit.B12 level 100 ~ 200 pmol/L, or a serum Vit.B12 level 200 ~ 300 pmol/L *and* a plasma MMA concentration $\geq$ 0.32 μmol/L *and* a serum creatinine concentration $\leq$ 120 μmol/L), Vit.B12 supplementation with or without folic acid led to improvements in memory function, but not in the domains of sensorimotor speed or executive function (Eussen et al. 2006). Paradoxically, both the treatment and placebo groups in this study showed improvements in memory function. Moreover, the improvement in the placebo group was even better than that in the Vit.B12 group, further questioning whether Vit.B12 supplementation can provide cognitive benefits.

Studies investigating the relationship between Vit.B12 dietary intake and cognitive performance often demonstrate similar positive effects from other targeted nutrients in the same cohort. A link between Vit.B12 and cognitive performance may therefore be less concretized when considering other consumed nutrients as confounders in addition to interpersonal variations of Vit.B12 bioabsorption. Therefore, serological tests may provide more direct evidence from a biological aspect.

Association Between Vit.B12 Status and Cognitive Performance

Several studies have reported no association between serum Vit.B12 itself and the incidence of dementia, AD (Crystal et al. 1994; Wang et al. 2001; Ravaglia et al. 2005; Kivipelto et al. 2009), or global cognitive function (McCracken et al. 2006; Clarke et al. 2007). However, one study suggested the potential value of holo-TC, an

B12* vitamin B12, *MMSE* Mini-mental state examination, *N.S.* No significance, *CERAD* The consortium to establish a registry for Alzheimer's disease, *VMI* The developmental test of visual-motor integratio, *WAIS-R* Wechsler Adult Intelligence Scale – revised, *CDR* Clinical dementia rating scale, *MCI* Mild cognitive impairment, *AD* Alzheimer's disease, *Hcy* homocysteine, *CAMCOG* Cognitive section of the Cambridge mental disorders of the elderly examination, *MMA* Methylmalonic acid, *holoTC* Holotranscobalamin, *RAVLT* Rey auditory verbal learning test, *APOE* apolipoprotein E, *CASI* Cognitive abilities screening instrument.

active form of Vit.B12, in attenuating the risk of AD (Hooshmand et al. 2010). Such clinical observations reflect the fact that serum Vit.B12 level does not represent the precise Vit.B12 status, and that it may be insufficient to evaluate biochemical utilization at a cellular level. To further elucidate the association between Vit.B12 level and cognitive performances, serum or plasma biochemical indicators reflecting Vit.B12 status (e.g., holo-TC, TC saturation, Hcy, and MMA) have attracted increasing attention. Interestingly, several studies have shown that a higher serum Vit.B12 concentration at baseline was associated with a better global cognitive reserve (Feng et al. 2009; Tangney et al. 2009), while a higher MMA level (Clarke et al. 2007; Tangney et al. 2009) or lower holo-TC (Clarke et al. 2007) were associated with more rapid global cognitive decline. Many studies have also addressed domain-specific effects related to Vit.B12 status by evaluating executive function (Tucker et al. 2005), working memory (Feng et al. 2009), attention (Feng et al. 2009), verbal memory (Feng et al. 2009), and constructional praxis (Tucker et al. 2005). In a study by Miller et al., a cohort with a high prevalence of low Vit.B12 status (plasma Vit.B12: $\leq$ 200 pg/mL in 6.5% of the participants, and 200–300 pg/mL in 16.4%), serum Hcy level was found to be correlated with global cognitive performance as well as performance in multiple cognitive domains including memory, attention, and visuospatial ability (Miller et al. 2003). Moreover, patients with predefined low serum Vit.B12 level have been reported to have defective language function, orientation, and mental manipulation (Hsu et al. 2016). However, other studies have not shown any remarkable relationship between Vit.B12 level and memory (La Rue et al. 1997; Ravaglia et al. 2005; Mooijaart et al. 2005), executive function (La Rue et al. 1997), attention (Mooijaart et al. 2005; Hsu et al. 2016), processing speed (Mooijaart et al. 2005), constructional praxis, verbal fluency, or abstract thinking (Hsu et al. 2016).

The inconclusive results in these studies may be due to variations in time frame, sample size and characteristics, diagnostic criteria (cut-off values in serology panels), and variable tools used to assess cognitive ability, in addition to the complex nature of the absorption process of Vit.B12. The preliminary results await further corroboration. However, as cognitive deficits are thought to be the consequence of neuronal dysfunction and/or damage, neuroimaging findings may provide additional information to determine the clinical impact of low Vit.B12 status.

Impact of Vit.B12 Deficiency on Changes in Brain MRI

Several brain MRI findings could be identified among the patients with Vit.B12 deficiency, including volume reduction, white matter changes, vascular occlusion, and even microstructural changes (Figs. 3, 4, 5, and 6). Several studies have recruited different populations or clinical phenotypes to investigate the association between brain parenchymal changes and low Vit.B12 status (Table 3). As hemato-neurological dissociations exist and the associations between serum biomarkers and cognition are diverse, some patients with cognitive syndromes related to vitamin B12 deficiency

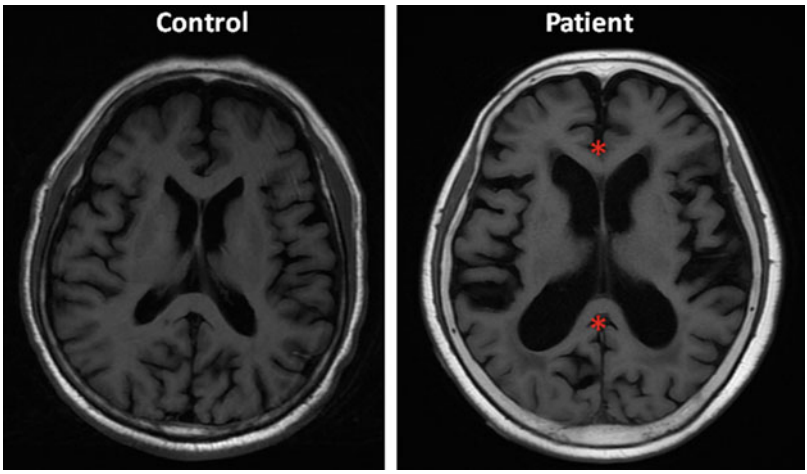

Fig. 3 Brain atrophy related to vitamin B12 deficiency. Example of a 77-year-old female patient with cognitive complaints for 2 years. Notice the pronounced ventricular dilatation and proportionate cortical atrophy in comparison with the images of age-matched control, obtained at approximately the same level. Notable thinning of the corpus callosum, either within the genu or splenium portion, is noted on axial T1-fluid attenuation inversion recovery images (*asterisk*) (Repetition time = 2000; echo time = 20)

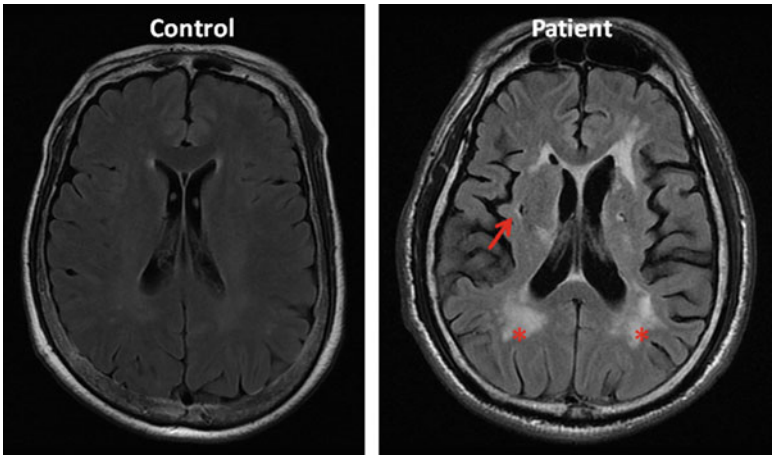

Fig. 4 White-matter hyperintensities related to vitamin B12 deficiency. Example of a 61-year-old, 6-year-education level, male patient with dull response for 1 year. Although he had no stroke history and his performance in Cognitive Abilities Screening Instrument was rated to be of borderline value (75/100), profound pathology was identified on axial T2-fluid attenuation inversion recovery images. Notice multifocal patchy areas of high signal in periventricular and deep white matter (*asterisk*) in comparison with images of age-matched control. There are several other small, discrete foci of hypointensities within bilateral basal ganglia, compatible with lacunes pathology (*arrow*) (Repetition time = 9000; echo time = 120)

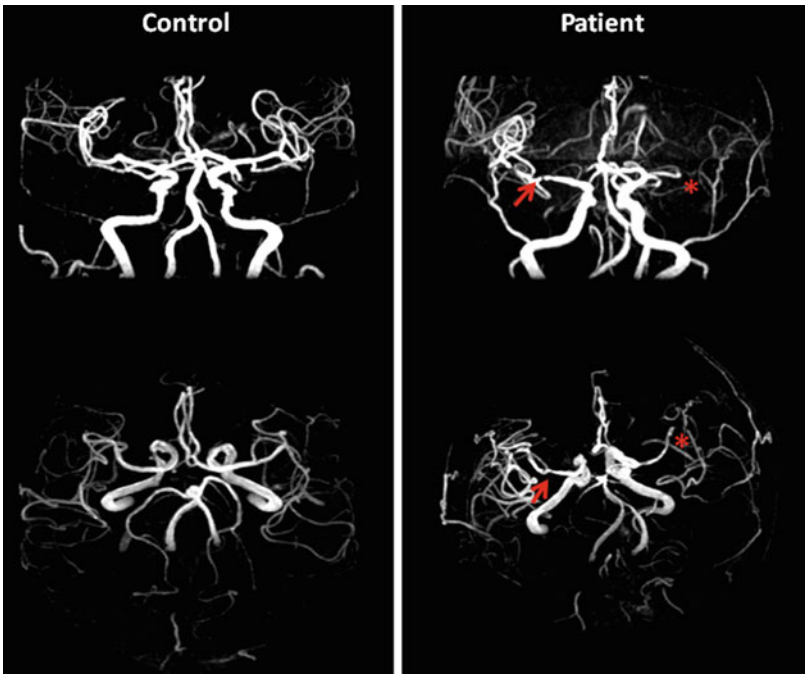

Fig. 5 Intracranial artery stenosis and occlusion precipitated by vitamin B12 deficiency. Example of an 86-year-old female patients with multiple recurrent stroke history. Although she had a history of hypertension and diabetes mellitus, both diseases were well controlled (baseline systolic blood pressure = 120 mmHg; glycated hemoglobin = 5.8%). Notice the absence of blood flow at proximal portion of the left middle cerebral artery (*asterisk*) in comparison with images of age-matched healthy control. Additionally, there is a narrowing of the right middle cerebral artery (*arrow*). Although there are still some other risk factors which may contribute to stroke events, intracranial artery stenosis/occlusion is frequently identified among patients with vitamin B12 deficiency (*upper row* frontal view, *lower row* bird's-eye view)

may demonstrate pure neurological symptoms in the absence of hematological changes. In clinical practice, their neurological complaints may also predate hematological derangements such as macrocytic anemia. The strength of studies incorporating MRI is to examine the negative impact of Vit.B12 deficiency on the brain through visualizing macro- and micro-structural changes. Through neuroimaging studies, issues related to the existence of domain-specific impacts related to Vit.B12 deficiency can be further clarified, as localization of relevant pathology may provide valuable information. Although this seems to be a potentially promising approach to explore the fundamental pathogenesis of cognitive syndromes related to vitamin B12 deficiency, several aspects should be considered with regard to interpretation. In addition to variables related to clinical status and demographic data, the neuroimaging protocols applied should be carefully reviewed, as not all provide spatially specific information.

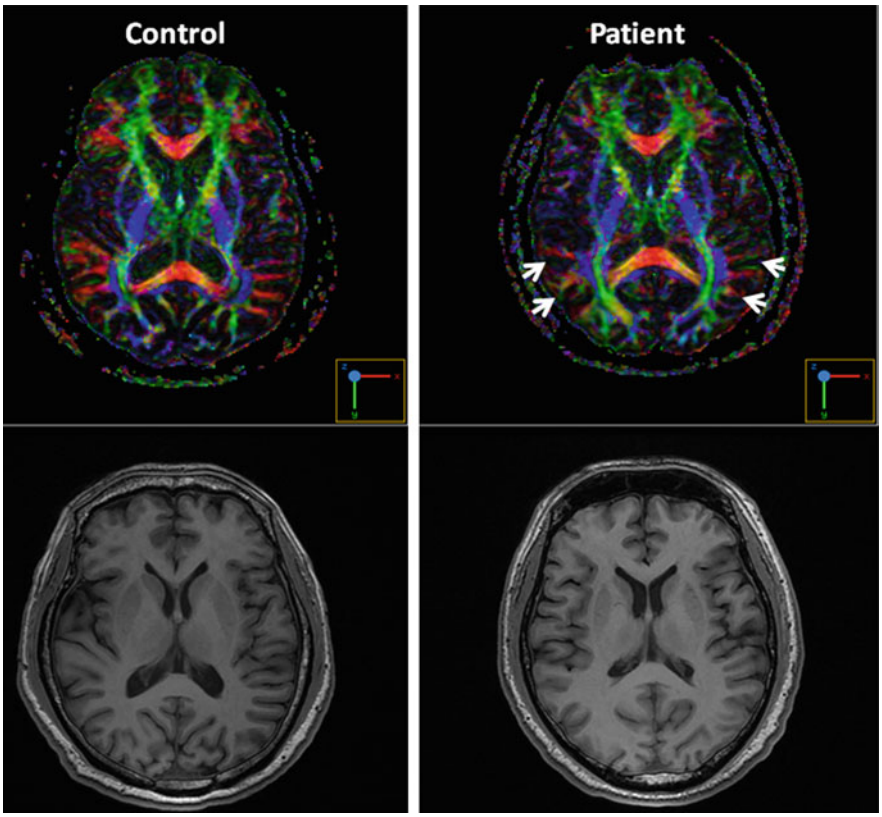

Fig. 6 Early cerebral microstructural changes related to vitamin B12 deficiency. Example of a 50-year-old, 10-year-education level, male patient with subtle cognitive complaints. His performance in Cognitive Abilities Screening Instrument was normal (93/100). Notice the loss of directionality within various association fibers on color-coded diffusion tensor images (*arrows*) compared with age-matched healthy control (*upper row*: repetition time = 8325; echo time = 83; diffusion weighting factor b = 1000 sec/mm2, plus one b = 0 image). In conventional MRI, his brain parenchyma is visually regarded to be normal in size (*lower row*: 3D fast-spoiled gradient; repetition time = 8; echo time = 3)

Healthy Elderly Subjects

A low Vit.B12 status has been associated with brain atrophy (Vogiatzoglou et al. 2008; Tangney et al. 2011), damage to the white matter (de Lau et al. 2009; Tangney et al. 2011), and gray matter volume reduction (Erickson et al. 2008) in healthy elderly people. Research recruiting cognitively normal subjects is of value to elucidate the impact of Vit.B12 status on occult brain lesions and/or cognitive decline in the context of a longitudinal study design.

In a longitudinal study by de Lau et al., a poor Vit.B12 status as assessed by measuring levels of Vit.B12, MMA, holo-TC, and TC saturation was significantly associated with a greater severity of white-matter lesions, particularly within

Table 3 Selected articles supporting negative impact of vitamin B12 deficiency on brain magnetic resonance imaging

References	Clinical phenotype	Methods	Major findings	
			Magnetic resonance imaging findings	Conclusion
Vogiatzoglou et al. (2008)	Healthy elderly	SIENA	Vit.B12 and holoTC↑: whole brain volume↑	Low Vit.B12 status in elderly subjects without dementia at baseline is associated with an increase rate of brain atrophy
Erickson et al. (2008)		Voxel-based morphometry	Intake of Vit.B12↑: gray matter volume↑. Effects were observed in the bilateral superior parietal lobules	Greater Vit.B12 intake is associated with protective effect on gray-matter volume
de Lau et al. (2009)		Semi-quantitative scoring for periventricular white matter lesions	Poorer Vit.B12 status (Vit.B12↓/holoTC↓/TC saturation↓/MMA↑): white-matter lesions↑(particularly those within periventricular regions/ in a concentration-related manner)	A concentration-related association between low Vit.B12 status and the severity of white-matter lesions, especially periventricular white-matter lesions, is identified and hypothesized to be related to myelin integrity damages
Tangney et al. (2011)		White-matter hyperintensity segmentation and total brain volume assessment	Hcy↑, MMA↑, cystathionine↑, 2-methylcitrate↑: total brain volume↓. Hcy↑: white matter hyperintensity volume↑	Poor Vit.B12 status is a risk factor for brain atrophy and white matter hyperintensity formation

Smith et al. (2010)	Mild cognitive impairment	SIENA	Users of Hcy-lowering B vitamins (folic acid, vitamins B6 and B12): brain atrophy rate↓(more favorable in participants with Hcy >13 μmol/L)	The brain atrophy rate in Pts with mild cognitive impairment can be slowed by treatment with Hcy-lowering B vitamins
Blasko et al. (2012)		Semiquantitative scoring for periventricular white-matter lesions	Users of Vit.B12 or folate: periventricular and deep white-matter hyperintensities↓	Vit.B12 or folate consumption may contribute to lower extent of white-matter hyperintensities formation
Köbe et al. (2016)		DTI (voxel-based analysis)	Pts with low-normal Vit.B12: mean diffusivity of the hippocampus↑ (mainly in the cornu ammonis 4 and dentate gyrus region)	Impaired microstructure integrity of the hippocampus, mainly in the cornu ammonis 4 and dentate gyrus region, is noted
Gupta et al. (2014)	Subacute combined degeneration	Voxel-based morphometry and DTI (tract-based statistics)	Compared with controls, the Pts: gray and white volumes: N.S. fractional anisotropy↓, mean and radial diffusivity↑in multiple brain regions	White-matter microstructural changes are seen in Pts with Vit.B12 deficiency
Roy et al. (2015)		DTI (tract-based statistics) and pseudo-continuous arterial spin labelling	Pts with Vit.B12 deficiency (pre- and posttreated state) had altered cerebral blood flow and fractional anisotropy values in various brain regions as compared with controls.	Vit.B12 supplement therapy can normalize cerebral microstructural changes. Microstructural recovery lags behind cerebral blood flow and cognition recovery at 6 weeks post therapy

SIENA Structural image evaluation using normalization of atrophy, *DTI* diffusion tensor imaging, *Vit.B12* vitamin B12, *N.S.* No significance, *MMA* methylmalonic acid, *holoTC* holotranscobalamin, *TC* transcobalamin, *Hcy* homocysteine, *Pts* patients.

periventricular areas, in a concentration-related manner (de Lau et al. 2009). These associations remained essentially unchanged after adjusting for potential clinical confounders. Although the associations appeared to be weakened after incorporating plasma Hcy and folate into the adjustment model, the association between TC saturation and periventricular white matter lesions remained robust and statistically significant. Of note, these associations occurred over a range of Vit.B12 levels and were not confined to the concentrations usually used to define deficiency. However, another cross-sectional study reported that higher levels of Vit.B12-related markers (i.e., serum Hcy, MMA, cystathionine, and 2-methylcitrate concentrations), but not serum Vit.B12 itself, were significantly associated with decreased total brain volume (Tangney et al. 2011). Interestingly, Hcy concentration was the only Vit.B12 marker that was associated with the volume of white matter hyperintensity (Tangney et al. 2011).

In contrast to the studies discussing a connection between Vit.B12 status and neuroimaging findings, one cohort study reported a positive association between dietary intake and brain structural changes (Erickson et al. 2008). In this study ($n = 32$), a greater total intake of Vit.B12 (diet plus supplementation) was reliably correlated with greater gray matter volume within bilateral superior parietal lobules. However, this effect was driven by the supplements, and the positive association with Vit.B12 was negated when only examining dietary intake. The authors did not identify any variables related to global gray or white matter. Of note, data of Vit.B12 consumption in this study were derived from 3-day food records/diaries (Erickson et al. 2008), and future studies incorporating serological data are warranted.

Subjects with Mild Cognitive Impairment (MCI)

MCI is an intermediate stage between the expected cognitive decline of normal aging and the more serious decline of dementia. Current opinion suggests that such transitional findings can also be observed from a neuroimaging aspect. That is, neuronal dysfunction and microstructural changes tend to predate overt brain volume loss by a considerable period of time. Therefore, sensitive MRI protocols are usually required to detect subtle changes in terms of this early disease process. For example, volumetry can provide information on brain volume in an overall or segmented method. Diffusion tensor imaging (DTI) usually includes parameters such as mean diffusivity and fractional anisotropy, and can delineate microstructural damage within regions that are of normal appearance in conventional MRI. Due to the fact that MCI is associated with the risk of dementia (Mufson et al. 2012), evaluating neuroimaging in these patients in association with Vit.B12 status provides the opportunity to determine whether Vit.B12 status has an additional impact on pre-existing (or ongoing) neurodegenerative processes.

By collecting information on both intake and status of Vit.B12 from a subset of a randomized double-blind controlled trial, Smith et al. suggested that patients over 70 years of age with MCI had a 29.6% lower rate of brain atrophy after 2 years of supplementation with high doses of vitamin B6, folic acid, and Vit.B12 compared with a placebo (Smith et al. 2010). Moreover, the rate of atrophy in the participants taking B vitamins was more than five times slower than in those taking the placebo. In addition, when focusing on the relationship between biological status and brain

atrophy, the rate of atrophy was significantly associated with changes in Hcy and inversely with changes in holo-TC and TC saturation, but not cystathionine (a marker of vitamin B6 status). The authors therefore concluded that the rate of brain atrophy in elderly patients with MCI can be slowed by treatment with homocysteine-lowering B vitamins, especially folic acid and Vit.B12 (Smith et al. 2010). In another study recruiting amnestic MCI patients, a novel finding suggested that the mean diffusivity of the hippocampus was higher in patients with low-normal Vit.B12 concentrations than in those with high-normal Vit.B12 concentrations (median split: 304 pmol/L) (Köbe et al. 2016). Comparing the volume of the total hippocampus and its subfields between these dichotomized groups, however, revealed unremarkable findings. These findings support that low Vit.B12 status has a detrimental impact on microstructural changes within the hippocampus before obvious volume reduction (Köbe et al. 2016).

However, patients with MCI are likely to be of heterogeneity from a pathological aspect (Mufson et al. 2012), which may explain the somewhat inconsistent findings of these studies. Current research also highlights the disagreement regarding the impact of Vit.B12 status across different stages of cognitive impairment. A cross-sectional study using data on 1095 participants (760 cognitively healthy individuals, 130 with MCI, and 205 with AD) found that Vit.B12 status was not significantly different between clinical groups after controlling for basic demographic confounders. Rather than group differences, a significant gender difference (higher Vit.B12 levels in females) was identified across all clinical groups (Faux et al. 2011). Likewise, a prospective study which retrospectively evaluated vitamin intake reported that serum levels of Hcy and Vit.B12 measured at baseline or at 5 years were not associated with dementia conversion rate, although users of Vit.B12 or folate had a lower grade of periventricular hyperintensities and a lower grade of deep white matter lesions compared to non-users (Blasko et al. 2012).

Subjects with Subacute Combined Degeneration

The patients with subacute combined degeneration (mostly in the 30s to 50s) appears to be younger than those with MCI, and the main findings of brain MRI are either microstructural or cerebral blood flow changes (Gupta et al. 2014a; Roy et al. 2015). Traditionally, therapeutic strategies in patients with subacute combined degeneration are mainly focused on gait performance related to myelopathy and polyneuropathies. Evaluating brain MRI among these patients can alert clinicians to the possibility of microstructural and/or functional changes within the cerebrum which tend to be ignored in patients with pronounced motor/sensory deficits. Gupta et al. investigated diffuse modification of DTI parameters in patients with subacute combined degeneration whose conventional MRI and gray/white matter volume appeared to be normal (Gupta et al. 2014a). Through a tract-based spatial statistics method, nearly global reductions in fractional anisotropy were noted. In addition, widespread increases in mean and radial diffusivity values, although predominantly within the right hemisphere, were also observed. Axial diffusivity was the only unchanged DTI parameter compared to the controls. Taken together, the authors suggested that demyelination rather than axonal loss is the major pathologic substrate in Vit.B12

deficiency. Similarly, another cohort study conducted by Roy et al. showed a global reduction in fractional anisotropy using tract-based spatial statistics (Roy et al. 2015). With the assistance of pseudocontinuous arterial spin labeling, the authors further identified significant alterations in cerebral blood flow values in both gray and white matter regions, and concluded that this technique could be an earlier predictor of complete recovery than DTI. These findings suggest the reversibility of metabolic dysfunction related to Vit.B12 deficiency, and that such damage occurs beyond the white matter tracts.

In summary, the multifaceted findings of MRI observations associated with Vit. B12 deficiency suggest that its pathology may vary according to clinical phenotypes, and that no single mechanism is responsible for cognitive decline related to Vit.B12 deficiency.

Evidence Through Incorporating Cognitive and Brain MRI Evaluations

In view of a priori knowledge suggesting the critical role of Vit.B12 in maintaining myelin integrity, lipid/protein metabolism, and the pathogenesis of vascular damage, it is reasonable that variable pathology relevant to low Vit.B12 status exists in neuroimaging evaluations (Fig. 7). A cross-sectional study also corroborated that Vit.B12 status affects the brain through multiple mechanisms such as brain volume reduction, increased white matter hyperintensity, and cerebral infarcts (Tangney et al. 2011). Identifying the clinical impact of these MRI findings would be an interesting issue, as the results may provide fascinating information on neuronal substrates with cognitive implications among patients with cognitive syndromes related to Vit.B12 deficiency (Table 4).

A cohort study which compared cognitive performance and morphometric indices of brain MRI between 34 pairs of consecutive patients with Vit.B12 deficiency and demographically matched controls indicated that the patients had global cognitive decline with selective impairment in language, orientation, and mental manipulation (Hsu et al. 2016). Preferential atrophy in frontal regions, evidenced as a larger frontal horn ratio, was the main neuroimaging feature in their study. In addition, among numerous morphometric indices significantly correlated with cognitive performance, the bicaudate ratio appeared to be the best index on the basis of its strong association with global cognition and related cognitive domains. The results seemed to imply that frontal regions are most vulnerable to damage related to low Vit.B12 status. On the basis of the robust cognitive association with preferential frontal region atrophy, the authors concluded that dysfunction of frontosubcortical circuits is the fundamental pathogenesis related to Vit.B12 deficiency (Hsu et al. 2016). These findings appear to be compatible with clinical observations, in which dysexecutive syndrome is a common presentation among the repertoire of cognitive syndromes related to vitamin B12 deficiency.

To date, two studies have assessed the clinical relevancy of DTI, although they used different assessment protocols and clinical phenotypes (Gupta et al. 2014a; Köbe et al.

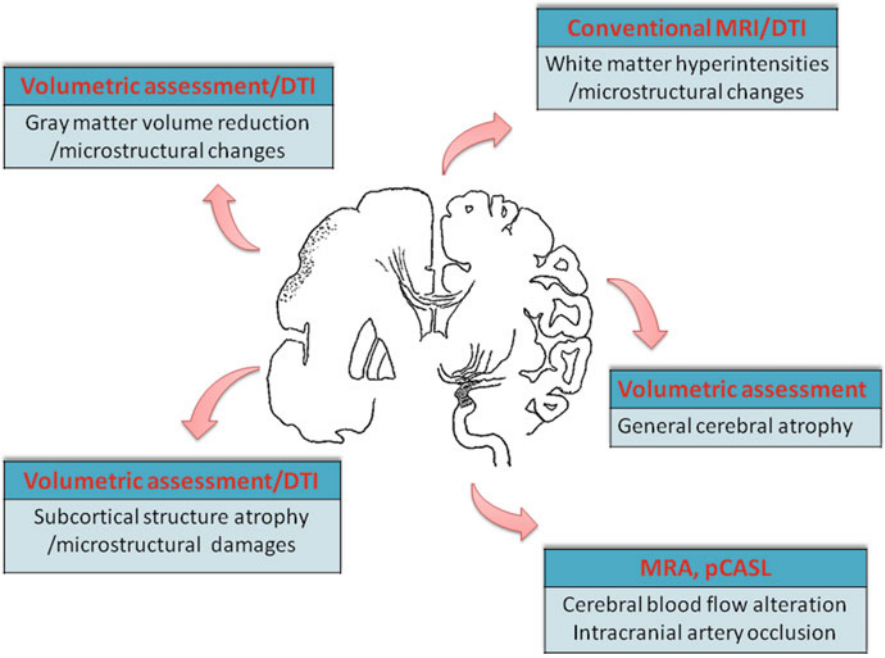

Fig. 7 Illustration picture of pathology related to vitamin B12 deficiency within the cerebrum. Several pathologies within human brain have been associated with low vitamin B12 status in magnetic resonance imaging research. Major findings and imaging protocols are labeled along with each representative pathology. *MRI* magnetic resonance imaging, *DTI* diffusion tensor imaging, *MRA* magnetic resonance angiography, *pCASL* pseudo-continuous arterial spin labeling

Table 4 Currently cited neural substrates related to low-vitamin B12 status by incorporating cognitive and brain magnetic resonance imaging findings.

2016). Gupta et al. evaluated patients with subacute combined degeneration with tract-based statistics (Gupta et al. 2014a), and Köbe et al. assessed patients with MCI using voxel-based analysis (Köbe et al. 2016). The former study, in which diffuse changes in diffusion parameters were identified, showed significant correlations between fractional anisotropy and radial diffusivity with tests related to visuospatial capacity and visuomotor speed (Gupta et al. 2014a). In comparison, Köbe et al. originally focused on segregated regions of the hippocampus and found that the microstructural integrity assessed by mean diffusivity in the cornu ammonis 4 and dentate gyrus region partially mediated the negative effect of low Vit.B12 status on memory performance (Köbe et al. 2016).

In summary, global changes in volume reduction or microstructural integrity reflect global cognitive decline and visuospatial capacity/visuomotor speed in patients with Vit.B12 deficiency. Some studies have addressed that frontal and temporal regions are associated with certain domain-specific cognitive deficits, however further studies are needed to assess the generalizability of these results. In contrast to volume reduction, the microstructural changes may imply that white matter integrity disconnection is an important neurobiological consequence related to Vit.B12 deficiency during the very early stage.

MRI as a Potential Tool to Predict or Monitor Therapeutic Responses

Several studies have investigated the possible factors related to therapeutic responses (Table 5). Milder dementia severity (Nilsson et al. 2000), elevation or certain range of MMA (Stabler et al. 1990; Hvas et al. 2001), and hyperhomocysteinemia (Stabler et al. 1990) have been associated with a better prognosis. In a cohort study aimed at identifying potential laboratory and neuroimaging biomarkers related to therapeutic responses, a greater load of total white matter hyperintensities, especially those defined within deep white matter regions, were associated with a poor prognosis (Tu et al. 2017).

A DTI study reported significant changes in diffusivity parameters and neuropsychological test scores between controls and patients with Vit.B12 deficiency in the pre- and posttreatment phases. In comparisons between the patients during the pretreatment phase and the controls, multiple regions of decreased fractional anisotropy and increased mean diffusivity were noted. These results are compatible with the defective formation of myelin sheaths, a consequence related to abnormal fatty acid formation and impaired methylation of myelin basic protein expected in patients with a low Vit.B12 status. In comparisons between pre- and posttreatment phases, the authors suggested that the corpus callosum and fornix were the most important tracts showing reciprocating changes in DTI parameters from the controls to the patients in the posttreatment phase (Gupta et al. 2014b).

Current articles describing therapeutic responses in patients with VBDNS are mainly confined to functional imaging or electrophysiology. The reversal of hypofrontality in single-photon emission computed tomography (Tu et al. 2015, 2016) has been reported to be responsible for clinical improvements after treatment.

Table 5 Possible factors in cognitive syndromes related to vitamin B12 deficiency that may predict therapeutic response.

Reference	Favorable	Less favorable
Stabler et al. (1990)	Hyperhomocysteinemia	Normal serum homocysteine level
Stabler et al. (1990) Hvas et al. (2001)	Elevation or certain range of methylmalonic acid	Normal serum methylmalonic acid level
Nilsson et al. (2000)	Milder dementia severity	More severe dementia severity
Tu et al. (2017)	Lesser load of total and deep white matter hyperintensities (MRI)	Greater load of total and deep white-matter hyperintensities
Tu et al. (2016)	Relatively intact frontal perfusion (SPECT)	More severe hypofrontality

MRI magnetic resonance imaging, *SPECT* single-photon emission-computed tomography.

Consistent with these findings, another study also identified reversible changes of prolonged P3 latency of evoked potentials in patients with VBDNS (Kalita et al. 2013). The P3 wave is an evoked potential involved in cognitive control and decision making, and the majority of signals are regarded to originate from frontal (and parietal) regions (Hall et al. 2015). Both studies highlighted that frontal regions are important neuronal substrates vulnerable to low Vit.B12 status, and that reversibility of the affected regions was suggestive of metabolic alterations in neuronal or myelin function. Intriguingly, a cohort study using novel MRI techniques (i.e., DTI and pseudocontinuous arterial spin labeling) demonstrated significant recovery both in microstructural changes and cerebral blood flow, in line with a complete reversal of neuropsychological scores at 6 weeks post therapy (Roy et al. 2015). As MRI is clinically feasible and avoids exposure to radiation, future studies incorporating MRI into assessments of neurobiological changes after Vit.B12 treatment would be of clinical value.

Supplementary Evidence from Other Neuroimaging and Electrophysiological Tools

As subtle neuronal dysfunction in the brain may precede overt structural changes in VBDNS, it is believed that functional evaluation may provide information fundamental to the underlying pathogenesis. A predominant decrease in postcentral cerebral blood flow with better preserved central and prefrontal flow has been described in patients with Vit.B12 deficiency with heterogeneous dementia subtypes and superimposed delirium (Nilsson et al. 2000). However, other single-photon emission computed tomography studies have indicated metabolic changes within frontotemporal regions and deep nuclei may account for the pathogenesis of cognitive syndromes related to Vit.B12 deficiency (Tu et al. 2015, 2016). Specifically, hypoperfusion within thalamus/basal ganglia/temporal regions and additional hypofrontality may contribute to psychiatric and cognitive symptoms, respectively. Moreover,

the extent and severity of hypofrontality may be associated with therapeutic responses, highlighting the role of frontosubcortical networks in cognitive syndromes related to Vit.B12 deficiency (Tu et al. 2016). Consistent with these findings, another study focusing on electrophysiological assessments reported clinical relevance at baseline and 3–6 months following treatment (Kalita et al. 2013). These sequential follow-up results suggested the role of P3 latency, which improved in accordance with clinical observations and was correlated with several subsets of neurobehavioral assessment. The authors hypothesized that P3 latency may be a surrogate marker for myelin function, and that a lower P3 amplitude may be the result of neuronal loss. On the basis of the significant correlation between P3 latency and Mini-Mental State Examination/Luria's three-step-test/motor speed and precision test, the authors suggested that their findings were primarily due to cortical and subcortical dysfunction (Kalita et al. 2013).

Conclusion

Although there is still a certain degree of disagreement regarding the causality between low Vit.B12 status and cognitive impairment, the associations are gradually being elucidated by integrated information from biochemical indicators, structuralized cognitive tests, and advanced neuroimaging evaluations. A review of the current literature indicated that global cognitive decline, with or without domain-specific impairment, may be a neurological consequence related to Vit.B12 deficiency. Consistent with these findings, many studies focusing on MRI observations have suggested that global alterations in cerebral blood flow, microstructural changes with certain reversibility, and reductions in brain parenchymal volume can be identified which vary according to the different clinical phenotype. On the basis of the current review, global disconnection syndrome, impaired frontosubcortical networks, and variable pathological changes within frontotemporal regions underlie the pathogenesis of cognitive syndromes related to vitamin B12 deficiency. Several recent studies have investigated issues related to regional spatial specificity related to Vit.B12 deficiency (e.g., frontosubcortical networks and frontotemporal regions), which is an interesting issue that remains to be confirmed in future study. With advances in MRI techniques and the clinical feasibility, its use in monitoring therapeutic responses and early identification of cognitive syndromes related to Vit.B12 deficiency can be expected.

Policies and Protocols

Vitamin B12 deficiency has been associated with cognitive impairment of various severity ranging from mild cognitive impairment to dementia. The role of the government in this important issue should focus on several aspects, including enhancing dietary supplements, implementing public education, and identifying those at risk of vitamin B12 deficiency. This chapter presents an overview of the

cognitive impact of vitamin B12 deficiency and its relevance to brain magnetic resonance imaging findings. Due to the increasing body of evidence supporting the negative impact of a low vitamin B12 status on cognition, policies focused on the prompt recognition of patients with vitamin B12 deficiency should be considered. Consistent with the results of epidemiological studies, our review emphasizes the importance of cognitive and magnetic resonance imaging evaluations in assessing elderly patients at potential risk of vitamin B12 deficiency (e.g., a vegan diet, cognitive complaints, and the chronic use of metformin/proton pump inhibitors/H2 blockers). In addition, both cognitive and magnetic resonance imaging evaluations have been validated to be potential tools in monitoring therapeutic responses across different clinical phenotypes related to vitamin B12 deficiency. Of note, magnetic resonance imaging appears to be major bottleneck in assisting the timely diagnosis of cognitive syndromes related to vitamin B12 deficiency, as it offers opportunity to detect subtle cerebral structural and perfusion changes that are frequently associated with vitamin B12 deficiency. Accountability for integrating medical resources and public health education should rest with the Department or Ministry of Health of individual countries.

Dictionary of Terms

- **Bicaudate ratio** – The minimum intercaudate distance divided by colinear skull internal diameter. Larger bicaudate ratio value could reflect greater extent of frontal subcortical region volume reduction.
- **Cognitive syndromes related to vitamin B12 deficiency** – A spectrum of cognitive disorders incorporating a wide range of disease severity, ranging from mild cognitive impairment to overt dementia.
- **Diffusion tensor imaging** – A magnetic resonance imaging-based technique which makes it possible to quantify anisotropy of water diffusion in different cerebral regions and structures. For example, the microstructural integrity of white matter tracts could be measured through variable sets of parameters. The location and orientation of specific fiber tracts could be tracked and visualized through color-coded diffusion tensor imaging and tractography.
- **Domain-specific effect** – Preferential involvement of certain cognitive domains, manifesting as more profound deficits from structuralized cognitive assessments.
- **Dysexcutive syndrome** – A neurological condition where patients have trouble with complex thinking and reasoning tasks, such as difficulty in applying previous knowledge to the new event, or losing track of conversations by other unexpected interruptions.
- **Frontal horn ratio** – The maximal frontal ventricular width divided by colinear skull internal diameter. Larger frontal horn ratio value indicates greater extent of frontal region volume reduction.
- **Frontosubcortical circuits** – Several segregated circuits connecting basal ganglia/thalamus with selected cortical areas within the frontal lobe. Except for

motor function, many of these circuits govern nonmotor function, including execution, motivation, and emotional/behavioral control.

- **Hemato-neurological dissociation** – A condition in which disproportional involvement between hematological and neurological systems is related to a low vitamin B12 status.
- **Pseudocontinuous arterial spin labeling** – A novel technique enabling the perfusion measurement (cerebral blood flow) in brain without the need of intravenous administration of contrast medium.
- **Vitamin B12 deficiency neuropsychological syndromes** – Neuropsychological disorders presumably relevant to a low vitamin B12 status, such as cognitive impairment, dementia, stroke, myelopathy, polyneuropathy, anxiety, and depression.

Summary Points

- A growing body of evidence supports the association between vitamin B12 intake/status with cognitive performance. Although the results of research are diverse, several lines of evidence highlight the negative impact on global cognition and possibly domain-specific impairments related to vitamin B12 deficiency.
- The results of research focusing on changes in magnetic resonance imaging associated with vitamin level vary according to the clinical phenotype. Overall, relevant pathology may range from alterations of cerebral blood flow, changes in microstructure with certain reversibility, to overt reductions in brain parenchymal volume. These findings have been identified globally, either within gray or white matter. Further studies are needed to confirm the preferentially involved regions.
- Research incorporating both cognitive and magnetic resonance imaging evaluations with regard to vitamin B12 status has found that (i) global changes in volume reduction/microstructural integrity with global cognitive decline and visuospatial capacity/visuomotor speed, (ii) microstructural integrity in the hippocampus with memory performance, and (iii) dysfunction of frontosubcortical circuits as part of the fundamental pathogenesis of cognitive syndromes are related to vitamin B12 deficiency.
- Several studies using novel magnetic resonance imaging techniques such as diffusion tensor imaging and pseudocontinuous arterial spin labeling have demonstrated changes consistent with recovery of cognition. Related clinical applications may be considered for the potential benefits in monitoring therapeutic responses and, possibly, the early detection of cognitive syndromes related to vitamin B12 deficiency.
- Clinico-radiological data derived from published articles suggest that a milder severity of dementia, elevation or certain range of methylmalonic acid, hyperhomocysteinemia, fewer deep and total white matter hyperintensities in magnetic resonance imaging, and lesser hypofrontality in single-photon emission

computed tomography are associated with a favorable prognosis with vitamin B12 supplement treatment.

Vitamin D Deficiency and Fertility: An Overview

84

Bianca Schröder-Heurich and Frauke von Versen-Höynck

Contents

Abstract

In recent years the interest in vitamin D is steadily growing. Numerous scientific publications and health guidebooks for the public have been published. Besides the well-known effects on calcium and bone metabolism, a positive impact of the sunshine vitamin on human wellbeing and health has been proposed. A high prevalence of vitamin D deficiency according to established optimal values has been described, although no increase of the classical diseases associated with vitamin D deficiency, e.g., rachitis and osteomalacia, has been observed. Besides infants and the elderly, populations at risk include women of childbearing age.

The discovery that human tissues with a role in reproductive function, e.g., ovaries, endometrium, and placenta, express the vitamin D receptor and enzymes involved in vitamin D metabolism, has provoked studies on the role of vitamin D in reproductive health. While observational studies suggest an association between low vitamin D status and impaired reproductive outcomes, there are only few high quality randomized clinical trials available that could prove causality. This chapter summarizes the current knowledge on vitamin D metabolism, epidemiology, and treatment of vitamin D deficiency with focus on women's reproductive health.

List of Abbreviations

aOR	Adjusted odds ratio
AFC	Antral follicle count
AMH	Anti-mullerian hormone
CI	Confidence interval
DBP	Vitamin D-binding protein
7-(DHC)	7-Dehydrocholesterol
DGE	German Nutrition Society
FSH	Follicle stimulating hormone
25(OH)D	25-Hydroxyvitamin D
$1,25(OH)_2D$	1,25-Dihydoxyvitamin D
IL-8	Interleukin-8
IR	Insulin resistance
IOM	Institute of Medicine
IVF	In vitro-fertilization
LH	Luteinising hormone
PCOS	Polycystic ovary syndrome
PTH	Parathyroid hormone
RCT	Randomized controlled trial
RDA	Recommended dietary allowance
RXR	Retinoic acid receptor
VDR	Vitamin D receptor

Introduction

Since the early 2000s, a wealth of scientific articles about vitamin D and its role for human biology have been published. The "sunshine" vitamin is involved in various functions in the body. Increasingly, scientific investigations are revealing the importance of vitamin D and its role in health and disease prevention. For the time being, it is known

that vitamin D is involved in immunomodulation processes, cell growth, differentiation, and hormonal balance. The secosteroid and prohormone is getting converted to its active metabolite, 1,25-alpha$(OH)_2$D through multiple converting steps in the body. By binding to its high-affinity receptor, activation of transcription occurs, which causes certain target genes to be activated or inhibited. The relationship between vitamin D and the reproductive system was established after detecting 1-alpha-hydroxylase and the vitamin D receptor (VDR) to be expressed in many female organs like placenta, ovary, endometrium, and decidua. Since vitamin D deficiency has been detected increasingly over the past decades among all racial groups and globally, a large proportion of the female population in their reproductive age is affected. Therefore, this chapter is focusing on the novel findings on vitamin D in the area of human reproduction, fertility, and disease prevention.

Metabolism and Synthesis of Vitamin D

Vitamin D is a group of fat-soluble vitamins, with vitamin D_2 and vitamin D_3 being the most common forms. Vitamin D is absorbed from food (vitamin D_3 [cholecalciferol], from animal sources, or from plant and fungi sources (vitamin D_2 [ergocalciferol]), in the form of food supplements (either vitamin D_2 or D_3) or through the self-synthesis in the skin (vitamin D_3) (Unholzer et al. 2017). Cholecalciferol, a prohormone and the physiologically most important representative, is formed from 7-dehydrocholesterol (7-DHC) by the action of UV-B rays in the keratinocytes of the skin (Unholzer et al. 2017) (Fig. 1). For its role in various processes in the body, cholecalciferol bound to its transport protein (vitamin D-binding protein (DBP)) is shuttled via the blood into the kidney, where it is metabolized into calcidiol (25(OH)D) (Unholzer et al. 2017) (a table of terms used in reference to vitamin D is given in Table 1 (modified after Unholzer et al. 2017)).The main steps of vitamin D metabolism include a multi-step hydroxylation process performed by cytochrome P450 mixed-function oxidases (CYPs). The enzymes responsible are located in the endoplasmic reticulum (e.g., CYP2R1) or in the mitochondria (e.g., CYP27A1, CYP27B1) and metabolize vitamin D_2 or D_3 into 25$(OH)D_2$ or D_3 (Bikle 2014).

25(OH)D (calcidiol) is the major circulating and storage form of vitamin D in the body and serves as a marker of vitamin D status, while most of all circulating 25(OH)D is 25$(OH)D_3$ (Unholzer et al. 2017). 25(OH)D is transported via its binding protein to the kidneys where it gets further hydroxylated by CYP27B1 (1-α hydroxylase), resulting in the biological active metabolite 1,25$(OH)_2$D (Christakos et al. 2010) also known as calcitriol. Calcitriol is released into the blood and exerts its effects through a change in gene expression. While calcitriol is produced according to its specific needs in the body, its own degradation occurs to the inactive metabolite calcitroic acid via CYP24A1 (Christakos et al. 2016; Unholzer et al. 2017). The impact of the active vitamin D on cell functions is influenced by the bioavailability at the target sites and highly dependent upon DBP concentrations and its polymorphisms, which can vary among ethnicities.

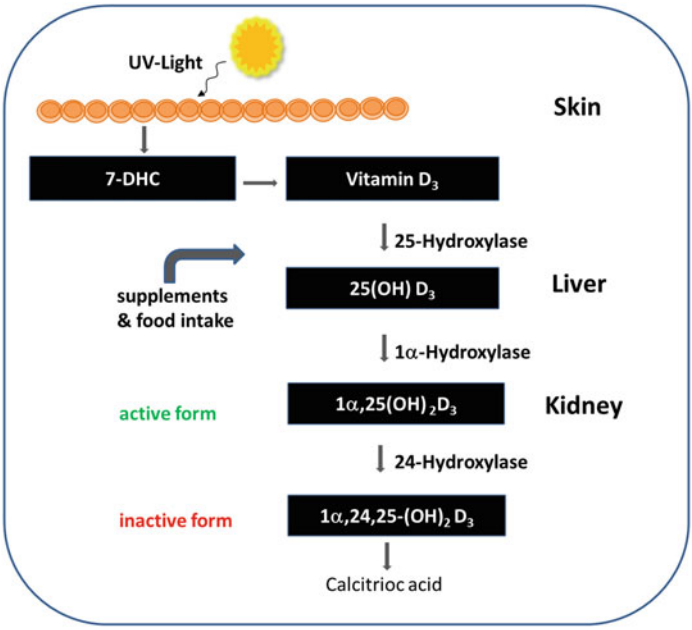

Fig. 1 Metabolism and synthesis of vitamin D. The formation of active $1,25(OH)_2D$ is a multi-step hydroxylation process. First, cholecalciferol (vitamin D_3) is formed in the skin after sufficient sunlight exposure from 7-DHC. After hydroxylation in the liver to calcidiol (25(OH)D), it gets metabolized in the kidney to the biological active form $1,25(OH)_2D$ (calcitriol). $1,25(OH)_2D$ is inactivated and degraded through further hydroxylation to calcitrioic acid

Table 1 Vitamin D metabolites, enzymes, and function. Terms of metabolites, function and food supplements used in reference to vitamin D (Modified after Unholzer et al. 2017, with permission of Springer Nature)

Terms	Affiliation and Function
Vitamin D (Calciferol)	Group of secosteroids; regulation of calcium balance
Cholecalciferol (vitamin D_3)	Prohormone; activated 7-DHC and precursor of calcitriol
Ergocalciferol (vitamin D_2)	From plant and fungi sources
Calcidiol (25(OH)D)	Storage form; reference molecule for vitamin D status in serum
Calcitriol ($1,25(OH)_2D_3$)	Biologically active form of vitamin D_3
Ercalcitriol ($1,25(OH)_2D_2$)	Biologically active form of vitamin D_2
Calcitroic acid	Inactive form; major terminal deactivation product of calcitriol
Vitamin D oral supplement (either vitamin D_2 or D_3)	Treatment of vitamin D deficiency or prevention (preferred vitamin D_3)

Table 2 Classification of serum 25(OH)D levels. The optimal vitamin D serum level lies between 50 and 100 ng/ml. Values below 20 ng/ml are considered deficient, values above 100 ng/ml can be toxic. To convert to nanomoles per liter multiply by 2.496 (Modified after Grant and Holick 2005, with permission from the Publisher)

Serum 25(OH)D concentration		Classification
<20 ng/ml	<50 nmol/l	Deficient
20–32ng/ml	50–80 nmol/l	Insufficient
50–70 ng/ml	125–175 nmol/l	Optimal
32–100 ng/ml	80–250 nmol/l	Sufficient
>150 ng/ml	>325 nmol/l	Intoxication

Determination of Vitamin D Status

Vitamin D deficiency is still a large and global problem of the human population. Depending on the geographic location, populations in the northern latitudes, older people, children, as well as women in their reproductive period are potentially at high risk for vitamin D deficiency.

Reference intake values for an adequate vitamin D status are incongruent and despite years of research it is still not clearly defined how high an optimal vitamin D level should be to have an overall preventive effect. The determination of a serum concentration of 25(OH)D is the accepted approach to identify individual vitamin D status (Holick 2009). To date, according to different investigators, a 25(OH)D serum level in the range between 30 and 50 ng/ml can be regarded as adequately and physiologically sufficient. Values below 20 ng/ml are considered as deficient, 21–29 ng/ml as insufficient (Grant and Holick 2005; Holick 2009) (Table 2). Measurement of serum 25(OH)D concentrations is not subject to a uniform standard procedure. At present, enzyme-linked immunosorbent assays, high-performance liquid chromatography, liquid chromatography–mass spectrometry, and radioimmunoassays are generally used, which, due to different detection limits and variabilities, make a direct comparison of the values challenging (Thierfelder et al. 2008; Unholzer et al. 2017). Therefore, development of a uniform reference test for determination of serum 25(OH)D concentration is urgently necessary.

Supplementation of Vitamin D and Prevention of Deficiency

Vitamin D deficiency may occur from inadequate intake or insufficient exposure to sun light. Synthesis of vitamin D mainly takes part in the skin after sufficient sunlight exposure (Böhles et al. 2011) and therefore is dependent on the season, daytime, and geographic factors. Other factors are the uncovered skin area, length of time staying outside, as well as the skin pigmentation which gets additionally influenced by decreasing age (Loomis 1967; Need et al. 1993; Holick 2002; Böhles et al. 2011; German Nutrition Society (DGE) 2012).

Table 3 Food sources of vitamin D_3. Vitamin D is found in a limited number of foods. Therefore, food supplementation or the intake of vitamin D supplements helps increase serum concentrations (USDA Food Composition Databases 1889)

Food sources of vitamin D	Measure	Vitamin D (IU) per measure
Cod liver oil	1 tablespoon	1360
Herring (Atlantic, pickled)	1 cup	158
Mackerel (jack, canned, drained solids)	1 oz	83
Salmon (pink, canned, drained solids)	3 oz	493
Swordfish (cooked, dry heat)	3 oz	566
Milk (lowfat, fluid, 1% milk fat, protein fortified, with added vitamin A and vitamin D)	1 cup	98
Yoghurt (plain, whole milk, 8 g protein per 8 ounce)	6 oz	3
Cheese, cheddar	1 oz	32
Cheese, camembert	1 oz	5
Cheese, feta	1 cup, crumbled	24
Egg (whole, cooked, fried)	1 Large	40
Orange juice (fortified with vitamin D), (varies among labels)	1 cup	137
Margarine (fortified)	1 tablespoon	60

The exogenous intake of vitamin D, which accounts for about 10%, is influenced by the consumption of certain foods or dietary supplements (Böhles et al. 2011). Vitamin D is found only in few foods naturally, which includes oily fish, liver, and margarine (enriched) (D-A-CH 2008; Böhles et al. 2011) (Table 3) (USDA Food Composition Databases 1889).

In some countries, e.g., the US and Canada, certain foods such as milk, some breakfast cereals, and breads are enriched with vitamin D (Institute of Medicine 1999), while food supplementation is mostly prohibited in Europe (Böhles et al. 2011). The daily intake recommendations for vitamin D, available in many countries of Europe and the USA (e.g., World Health Organization/Food and Agriculture Organization, Institute of Medicine, German Nutrition Society) are not uniform (Lanham-New et al. 2011; Ross 2011). The Food and Nutrition Board at the IOM established a recommended dietary allowance (RDA) for vitamin D which is defined as "average daily level of intake sufficient to meet the nutrient requirements of nearly all (97–98%) healthy people" (Institute of Medicine 2010). The Recommendation of the Associations for Nutrition of German-speaking Countries for daily intake is much higher (Table 4) (Institute of Medicine 2010; German Nutrition Society (DGE) 2012). These recommendations are mainly based on dietary intake and because of the many variable factors, which influence the synthesis of vitamin D, a standard for recommended adequate intake for all ages, sexes, and races is hard to define (Institute of Medicine 1999). Therefore, intake reference values from different countries could be eventually too low to maintain healthiness.

Table 4 Recommended daily allowance values of vitamin D_3. The RDA values of the IOM and the DGE depend on age or health status (e.g., pregnancy) (Institute of Medicine 2010; German Nutrition Society (DGE) 2012).

	Institute of Medicine (IOM), US	German Nutrition Society (DGE), D
	Recommended intake [μg/d]	Recommended intake [μg/d][a]
Infants 0–12 months	10	10
Children 1–13 years	15	20
Adolescents 14–18 years	15	20
Adults 18–65/70 years	15 (adults under 70)	20 (adults under 65)
Adults above 65/70 years	20	20
Pregnant women 14–50 years	15	20

[a]Estimated value while endogenous synthesis is lacking

Vitamin D and the Female Reproductive System

In northern countries, a peak in conception rates in the summer has been observed. Therefore, it seems likely that an association between vitamin D and fertility exists (Rojansky et al. 1992). The detection of the VDR in granulosa and cumulus oophorus cells of the human ovary (Perez-Fernandez et al. 1997) and enzymes involved in vitamin D metabolism in several female reproductive tissues (Thill et al. 2009; Parikh et al. 2010), e.g., the endometrium and fallopian epithelial cells (Agic et al. 2007), the decidua and placenta (Agic et al. 2007), and the pituitary gland, supports this assumption. Further, enzymes involved in vitamin D metabolism, e.g., 1-alpha hydroxylase, are expressed in female reproductive tissues indicating that locally the active $1,25(OH)_2D$ can be synthesized (Vigano et al. 2006; Fischer et al. 2009; Tamblyn et al. 2017). It has been proposed that the ovary is a target organ for $1,25(OH)_2D$ (Dokoh et al. 1983). In conjunction with estradiol, it labilizes lysosomes to weaken the tunica albuginea and to enhance ovum release during ovulation. Steroid hormone production (progesterone, estradiol, and estrone) of the ovary and placenta as well as the synthesis of chorionic gonadotropin and placental lactogen expression in human syncytiotrophoblasts is regulated by the vitamin (Barrera et al. 2008). In addition, $1,25(OH)_2D$ alters the expression and activity of the estrogen biosynthesis catalyzing enzyme P450 (Sun et al. 1998) and affects anti-mullerian hormone (AMH) signaling and steroidogenesis in human cumulus granulosa cells, both pathways with importance for folliculogenesis (Merhi et al. 2014).

Vitamin D and Assisted Reproduction

Utilization of assisted reproductive technologies (ART), especially *in vitro* fertilization (IVF), is growing (Kamphuis et al. 2014). IVF is now being used not only by infertile couples but also by couples carrying single gene mutations who use IVF

with pre-implantation embryo biopsy and transfer of unaffected embryos to the uterus (Berger and Baker 2014). ART allows the separate evaluation of the impact of vitamin D deficiency on various steps of reproduction from folliculogenesis to embryo implantation.

In several observational studies, serum 25(OH)D levels were highly deficient in women seeking medical help for couple's infertility (Pagliardini et al. 2015). In a cohort of 1,072 women in Northern Italy, 11% of women reached a sufficient level in this prospective cross-sectional study (Pagliardini et al. 2015). At a higher latitude (50°N) in Germany, vitamin D insufficiency affected 81–93% of women presenting for infertility treatment ($N = 312$) (Dressler et al. 2016). As with the previous study BMI and limited exposure to sun were associated with an increased risk of vitamin D deficiency.

The relationship between vitamin D serum levels and IVF outcomes has been investigated with controversial results. One of the first studies that investigated IVF success and vitamin D status in 10 women found an association of raised estradiol levels during gonadotrophin-induced ovarian stimulation and a significant increase of serum $1,25(OH)_2D$ ($r = 0.787$, $p < 0.001$) (Potashnik et al. 1992; Wehr et al. 2010). Several studies focused on 25(OH)D levels in follicular fluid as an independent predictor to success of an IVF-cycle. While Ozkan et al. showed higher pregnancy and implantation rates across tertiles of 25(OH)D in 84 infertile women undergoing IVF (Ozkan et al. 2010), two prospective studies with 101 and 82 women could not confirm these findings (Anifandis et al. 2010; Aleyasin et al. 2011). No significant differences in pregnancy rates and embryo quality were found between patients with low (<20 ng/ml) and moderate (20–30 ng/ml) 25(OH)D follicular fluid levels. Women with high vitamin D follicular fluid levels (>30 ng/ml) had even lower pregnancy rates and embryo quality (Anifandis et al. 2010; Aleyasin et al. 2011).

Rudick et al. observed a relationship between serum 25(OH)D levels and implantation, clinical pregnancy, and live birth rates in 188 women (Rudick et al. 2012). These findings were significant in non-hispanic whites but did not apply to the Asian ethnicity (Rudick et al. 2012). The same group demonstrated a positive association between vitamin D status and clinical pregnancy rate among recipients of oocyte donation (Rudick et al. 2014). This observation is supportive of an effect of 25(OH)D levels on ART outcomes possibly due to a mediation of endometrial receptivity. Women with 25(OH)D > 20 ng/ml ($n = 181$) had a higher chance of obtaining top quality embryos, higher implantation (1.91 [95% confidence interval (CI): 1.20–3.05, $P = 0.006$]) and clinical pregnancy rates (adjusted odds ratio (aOR) 2.15 [95%]) compared to those with levels < 20 ng/ml ($n = 154$) (Paffoni et al. 2014). In a retrospective cohort of 368 women, vitamin D deficiency measured seven days' prior blastocyst transfer, appeared as an independent predictor of lower clinical pregnancy rates (Polyzos et al. 2014). When the analysis was restricted to women undergoing elective single embryo transfer (274 patients), vitamin D deficiency was still independently associated with pregnancy rates [OR (95% CI) 0.56 (0.33–0.93), $P = 0.024$]. In a larger sample of 517 analyzed cycles, this finding was not confirmed (Franasiak et al. 2015). Vitamin D levels from serum samples obtained on the day of

ovulation trigger in the fresh IVF cycle were analyzed. In this cohort with extended embryo culture, blastocyst biopsy for comprehensive chromosome screening and subsequent euploid embryo transfer vitamin D levels were unrelated to ongoing pregnancy rate (Franasiak et al. 2015). However, in a recent systematic review and meta-analysis of five studies, a deficient vitamin D level was related to lower live birth rate (relative risk (RR) 0.76, 95% CI 0.61–0.93) but not to a lower clinical pregnancy rate (RR 0.88, 95% CI 0.69–1.11) (Lv et al. 2016). Although a biologically plausible effect of vitamin D on reproductive tissues is very likely, it is still controversial whether vitamin D levels are reliable predictors of ART outcomes. Current evidence relies on heterogeneous results of small cohort studies while findings from RCTs are not yet available.

Vitamin D and Ovarian Reserve

AMH is an ovarian reserve marker and produced in the granulosa cells of the ovaries. While the AMH gene promoter contains a vitamin D response element, it is suggested that vitamin D might be involved in the regulation of the gonadal status. When granulosa cells were directly incubated with the active $1,25(OH)_2D$, changes in AMH receptor expression and downstream signaling were noted. In this experimental set-up direct effects on AMH levels were studied eliminating issues of vitamin DBP that affects the bioavailability of the active hormone in the circulation (Merhi et al. 2014). In a cross-sectional study including 388 premenopausal women with regular menstrual cycles, the authors observed a positive independent association of 25(OH)D levels with AMH in women aged 40 years and older ($N = 141$) (Merhi et al. 2012). In a prospective cross-sectional study of 283 infertile women starting their first cycle of infertility treatment serum AMH and vitamin D were determined and antral follicle count (AFC) measured on the second or third day. In contrast to the previous study, no significant association was observed between AMH levels or AFC and vitamin D concentrations, even after controlling for relevant co-variants (Drakopoulos et al. 2017). Thus, it is unclear from the available data if vitamin D deficiency is associated with lower ovarian reserve in reproductive aged women.

Vitamin D and Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is among the most common endocrine disorders affecting women of reproductive age and contributes to sub- and infertility. Clinical characteristics include hyperandrogenism, menstrual disturbances, and polycystic ovaries on ultrasound. The associated ovarian dysfunction is noticeable by oligo-/anovulation. While many, but not all, women with PCOS are overweight or obese, insulin resistance (IR) and dyslipidemia are core pathophysiologic features of this syndrome. However, a substantial number of lean women affected by PCOS have IR as well, independent of obesity (Dunaif et al. 1989). There is increasing evidence

that vitamin D affects insulin and glucose metabolism (Scragg et al. 2004; Liu et al. 2009). Vitamin D deficiency therefore has been proposed as the possible missing link between IR and PCOS. This assumption is supported by the finding that the active VDR regulates genes that are important for glucose and lipid metabolism as well as blood pressure regulation (Bouillon et al. 2008).

Several studies suggest associations between VDR polymorphisms and the development of PCOS and IR. Most of them had only modest sample sizes (Chiu et al. 2001; Mahmoudi 2009; Ranjzad et al. 2010; 2011; Wehr et al. 2011). Possible explanations of the role of VDR variants in the pathogenesis of PCOS include effects on luteinizing hormone, sex hormone binding globulin levels, and testosterone (Ranjzad et al. 2010; Wehr et al. 2011).

In a systematic review to gain insights into the association between vitamin D, BMI, and IR, 29 eligible trials with only one randomized controlled trial have been analyzed. Although univariate regression analyses revealed vitamin D to be a significant and independent predictor of IR in both PCOS and control women, the significance disappeared after adjustment for BMI in women with PCOS (Krul-Poel et al. 2013). Due to the heterogeneity of the available studies and the lack of randomized trials, it is currently hard to draw a definite conclusion about a causal relationship between vitamin D status and metabolic disturbances in PCOS.

Vitamin D and Menstrual Cycle

Animal data from knock-out mice models for 1-alpha hydroxylase, the enzyme converting vitamin D to its active form, show delayed puberty, anovulation, and irregular menstrual cycles (Panda et al. 2001; Dicken et al. 2012). Human data about vitamin D levels in the menstrual cycle and an association with irregularities are sparse and partially contradictory.

A study of 33 women included 202 serum samples collected at different time points in the follicular phase of the menstrual cycle found no differences in mean levels of 25(OH)D, free 25(OH)D, and bioavailable 25(OH)D (Franasiak et al. 2016). Several observational studies described a mid-cycle rise in the serum level of human $1,25(OH)_2D$ with a near doubling of its concentration compared to early follicular levels (Pitkin et al. 1978; Gray et al. 1982; Buchanan et al. 1986). This finding, however, was not confirmed by other studies (Baran et al. 1980; Muse et al. 1986). The mid-cyclic peak was not associated with changes of serum calcium levels or other markers of bone health and not found in women on oral contraceptives (Gray et al. 1982; Tjellesen et al. 1983). Therefore, it was suggested that the mid-cycle endogenous estrogen increase induces the rise of 25(OH)D (Buchanan et al. 1986). As the vitamin D converting enzymes are found in human endometrium, the stage of menstrual cycle must be considered when serum concentrations of $1,25(OH)_2D$ are analyzed. While 25(OH)D appears to be stable in the follicular phase, the measurement could be reliably performed during that time window of the menstrual cycle.

In a recent population-based study, lower levels of 25(OH)D were associated with irregular menstrual cycles of late reproductive-aged women (Jukic et al. 2015). However, the same group performed a community-based, cross-sectional study of 1,102 African American women. In this population a doubling of 25(OH)D serum levels was associated with half the odds of having long menstrual cycles (aOR 0.54, 95% CI 0.32–0.89) but not with the occurrence of short (aOR 1.03, 95% CI 0.82–1.29) or irregular (aOR 1.46, 95% CI 0.88–2.41) menstrual cycles (Jukic et al. 2016).

A role for vitamin D has been suggested in primary dysmenorrhea, as vitamin D inhibits synthesis of prostaglandins and VDR is located in the human uterus (Lerchbaum and Obermayer-Pietsch 2012). The first RCT investigating the effect of a single loading dose of vitamin D (300,000 IU) versus placebo on primary dysmenorrhea observed an inverse correlation of 25(OH)D levels with pain score as well as a significant reduction of pain in the vitamin D group with the greatest reduction in women with severe pain at baseline (Lasco et al. 2012). Although in another RCT the mean pain intensity in women with primary dysmenorrhea was lower in both the calcium-alone (1,000 mg calcium) and calcium-vitamin D (1,000 mg calcium + 5,000 IU vitamin D_3) groups compared to placebo, the difference was statistically significant only in the calcium alone group (Zarei et al. 2016).

Vitamin D and Endometriosis

Endometriosis is a chronic and painful disease affecting up to 10% of women in their reproductive age (Eskenazi and Warner 1997). It leads to benign growths of endometrial cells outside the uterine cavity, such as in the pelvis, fallopian tubes, and ovaries. Endometriosis is strongly associated with female infertility (Eskenazi and Warner 1997).

Various studies suggest that there is a link between vitamin D and endometriosis. The endometrium represents a target tissue of vitamin D since it expresses the VDR as well as special vitamin D metabolizing enzymes. A dysregulation of vitamin D, vitamin D metabolites, and specific enzymes was observed in different studies of patients with endometriosis. The expression of 1α-hydoxylase and the VDR are increased in endometric tissue compared to normal endometrium (Agic et al. 2007). As part of a prospective cohort study with 1,385 endometric patients, a decrease of serum 25(OH)D in patients with the disease was observed (Harris et al. 2013). In contrast, serum levels of 25(OH)D have also been reported to be higher (Somigliana et al. 2007) or showed no difference (Agic et al. 2007) in patients suffering from endometriosis compared to healthy controls. Faserl et al. have found higher serum DBP levels in women with endometriosis in a cross-sectional study including 56 cases and 20 controls (Faserl et al. 2011). In the past years, *in vivo* and *in vitro* studies have been published suggesting a role of inflammation in endometriosis leading to the shift of anti-inflammatory treatments of the disease. Nevertheless, some results were found to be ambiguous (Ahn et al. 2015). Since these findings

remain conflictive, further epidemiologic studies and clinical trials are needed to investigate this complex relationship and underlying mechanism of endometriosis and vitamin D.

Summary and Conclusions

In recent years, several studies suggest that vitamin D modulates female reproductive biology due to the expression of VDR and 1α-hydroxylase in reproductive tissues. This is supported by a regulation of steroidogenesis of sex hormones by the vitamin. A growing body of literature proposes that an individual's vitamin D status may adversely impact reproductive functions (Fig. 2). Observational studies suggest a regulatory role of vitamin D in pathophysiological aspects of PCOS and endometriosis. Vitamin D might play a favorable role in IVF success and further beneficial effects include an improvement of primary dysmenorrhea following vitamin D supplementation and a possible association of high vitamin D levels with better ovarian reserve in women of late reproductive age. However, convincing evidence demonstrating a causal link between vitamin D and the pathophysiology of the diseases is still lacking. Most available studies are observational with an uneven distribution of populations, small numbers of participants, and different protocols for supplementation studies. Findings of observational studies must be confirmed by high quality randomized and interventional trials to obtain a better understanding of the underlying mechanisms and causality. Vitamin D supplementation is advised in the general population and in women planning on starting a family.

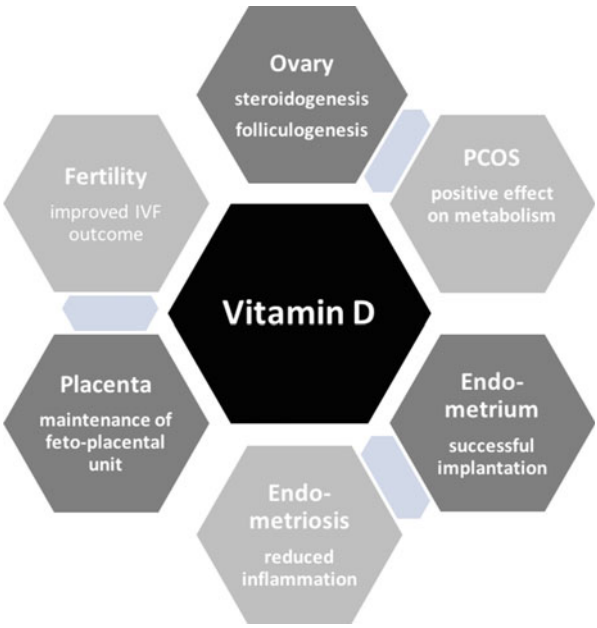

Fig. 2 Vitamin D in reproductive biology. Vitamin D status is associated with reproductive tissue and outcomes. A positive effect of vitamin D on reproductive health, fertility and on the metabolism of women suffering from PCOS and dysmenorrhea has been reported in observational studies

Policies and Protocols

- Researchers and clinicians should agree on a uniform method to measure serum 25(OH)D concentrations. For this purpose, not only a uniform method (e.g., enzyme-linked immunosorbent assay or high performance liquid chromatography) but also a uniform procedure for the collection and processing of the samples should be carried out. The serum should be worked up within a specific time frame and stored under uniform conditions until testing. It is recommended to store the samples in a biobank which meets the uniform technical and practical requirements and which underlies quality controls. This will help with the interpretation and comparison of study results in the future.
- In addition to the uniform determination of the vitamin D status, a uniform procedure to control the effects of vitamin D therapy to increase vitamin D levels to a normal range should also be established. For this, patients should take vitamin D supplements long-term under observation because medication is very different and vitamin D deficiency has to be treated over a very long period of time.
- The measurement of serum 25(OH)D has hitherto been the only method for determining vitamin D deficiency or sufficiency in the blood of patients. A further method or parameter for determination should be developed which can also be used as standard by the patient himself for the daily determination of vitamin D status, for example, via measurement in the urine or via skin.
- Awareness should be raised in the society about the relevance of a sufficient vitamin D status by physicians and clinical staff. Especially in groups at high risk, like pregnant women or the elderly, regular supplement intake can prevent vitamin D deficiency.
- Large scale randomized controlled trials (RCTs) need to be performed to prove a causal effect of vitamin D on reproductive health outcomes.

Dictionary of Terms

- **Active vitamin D** – There is an active form of vitamin D, called calcitriol (1,25-dihydroxyvitamin D), in the body that is converted from the inactive form (25-hydroxyvitamin D (25-(OH)D)). The active form is needed to fulfill vitamin D function in human cells.
- **Inactive vitamin D** – The inactive form of vitamin D is a precursor of the active form. It is used to determine a human's vitamin D status as it is measured in the blood.
- **Bioavailability** – If the active form of vitamin D can exert its actions in the body depends on the available free active vitamin D. A major proportion of the active vitamin D is bound to proteins in the blood (e.g., vitamin D-binding protein (DBP) and albumin) and therefore not readily available.
- **Vitamin D status** – The individual vitamin D status is determined by the measurement of 25(OH)D in the blood serum by various methods.

- **Vitamin D deficiency** – Serum levels of 25(OH)D below 20 ng/ml are considered as deficient.
- **Vitamin D insufficiency** – Serum levels of 25(OH)D of 21–29 ng/ml are in the insufficient range.
- **Vitamin D sufficiency** – A 25(OH)D serum level in the range of 30–50 ng/ml is considered physiologically sufficient.

Summary Points

- A uniform standard method to measure 25(OH)D concentrations to determine a person's vitamin D status does not exist, what makes a direct comparison of vitamin D levels between studies challenging.
- Vitamin D insufficiency and deficiency have a high incidence in reproductive age women around the world.
- Although the optimal level of vitamin D serum concentrations is still discussed among researchers, the currently widely accepted range for sufficient levels lies between 30 and 50 ng/ml.
- Fortified foods or vitamin D supplements are a cost-efficient and safe way to increase serum vitamin D levels.
- Vitamin D receptor and metabolizing enzymes are present in reproductive tissues and cells suggesting paracrine/autocrine functions of the vitamin.
- An effect on steroid hormone synthesis (progesterone, estradiol, and estrone) and hormones related to pregnancy (placental lactogen, chorionic gonadotropin) has been reported in in vitro studies.
- Vitamin D status is suggested to be associated with reproductive outcomes.
- A positive effect of vitamin D on the metabolism of women suffering from PCOS, the outcome of in vitro fertilization, and dysmenorrhea has been reported in observational studies.
- Available data are not consistent and limited due to methodological, ethnic, and racial differences and small sample sizes.
- In order to determine causality and prove benefits of vitamin D in the prevention of diseases and therapeutic measures, further large-scale randomized controlled trials (RCTs) must be performed and uniform clinical guidelines are needed.

Abstract

Vitamin D is required for adequate calcium and phosphate metabolism, maintenance of bone structure, and maximum muscle function. Older adults, however, are at risk of inadequate vitamin D levels due to decreased skin synthesis, decreased metabolism in the kidneys, decreased gut absorption, and comorbid medical conditions. A person's vitamin D status is assessed by measuring the blood level of 25-hydroxyvitamin D. There is no generally accepted criterion for vitamin D deficiency and insufficiency. Serum 25OHD thresholds <25 nmol/l is defined as deficient, 25 – 50 nmol/l as insufficient, and >50 nmol/l as adequate for vitamin D. Vitamin D_3 is recommended as the vitamin D preparation of choice for the treatment of vitamin D deficiency. Oral administration of vitamin D is recommended over intramuscular administration. A guideline for the treatment of vitamin D deficiency and insufficiency in older adults has been suggested. Compliance to prescribed medications is also a major factor for consideration in older adults. Individualized vitamin D therapy focusing on knowledge of the elderly and/or their carers about their medications and health may help improve adherence.

Vitamin D_3	Cholecalciferol
WHO	World Health Organisation

Introduction

Vitamin D is obtained mainly from sunlight and from diet. It is required for adequate calcium and phosphate metabolism, maintenance of bone structure, and maximum muscle function. Its deficiency causes osteomalacia in adults and rickets in children. Older adults in this context refers to individuals from the age of 65 years and above. This group includes healthy community-living older adults, acutely unwell and hospitalized or living in a residential or nursing home. This population is prone to a higher risk of chronic diseases and nutritional deficiencies which can negatively affect their quality of life. In this chapter, the assessment of Vitamin D in older adults in relation to its sources and benefits, prevalence of Vitamin D deficiency in older adults, and strategies for its management are discussed.

Sources and Biochemistry of Vitamin D

Vitamin D can be made in the skin from exposure to sunlight. This is the major source of Vitamin D. Solar ultraviolet (UV) B radiation (wavelength, 290–315 nm) penetrates the skin and converts 7-dehydrocholesterol in the skin to previtamin D_3, which is rapidly converted to vitamin D3 (Holick 2006a, 2007). Vitamin D_3 also known as cholecalciferol is one of the two dominant forms of vitamin D, the other being Vitamin D_2 also known as ergocalciferol which is manufactured by invertebrates and plants after exposure to ultraviolet radiation (McGreevy and Williams 2011). In this chapter, the term vitamin D refers to both D_2 and D_3 unless indicated otherwise. Season, time of day, length of day, cloud cover, smog, skin melanin content, and sunscreen are among the factors that affect UV radiation exposure and vitamin D synthesis (IOM 2010).

Vitamin D is also obtained from diet and nutritional supplements. Though few foods naturally contain or are fortified with vitamin D, most oil-rich fish such as salmon, mackerel, and herring contain vitamin D_3 as well as egg yolk, red meat, liver, and some fortified breakfast cereals and fat spreads (Ovesen et al. 2003; Holick 2007; Nair and Maseeh 2012; Finglas et al. 2015; Bolland et al. 2016; Spector and Levy 2016). Both vitamin D_2 and D_3 are used to fortify milk, bread, and multivitamins in the United States. The fortification of milk with vitamin D beginning in the 1930s has made rickets a rare disease in the United States (Wharton and Bishop 2003). In Europe, vitamin D_3 is almost exclusively used for multivitamins and food fortification (Holick 2005).

Vitamin D from the skin and diet is converted to the active form in two steps. The first is hydroxylation in the liver by the enzyme vitamin D-25-hydroxylase (25-OHase) to 25-hydroxyvitamin D (25OHD). The second is further hydroxylation of the 25OHD in the kidneys by the enzyme 25-hydroxyvitamin D-1α-Hydroxylase (25(OH)D-1-OHase) to form the biologically active form of vitamin D, 1,25-dihydroxyvitamin D (1,25(OH)2D) (Holick 2006b, 2007).

Vitamin D intake is expressed in International Units (IU) or in micrograms (μg). One microgram of vitamin D3 is equivalent to 40 IU (SACN 2016). For this chapter, intake will be expressed as IU.

The Older Adults

Older adults refer to individuals aged 65 years and above. This is the chronological age accepted by most developed countries as the definition of elderly or older person as it is roughly equivalent to retirement age in most developed countries (WHO 2002). In relation to location, older adults could refer to healthy community-dwelling older adults, the acutely unwell and hospitalized older adults, or nursing home/institutionalized adults.

Older adults are at risk of inadequate vitamin D levels (Lips 2001; Durvasula et al. 2010). With advancing age, there is a decreased capacity to synthesize vitamin D3 in the skin. It has been shown that there is a decrease in the concentration of 7-dehydrocholesterol in the epidermis in old compared with young individuals and a reduced response to UV light, resulting in a 50% decrease in the formation of previtamin D_3 (MacLaughlin and Holick 1985; Gallagher 2013). Again, vitamin D metabolism in the kidneys is impaired. As renal function declines with age, there is a decrease in the activity of the kidney enzyme 25(OH)D-1-OHase that converts 25OHD into 1,25(OH)2D. Serum 1,25(OH)2D levels, therefore, decrease as a result of an age-related decline in renal function (Tsai et al. 1984; Gallagher 2013). Also, gut absorption of vitamin D is also reduced with aging (Barragry et al. 1978). Finally, older adults are more likely to spend more time indoors either because of frailty or being institutionalized, leading to reduced exposure to sunlight (Lips 2001; IOM 2010; Nair and Maseeh 2012; SACN 2016; Spector and Levy 2016).

Other comorbid conditions in older adults like malabsorption syndromes, obesity, smoking, chronic liver disease, chronic kidney disease, and use of certain medications like anticonvulsants, antiretrovirals, and corticosteroids increase the risk for vitamin D deficiency. Table 1 lists the risk factors for vitamin D deficiency (McGreevy and Williams 2011).

Based on the SACN report, the Required Nutritional Intake (RNI) for the UK older adult population recommendation for vitamin D is 400 IU per day (Table 2). In UK for community-dwelling older adults, the mean daily vitamin D intake from dietary sources and dietary supplements was 204 IU in men and 208 IU in women. This mean intake makes up 51% of their RNI. For institutionalized older adults, mean daily vitamin D intake was 156 IU for men and 136 IU for women, taking into account all sources. This daily intake of vitamin D was 39% of the RNI for men and 34% for women (SACN 2016).

Role of Vitamin D in Older Adults

Vitamin D is essential for bone health maintenance in older adults (Jansen 1950; Boucher 2012). It is required for calcium, phosphorus, and bone metabolism. It promotes calcium and phosphorus absorption from the bowel and enables

Table 1 Risk factors for vitamin D deficiency in older adults (Copyright permission obtained from author; McGreevy and Williams 2011)

Risk factors for vitamin D deficiency in older adults
Advanced age
Institutionalized or home-bound
Use of sunscreen with sun protection factor >15
Heavily pigmented skin
Smoking
Obesity
Malabsorption syndromes
Renal or liver disease
Medications like antiepileptics (phenytoin, phenobarbital), cholestyramine, orlistat, corticosteroids, and antiretrovirals

Table 2 Conversion of International Units (IU) to micrograms (μg)

Formula	40 IU = 1 μg
Example	204 IU = 204 ÷ 40 = 5.1 μg

mineralization of newly formed osteoid tissue in bone (Holick 2007). Low vitamin D as well as calcium leads to poorly mineralized (or weak) bones causing osteomalacia (Holick 2006a, 2007). This presents with severe aching in bone and muscles, marked proximal muscle weakness making standing up and walking difficult, and painful and a marked "waddling" gait. This increases the risk of frequent falls, thereby increasing the risk of fractures (Bischoff-Ferrari et al. 2005). Treatment with vitamin D is curative (Boucher 2012).

Also, a decrease in the absorption of dietary calcium and phosphorus also results in an increase in parathyroid hormone (PTH) levels (Lips 2001; Nair and Maseeh 2012). PTH-mediated increase in osteoclastic activity creates local foci of bone weakness and causes a generalized decrease in bone mineral density (BMD), resulting in osteopenia and osteoporosis (Nair and Maseeh 2012). The primary risk factors for low BMD, osteoporosis, and osteopenia include vitamin D insufficiency, inadequate calcium intake, and lack of exercise (Grant and Holick 2005).

Supplementation with vitamin D (800 IU daily or more in older people) reduces rates of bone loss over time (Boucher 2012). Among postmenopausal women and older men, supplements of both vitamin D and calcium result in small increases in bone mineral density throughout the skeleton. They also help to reduce fractures in institutionalized older adults, although the benefit is inconsistent in community-dwelling individuals (IOM 2010).

Vitamin D plays an important role in muscle function (Holick 2007). The skeletal muscles express nuclear vitamin D receptors, which promotes vitamin D-directed protein synthesis. Vitamin D is therefore required for maximum function with Vitamin D deficiency being expressed as muscle weakness (Holick 2006a, b, 2007). The secondary hyperparathyroidism from vitamin D deficiency by itself may also exert a negative influence on muscle function (Joborn et al. 1989). The impaired muscle function and muscle weakness from vitamin D deficiency are

reversible following vitamin D supplementation (Glerup et al. 2000). In a recent meta-analysis, however, looking at the role of vitamin D supplementation in maintaining or improving muscle strength and mobility in community-dwelling older persons, there was no improvement in muscle strength after the administration of vitamin D with or without calcium supplements (Rosendahl-Riise et al. 2017). Vitamin D treatment still has a role in institutionalized older adults with proven deficiency (Spector and Levy 2016).

Nonmusculoskeletal health outcomes of vitamin D have been shown in observational studies in conditions such as breast cancer, colorectal cancer, cardiovascular disease, inflammatory bowel diseases, diabetes, metabolic syndrome, dyslipidaemia, rheumatoid arthritis, chronic pain, multiple sclerosis, Alzheimer's disease, cognitive decline, Parkinson's disease, mood disorders including depression, respiratory infections, tuberculosis, bronchiectasis, systemic lupus erythematosus, and in all-cause mortality, cardiovascular mortality, and cancer mortality (Mosekilde 2005; Holick 2007, McGreevy and Williams 2011; Bolland et al. 2014, 2016). However, the results from systematic reviews of RCTs of vitamin D supplementation have been inconsistent (Bolland et al. 2014, 2016).

Policies and Protocols

Vitamin D Assessment Methodology

A person's vitamin D status is assessed by measuring the blood level of 25(OH)D (Holick 2006a, 2007; Aspray et al. 2014). It is the logical metabolite for assessment, believed to reflect medium term levels of substrate for vitamin D metabolism (Aspray et al. 2014). It reflects vitamin D supply from cutaneous synthesis and diet, has a long half-life in the circulation (about 2 – 3 weeks), and is not under tight homeostatic control (SACN 2016). Serum concentration of 25(OH)D is expressed as nanomoles per liter (nmol/l) or nanograms per milliliter (ng/ml); 1 ng/ml is equivalent to 2.5 nmol/l. For this chapter, concentration will be expressed as nmol/l.

The gold standard assay method is liquid chromatography-tandem mass spectrometry (LC-MS/MS) (Zerwekh 2008; IOM 2010; Aspray et al. 2014; Osuafor et al. 2016). Alternative assays for evaluation of vitamin D status include serum 1,25 (OH) 2 vitamin D, PTH, and markers of bone turnover. These are not recommended for routine use (Aspray et al. 2014).

Vitamin D Deficiency in Older Adults

There is no generally accepted criterion for vitamin D deficiency. This, together with differences in serum vitamin D measurement, can make comparisons between different reports problematic (Hirani and Primatesta 2005).

The Endocrine Society Task Force on Vitamin D stated that individuals should be identified as vitamin-D deficient at a serum 25OHD level of 50 nmol/l and sufficient

at >75 nmol/l to maximize the effect of vitamin D on calcium, bone, and muscle metabolism (Holick 2011). However, the overall evidence suggests that risk of poor musculoskeletal health is increased at serum 25OHD concentrations below ~20–30 nmol/l. The Scientific Advisory Committee on Nutrition (SACN) maintains a threshold of 25 nmol/l to define the concentration below which risk of vitamin D deficiency increases (SACN 2016).

The National Osteoporosis Society (NOS) published a practical clinical guideline on the management of vitamin D deficiency in adult patients with, or at risk of developing, bone disease (Aspray et al. 2014). Based on this guideline, the serum 25OHD thresholds define <30 nmol/l as deficient; 30 – 50 nmol/l as inadequate in patients with osteoporosis, fragility fractures, malabsorption, or on steroids; and >50 nmol/l as sufficient. This is in agreement with the thresholds set by the Institute of Medicine (IOM) based on evidence from two systematic reviews (IOM 2010; NOS 2013).

For this chapter and the treatment algorithm, serum 25OHD thresholds <25 nmol/l is defined as deficient, 25 – 50 nmol/l as insufficient, and >50 nmol/l as adequate.

Vitamin D insufficiency affects almost 50% of the population worldwide (Nair and Maseeh 2012). Its prevalence is highly variable ranging from 28% to 100% of healthy adults and 70 – 100% of hospitalized adults in Europe (Passeri et al. 2003).

In older adults, the prevalence of vitamin D deficiency ranges from 20% to 55% in institutionalized adults in the United Kingdom (Hirani and Primatesta 2005) and community dwelling older adults in Ireland (Hill et al. 2006; McCarthy et al. 2006; Osuafor et al. 2016). Representative residents from the SENECA study of older Europeans aged 75 – 76 years old showed 36% of men and 47% of women were vitamin D deficient (Van der Wielen et al. 1995).

Patients living in nursing homes and in homes for the elderly had plasma 25OHD levels of 9 – 37 nmol/l in Europe compared with 53 – 45 nmol/l in the United States and 26 – 40 nmol/l in Australia (Lips 2001). In Denmark, 7% of postmenopausal women have vitamin D deficiency and 40% have insufficiency while 80% of elderly over 65 years have vitamin D insufficiency (Brot et al. 2001; Larsen 2002).

Regarding inpatient populations, as many as half of older adults in the United States with hip fractures could have serum 25(OH)D levels <30 nmol/l (Cranney et al. 2007), while a study in Singapore showed a vitamin D deficiency prevalence of 57.5% and vitamin D insufficiency of 34.5% in elderly patients admitted to hospital with hip fractures (Ramason et al. 2014).

Treatment Modality

Vitamin D_3 is recommended as the vitamin D preparation of choice for the treatment of vitamin D deficiency. This is because vitamin D_2 does appear to have quicker clearance than vitamin D_3 and lower tissue bioavailability. Vitamin D_2, however, may be preferred by vegetarians and those who wish to avoid animal-derived products (Romagnoli et al. 2008; Heaney et al. 2011; NOS 2013).

Oral administration of vitamin D is recommended over intramuscular (IM) administration. This is because the IM route has an unpredictable bioavailability, slower onset of repletion, and additional administration burden in comparison to oral preparations (Romagnoli et al. 2008; NOS 2013).

In the past, it was advocated that a single large dose (300,000 IU or higher) of vitamin D might lead to sustained correction of vitamin D deficiency and potentially avoid adherence problems with regular lower dose supplementation. However, more reports have suggested that large doses of vitamin D given intermittently are ineffective and might actually increase fracture risk (Smith et al. 2007; Sanders et al. 2010; NOS 2013).

Figure 1 shows a guideline for the treatment of vitamin D deficiency in older adults while Fig. 2 shows a guideline for the treatment of vitamin D insufficiency in older adults. Both protocols show the need for initial assessments of dietary habits, use of medications that may interfere with vitamin D metabolism and comorbid disease states mentioned earlier. Initial bloods investigations will also include bone, liver, renal profiles, and PTH level. Any abnormalities noted at this point will require the advice from an expert who may be a geriatrician, endocrinologist, nephrologist, or a specialist in bone health. If no abnormalities are found, then treatment can be commenced as per the guideline. This is only a guideline, and in all cases, it is recommended that expert advice should always be sought at every step in the assessment and treatment of older adults with vitamin D deficiency or insufficiency.

Monitoring and Assessment of Efficacy of Treatment

It is known that vitamin D treatment can unmask previously undiagnosed primary hyperparathyroidism (Hannan et al. 2004; NOS 2013). In order to monitor this outcome, adjusted serum calcium levels should be measured. Reassuringly, a report by Wagner et al. has shown that replacing vitamin D in mild primary hyperparathyroidism is safe and effective and does not increase calcium to dangerous levels (Wagner et al. 2013; Osuafor et al. 2016). According to the NOS, however, adjusted serum calcium levels should be measured within 1 month after the administration of the last loading dose of vitamin D. If hypercalcemia is observed at this time, further vitamin D supplementation should be stopped prior to investigation of the hypercalcemia (NOS 2013).

Due to confounding effects of UV exposure in the summer months, dose response to vitamin D supplementation shows considerable variability in different studies. When confined to winter levels, a daily supplement of 800–1000 IU cholecalciferol will cause an increase in 25OHD of 24 – 29 nmol/l (NOS 2013). Hence, the NOS guideline recommends that routine monitoring of serum 25OHD is unnecessary. It may however be appropriate in patients with symptomatic vitamin D deficiency or malabsorption and where poor compliance with medication is suspected, and this should be done not earlier than 3 months (NOS 2013; Aspray et al. 2014). Unnecessary retesting of vitamin D leads to increased laboratory expenditure, and it is recommended that hospitals work in conjunction with the laboratory and/or

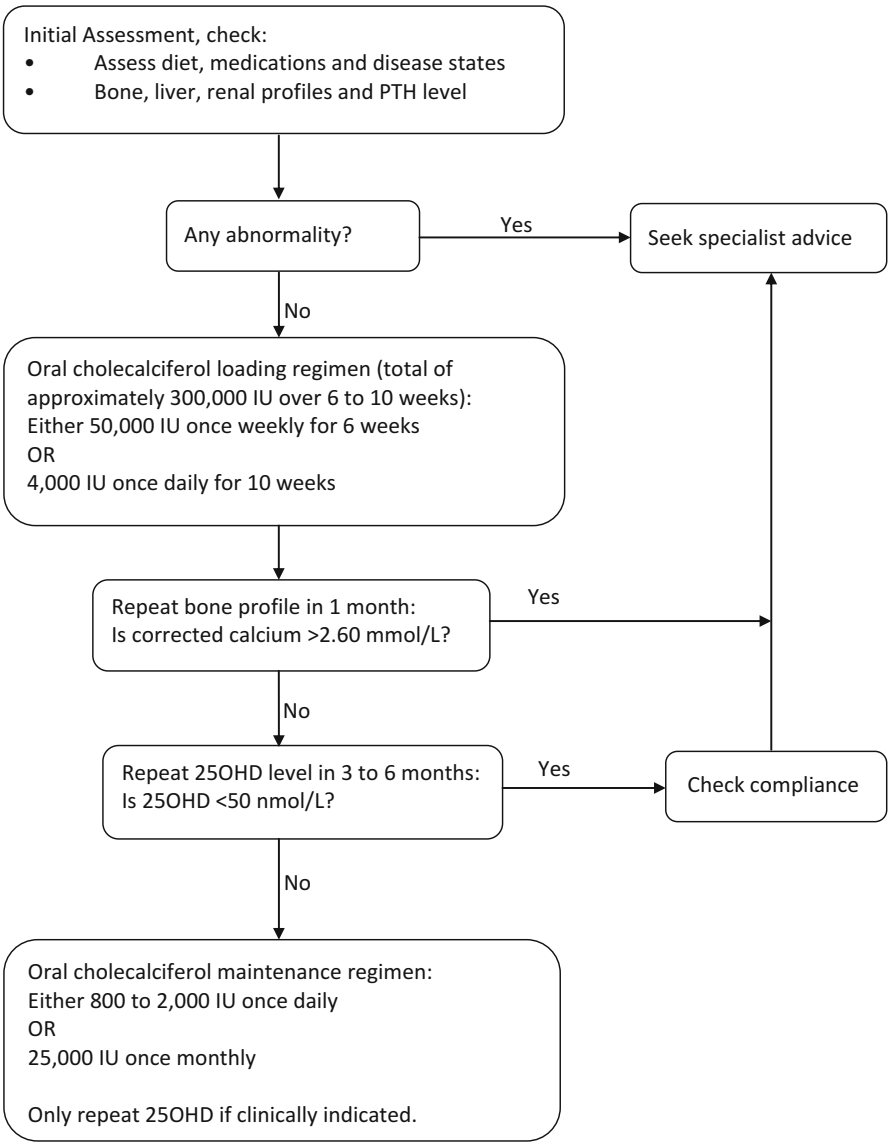

Fig. 1 Guideline for the treatment of vitamin D deficiency in older adults (Serum 25OHD <25 nmol/l)

information technology service to draw up policies regarding vitamin D retesting in patients known to their service (Osuafor et al. 2016).

Compliance to prescribed medications is also a factor for consideration as adherence to medications has always been an issue among the elderly (Yap et al. 2016). Extent of noncompliance in the elderly is estimated to vary from 40% to

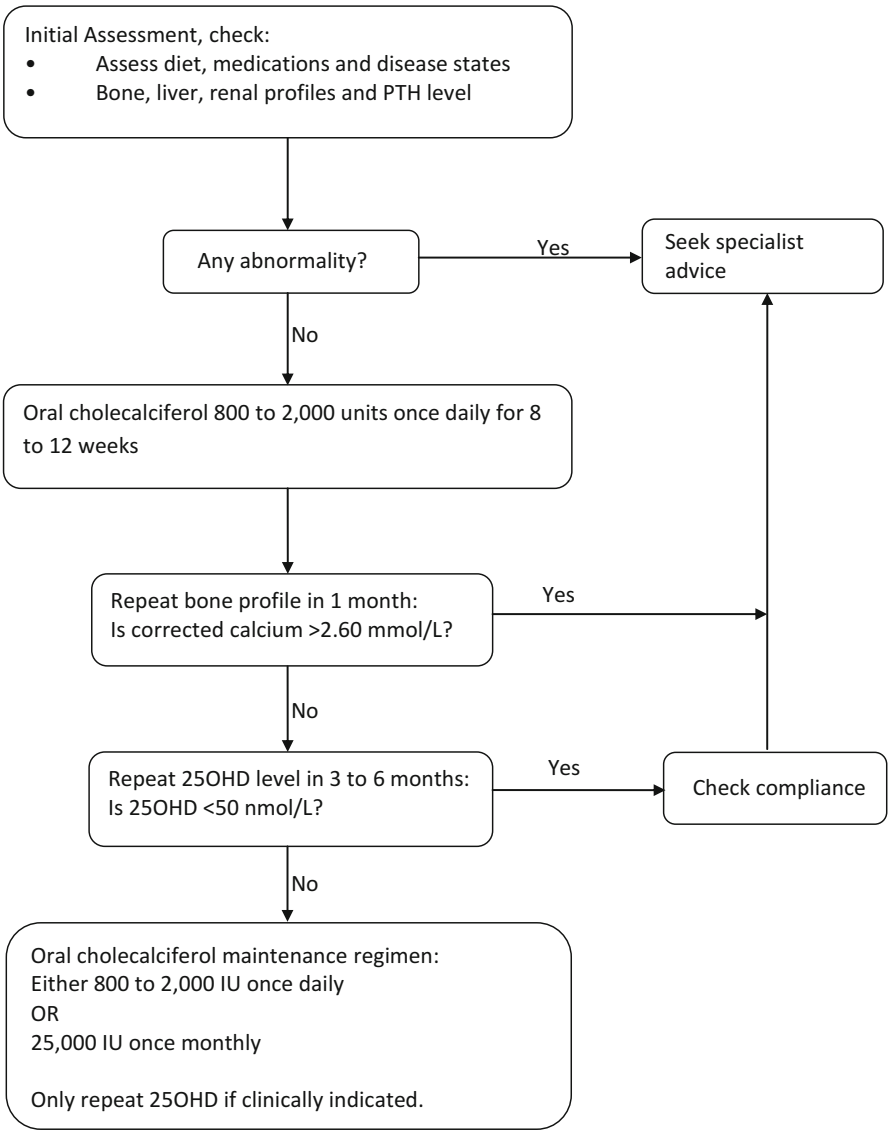

Fig. 2 Guideline for the treatment of vitamin D insufficiency in older adults (Serum 25OHD: 25 – 50 nmol/l)

75% (Salzman 1995). Overuse of prescribed medications is clearly associated with adverse drug reactions. Excessive vitamin D intake has been shown to have toxic effects (Vieth 2006). Vitamin D toxicity results in hypercalcemia caused by increased intestinal calcium absorption and mobilization of calcium from the bone which in turn can result in deposition of calcium in soft tissues, diffuse

demineralization of bones, and irreversible renal and cardiovascular toxicity (Jones 2008; SACN 2016). Reassuringly, the dosing regimen of vitamin D is unlikely to result in toxicity (NOS 2013).

The most common noncompliant behavior of the elderly appears to be underuse of the prescribed drug (Salzman 1995). An individualized therapy focusing on a patient's knowledge about his medications and health and use of a pharmacy-led medication reconciliation service may help improve adherence (Yap et al. 2016). In situations where the individual's cognition is a concern, as is the case often with frailer older adults, education of their carers on the patient's medications and health may help improve adherence.

Dictionary of Terms

- **1α-hydroxycholecalciferol** – A synthetic analogue of 1,25-dihydroxyvitamin D.
- **1,25-dihydroxyvitamin D (1,25(OH)2D)** – The main active metabolite of vitamin D in the body. Produced in the kidney from 25-hydroxyvitamin D.
- **7-dehydrocholesterol (7-DHC)** – A sterol found in the skin of humans and animals that is converted to vitamin D3 by the action of UVB rays in sunlight.
- **25-hydroxyvitamin D (25(OH)D)** – A metabolite of vitamin D produced in the liver from vitamin D. Circulates in the blood and is a marker of exposure to vitamin D, reflecting vitamin D supply from cutaneous synthesis and the diet.
- **Alfacalcidol** – Another name for 1α-hydroxycholecalciferol
- **Bone mineral density (BMD)** – The density of bone mineral in a skeletal unit (g/cm^3). When measured by single or dual-energy X-ray techniques it represents the mass of bone mineral measured within a scanned area (g/cm^2) and is not a true density measurement.
- **Bone profile** – Panel of tests for serum concentrations of albumin, calcium, corrected calcium, and phosphate.
- **Cholecalciferol** – Another name for vitamin D_3.
- **Reference Nutrient Intake (RNI)** – The nutrient intake that will be adequate to meet the needs of 97.5% of the population.
- **Fortification** – Addition of nutrients to foods during the manufacturing process.
- **Half-life** – Time required for concentration of a substance in the body to decrease by half.
- **Hypercalcemia** – A raised serum calcium concentration usually greater than 2.65 mmol/l.
- **Hyperparathyroidism** – Overactivity of the parathyroid glands that results in high concentration of parathyroid hormone. This leads to weakening of the bones through bone resorption to release calcium from the bone.
- **Liver profile** – Panel of tests for serum concentrations of alanine transaminases, aspartate transaminase, alkaline phosphatase, and gama-glutamyl transaminase.
- **Older adults** – Individuals above the age of 65 years.
- **Osteoclast** – Bone cell that resorbs bone tissue as part of the processes of skeletal development, maintenance, and repair.

- **Osteomalacia** – A skeletal disorder that develops as result of vitamin D deficiency. Causes severe aching in bones and muscles and muscle weakness. Caused by impairment in mineralization phase of bone remodeling, resulting in a lower ratio of bone mineral to osteoid than normal. Kidney or liver damage, which interferes with vitamin D metabolism, can also cause osteomalacia.
- **Osteoporosis** – A progressive skeletal disorder characterized by reduced bone strength due to loss of bone mass and deterioration in microarchitecture of bone, where the ratio of bone mineral to osteoid is normal. Leads to increased bone fragility and risk of fracture.
- **Parathyroid hormone (PTH)** – Hormone secreted by the parathyroid glands. Involved in regulation of calcium homeostasis.
- **Renal profile** – Panel of tests for serum concentrations of sodium, potassium, chloride, urea, and creatinine.
- **Rickets** – A disorder of the growth plates of infants and children that affects skeletal development. The most common cause is insufficient vitamin D (vitamin D deficiency rickets), calcium, or phosphate during growth, which leads to pain, softening and weakening of the bones, and characteristic deformities of the long bones.
- **Vitamin D_2** – Also known as ergocalciferol. Formed in fungi and yeast by UVB exposure of the steroid, ergosterol.
- **Vitamin D_3** – Also known as cholecalciferol. Synthesized in skin of humans from 7-dehydrocholesterol by the action of solar UVB radiation.

Summary Points

- Vitamin D is required for adequate calcium and phosphate metabolism, maintenance of bone structure, and maximum muscle function.
- Older adults whether healthy community-living older adults, acutely unwell and hospitalized, or living in a residential or nursing home are at risk of low levels of vitamin D.
- Vitamin D plays a significant role in musculoskeletal outcomes and probably plays a role in other nonmusculoskeletal conditions.
- A person's vitamin D status is assessed by measuring the blood level of 25-hydroxyvitamin D.
- We define serum 25OHD thresholds <25 nmol/l as deficient, 25 – 50 nmol/l as insufficient, and >50 nmol/l as adequate.
- Vitamin D insufficiency and deficiency has a worldwide prevalence.
- Oral Vitamin D_3 is a recommended choice for the treatment of vitamin D deficiency and insufficiency.
- Protocols have been proposed for the treatment of vitamin D deficiency and insufficiency in older adults. Expert advice should be sought at every step of the assessment and treatment.
- Compliance to prescribed medications is an ongoing concern in older adults and hence replacement requires monitoring.

Congenital Vitamin E Deficiency

86

Hamza El Hadi, Roberto Vettor, and Marco Rossato

Contents

Abstract

A growing body of literature has begun to delineate the unique and potent biological properties of vitamin E involved in cardiovascular disease, cancer, chronic inflammation, and neurodegeneration. Vitamin E was initally proposed as a dietary factor essential in preventing embryonic mortality and soon after considered as lipid-soluble antioxidant that inhibits lipid peroxidation by scavenging reactive oxygen species. Recent mechanistic studies indicate that vitamin

E possesses functions that are independent of its antioxidant ability and mainly modulate cell signal transduction and gene expression. Despite overt vitamin E deficiency is rare, most commonly it can be found in children with inherited abnormalities that prevent the absorption or maintenance of normal blood concentration of vitamin E. This review summarizes the genetic disorders associated with congenital vitamin E deficiency. In parallel, it provides a brief overview on the historical, metabolic, and functional aspects of vitamin E.

Introduction

Since its discovery, research recognized potential ability of vitamin E to prevent chronic diseases and clinical syndromes. Particularly this was supported by a number of clinical conditions believed to have an oxidative stress component such as diabetes (Evans et al. 2002), cardiovascular (Rimm et al. 1993), neurodegenerative

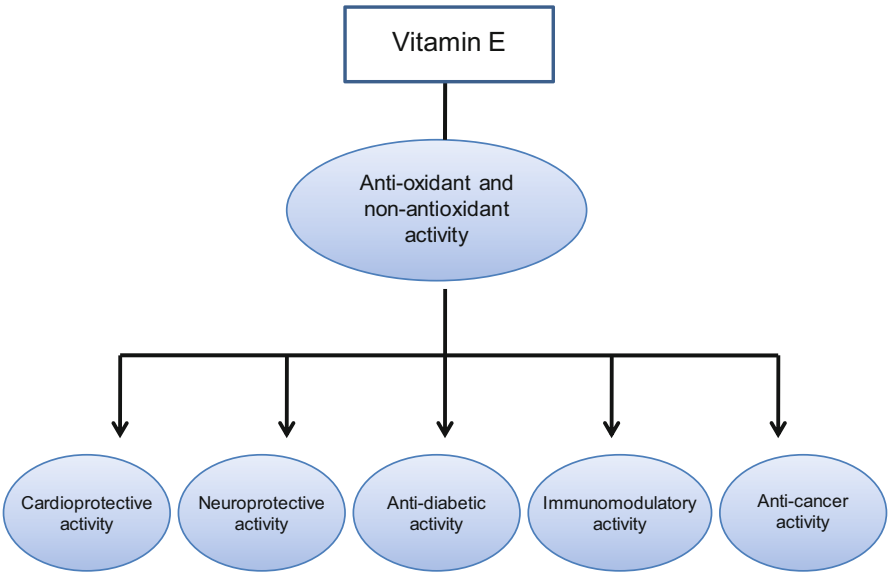

Fig. 1 Summary of vitamin E activities

diseases (Butterfield et al. 2002), and cancer (London et al. 1992) (Fig. 1). Nonetheless, the role of this vitamin in other conditions is still debated (Rossato and Mariotti 2014).

In the recent years, it has become increasingly evident that not all actions of vitamin E are dependent on its antioxidant properties, but may involve non-antioxidant activities, especially those connected with cell signal transduction, protein expression, enzyme activities, and gene expression regulation (Zingg and Azzi 2004).

The purpose of this review is to describe the congenital disorders associated with vitamin E deficiency. In addition, we sought to provide a concise summary of the history, metabolism, and regulatory functions of vitamin E.

History, Metabolism, and Function of Vitamin E: General Overview

Historical Background

Vitamin E was first discovered in 1922 by Evans and Bishop as a dietary factor essential for reproduction in rats. They found that laboratory rats failed to reproduce when lard was their only source of food fat. According to the researchers, there was a compound in both wheat germ and lettuce that corrected the problem and they decided to call it "Factor X" and the "antisterility factor" (Evans and Bishop 1922). Similar results were observed by Sure and he called it "Vitamin E," as by

then vitamins A, B, C, and D were already known (Sure 1924). In 1936, Evans et al. isolated a pure compound from the nonsaponifiable fraction of wheat-germ oil having the properties of vitamin E. This active compound was called alpha-tocopherol (α-tocopherol), from the ancient Greek word *phero* meaning "to bring" and *tocos*, meaning "childbirth" (Evans et al. 1936).

Natural vitamin E now encompasses a family of eight fat-soluble isoforms that exhibit the biological activity of α-tocopherol: the α-, β-, γ-, and δ-tocopherols and the α-, β-, γ-, and δ-tocotrienols, which are synthesized by plants from homogentisic acid (Rimbach et al. 2002).

Tocopherols and tocotrienols both include a chromanol ring and differ in their side chains. Saturated phytyl side chain is involved in the structure of tocopherols, while unsaturated geranylgeranyl side chain with three double bonds is involved in the structure of tocotrienols (Kamal-Eldin and Appelqvist 1996). Tocopherols and tocotrienols are classified as α-, β-, γ-, and δ according to the methyl group on the chromanol ring. Among the eight naturally occurring forms of vitamin E family, α-tocopherol is considered the most common form in human tissues followed by γ-tocopherol, while tocotrienols are usually not detected in tissues (Frank et al. 2012). Tocopherols are exclusively synthesized by photosynthetic organisms, and plant-derived oils are the major sources of vitamin E in the human diet. The most common form of tocopherol in the North American diet is γ-tocopherol, the predominant form of vitamin E in corn oils, while the most common form in European diets is α-tocopherol, found in olive and sunflower oils (Dutta and Dutta 2003). Tocotrienols are found in palm oil, barley, oats, and rice bran, and have higher antioxidant activity than tocopherols.

Metabolism

The vitamin Es present in ingested food, either as a free molecule or esterified, leave the stomach to be hydrolyzed in the duodenal lumen by the pancreatic lipases and subsequently absorbed through the brush border membrane of the enterocytes (Borel et al. 2001; Hacquebard and Carpentier 2005). After their uptake, vitamin E isomers reach the basolateral side of enterocytes to be equally incorporated into chylomicrons together with triacylglycerol, phospholipids, and cholesterol (Hacquebard and Carpentier 2005). The chylomicron-bound vitamin E forms are transported via lymphatic system into the circulation where the triaclyglycerol components of the chylomicrons are hydrolyzed by lipoprotein lipase of the capillary endothelium and adipose tissue forming lipid-depleted chylomicrons components (Hacquebard and Carpentier 2005). The chylomicrons remnants containing most of the absorbed tocopherols and tocotrienols are then taken up by the liver (via the endocytic receptors, such as the low-density lipoprotein (LDL) receptor and heparin sulfate proteoglycans) which sorts out α-tocopherol and preferentially secretes it within very low-density lipoprotein (VLDL) and high-density lipoprotein (HDL) into the bloodstream for distribution in the body (Traber et al. 1993). On the other hand, excess α-tocopherol and the other tocopherols and tocotrienol analogues are either excreted unchanged or metabolized before elimination in urine and bile (Traber

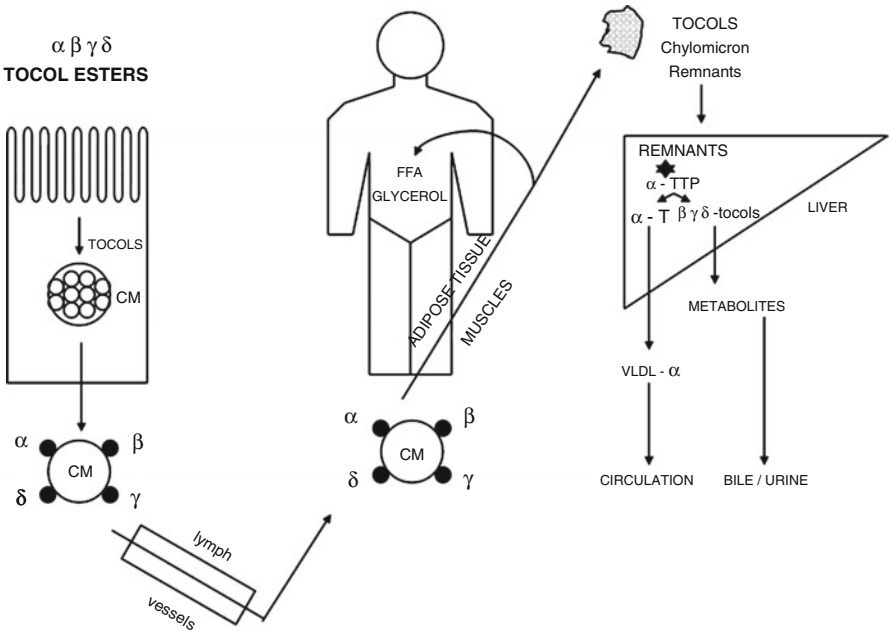

Fig. 2 Absorption, transport, and metabolism of vitamin E. All forms of vitamin E are absorbed equally. Intestinal enzymatic digestion is followed by the distribution to the liver and nonhepatic tissues. Discrimination between the different forms of vitamin E in favor of α-tocopherol occurs mainly in the liver by α-TTP, which protects α-tocopherol from excessive degradation and excretion (With permission from Eggermont 2006)

et al. 1993). This selective accumulation of α-tocopherol is mediated by hepatic cytosolic protein, α-tocopherol-transfer protein (α-TTP) which preferentially binds to α-tocopherol over other vitamers (Eggermont 2006) (Fig. 2). While α-TTP presents high affinity to α-tocopherol (100%), it has much lower affinity toward other vitamin E forms, e.g., 38%, 9%, or 1% affinity to β-, γ-, and δ- tocopherols, respectively (Eggermont 2006). In addition, it was proposed that non-α-tocopherol forms of vitamin E are catabolized in liver into carboxyethyl hydroxychromanol (CEHC) metabolites via cytochrome P450 (CYP4F2) initiated ω-hydroxylation and oxidation followed by β-oxidation of the phytyl chain (Birringer et al. 2002; Sontag and Parker 2007).

Molecular Function of Vitamin E

Antioxidant Activity

Vitamin E is widely accepted as one of the most potent antioxidant. Biochemically, tocopherols and tocotrienols are potent lipophilic antioxidants by scavenging lipid peroxyl radicals via donating hydrogen from the phenolic group on the chromanol ring and thus neutralize free radicals or reactive oxygen species (ROS) (Jiang et al.

2001). At equal molar concentrations in vitro, because of possessing similar phenolic moiety, all vitamin E forms are considered to have potent antioxidant activities. It was reported that the α-tocopherol and γ-tocopherol isoforms and the tocotrienol forms have relatively similar capacity to scavenge ROS during lipid oxidation (Yoshida et al. 2007). In vivo, there is likely more ROS scavenging by α-tocopherol than γ- tocopherol since it is at a 10-fold higher concentration within tissues. In addition to scavenging ROS, γ-tocopherol, in contrast to α-tocopherol, also reacts with nitrogen species such as peroxynitrite forming 5-nitro-γ-tocopherol (Wolf 1997).

Nonantioxidant Activity

As already mentioned in the introduction, it has been reported that vitamin E exhibits some properties that cannot be assigned to its antioxidant capacity. Here below we summarize some of those nonantioxidant functions.

Effects on Enzyme Inhibition

Protein kinase C (PKC) is a serine/threonine kinase that utilizes the cofactors phosphatidylserine, diacylglycerol, and calcium for activation. It is considered one of the major cellular transduction systems triggered by various ligands as hormones, neurotransmitters, and growth factors (Azzi et al. 1992). PKC is one of the pathways used by α-tocopherol (Boscoboinik et al. 1991) where it exerts a specific inhibitory activity compared to β-tocopherol (Tasinato et al. 1995). In monocytes this leads to the inhibition of phosphorylation and translocation of the cytosolic factor p47 (phox) and to an impaired assembly of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and of superoxide production (Cachia et al. 1998). Moreover, α-tocopherol exerted an antiproliferative effect on vascular smooth muscle cell model by inhibiting PKC pathway (Özer et al. 1998). However, these inhibitory effects were not observed by its isomer β-tocopherol or another antioxidant (probucol) (Özer et al. 1998). Additionally, α-tocopherol protects against endothelial damage by regulating the endothelial cell PKC (Abdala-Valencia et al. 2012). Remaining within this context, vitamin E has shown to increase the production of vasodilator prostanoids by suppressing cyclooxygenase (COX) activity in cellular environments and therefore effectively contribute to the anti-inflammatory process (Wu et al. 2005).

Effects on Gene Expression

It has been reported that vitamin E regulates the expression of genes involved in oxidative stress, proliferation, inflammation, and apoptosis. Some of these gene classes modulated by vitamin E include α-TTP, scavenger receptors (CD36, SR-BI, SR-AI/II), P450-Cytochromes, transcriptional factors (NF-κB, AP-1), genes involved in the modulation of extracellular proteins (tropomyosin, collagen-alpha-1, matrix metalloproteinases (MMP-1, -19), and connective tissue growth factor) (Azzi et al. 2004; Brigelius-Flohé 2009).

Moreover, genes connected to adhesion and inflammation (E-selectin, Intercellular Adhesion Molecule 1, integrins, glycoprotein IIb, IL-2, IL-4, IL-1b, and transforming growth factor-beta), lipid metabolism (Apolipoprotein E, peroxisome proliferator-activated receptor gamma, LDL- receptor), and cell

cycle regulation are also affected by α-tocopherol at the transcriptional level (Brigelius-Flohé 2009).

Despite well-documented antioxidant and other beneficial effects as well as negative association between α-tocopherol intake and chronic diseases, supplementation of α-tocopherol has failed to offer consistent benefits to prevention of chronic diseases including cancer and cardiovascular diseases in many large clinical intervention studies (Moya-Camarena and Jiang 2012; Myung et al. 2013; Papaioannou et al. 2011; Dolara et al. 2013). On the other hand, accumulating evidence suggests that metabolites mainly deriving from non-α-tocopherol vitamers have unique properties that are superior to α-tocopherols.

For instance, short-chain carboxychromanols like CEHCs generated by CYP4F2-initiated ω- oxidation of the side chain have been shown to have natriuretic activities (Wechter et al. 1996). In hemodialysis patients, supplementation of γ-tocopherol but not α-tocopherol is associated with a consistent increase of serum CEHC and a decrease in pro-inflammatory IL-6 and C-reactive protein (Himmelfarb et al. 2003). Moreover, long-chain carboxychromanols, including 13′-carboxychromanol, exhibit a potent anti-inflammatory (Jiang et al. 2008) and anticancer (Birringer et al. 2010) effects that may provide new insights into physiological role of less tissue-preserved forms of vitamin E.

Serum Vitamin E Assessment

The adequacy of the mean range of α-tocopherol intake is difficult to define being strongly influenced by concentration of circulating lipids, and does not accurately reflect tissue vitamin levels. Serum α-tocopherol concentrations less than 12 μmol/L were defined by the Institute of Medicine (IOM) to be in the deficient/inadequate range for healthy adults (Institute of Medicine 2000). It is recognized that vitamin E inadequacy is associated with increased erythrocyte fragility. Therefore, results from hydrogen peroxide-induced erythrocyte lysis test were used to define vitamin E status and consequently to assess vitamin E supplementation (Institute of Medicine 2000). As will be discussed in the next section, most commonly low α-tocopherol concentrations are caused by the combination of consumption of diets low in vitamin E, along with inadequate intakes or absorption of fat, protein, and calories. These latter dietary components are necessary for fat absorption and thus for vitamin E absorption and its lipoprotein transport.

Congenital Disorders with Vitamin E Deficiency

Vitamin E deficiency is seldom found in adults but more frequently can be found in children, likely as a result of genetic defects that lead to fat-malabsorption syndromes or a rapid depletion of plasma α-tocopherol. In this section we highlight the pathophysiology, clinical presentation, and management of the main genetic disorders associated with vitamin E deficiency (Table 1).

Table 1 Genetic diseases with vitamin E deficiency (Modified with permission from Eggermont 2006)

Disease	MIM number	Location	Inheritance	Gene defect
Ataxia with vitamin E deficiency	277460	8q13.1	AR	α-TTP
Abetalipoproteinemia	200100	4q22-24	AR	MTP
Familial hypobetalipoproteinemia	107730	3p21.1-22	AD	APOB
Chylomicron retention disease	246700	5q31	AR	SAR1B
Cystic fibrosis	219700	7q31.2	AR	CFTR

Ataxia with Vitamin E Deficiency

Human vitamin E deficiency symptoms began to be reported in the 1960s in various case studies of patients with lipoprotein abnormalities. Since these patients had malabsorption of other nutrients, it was not clear the extent to which various symptoms could be attributed to lack of vitamin E (Kayden et al. 1965). In the early 1980s, studies of humans with vitamin E deficiency symptoms without fat malabsorption began to appear in the literature (Burck et al. 1981). This form of vitamin E deficiency was later called AVED, or familial isolated vitamin E deficiency (Doerflinger et al. 1995). AVED (MIM 277460) is a rare genetic neurodegenerative disease transmitted in an autosomal recessive mode, and caused by mutations in the α-tocopherol transfer protein gene (TTPA) located on chromosome 8q13 (Doerflinger et al. 1995). This defect impairs incorporation of vitamin E into plasma VLDL and thus cannot reach peripheral circulation.

The concomitant presence of specific neurological phenotype and low plasma levels of vitamin E, in the absence of other clinical conditions associated with fat malabsorption, can guide the diagnosis for AVED (Anheim et al. 2010). The onset of neurologic features in AVED is between 4 and 18 years of age with a phenotype that resembles patients with Friedreich's ataxia, a genetic disorder caused by a mutation in the gene for frataxin, a mitochondrial iron-binding protein (Bradley et al. 2000; Yokota et al. 1997).

The signs and symptoms are usually devastating and progressive and mainly including truncal and extremity ataxia, loss of deep tendon reflexes, disturbances in proprioceptive and vibratory sensations, dysarthria, and positive Babinski sign (El Euch-Fayache et al. 2014). Head titubation, retinopathy, and dystonia are more common in patients with AVED while cardiomyopathy, glucose intolerance, scoliosis, and foot deformities in Friedreich ataxia (Cavalier et al. 1998; Benomar et al. 2002).

The molecular mechanism that underlies the neurological damage in patients with AVED is not yet known in detail, but oxidative stress due to reduced delivery of vitamin E to the central nervous system is likely to play a major role (Copp et al. 1999). Neuropathological findings derived from human and animal models with vitamin E deficiency documented the presence of severe dying back-type degeneration of the posterior column and massive accumulation of lipofuscin in neurons including dorsal root ganglion cells (Yokota et al. 2000).

Different mutations have been described in different ethnic groups. In North Africa populations, the most frequent mutation is 744delA on chromosome 8q13 (Cavalier et al. 1998; Gabsi et al. 2001). The mutation 513insTT predominates in AVED families of North European origin, 175 C4T (R59W) on exon 1 and 437delT on exon 3 in the case reported from Netherland as well as G552A on exon 3 in Japan (Yokota et al. 1997). In Mediterranean region, both the 744delA and 513insTT account for approximately 80% of the TTPA mutated alleles in Italian AVED (Doerflinger et al 1998, Cavalier et al. 1998).

Several studies described a correlation between the type of mutation and the function of the α-tocopherol protein and thereby vitamin E serum level and the severity of the neurological signs (Cavalier et al. 1998; Mariotti et al. 2004). Different mutations have been reported, including missense, nonsense, frameshift, and splice site mutations, and may affect the severity of the disease, presumably via residual protein activity with certain mutations (Cavalier et al. 1998).

Today experts agree that there is no specific instrumental approach for establishing the diagnosis of AVED (Harding et al. 1982). However, the presence of sensory neuropathy with normal motor conduction and absent or markedly reduced sensory nerve action potentials (SNAPs) is considered a neurophysiologic hallmark of this disease. Additionally, it has been described a distal motor neuropathy with normal sensory conduction AVED patient (Fusco et al. 2008).

Individuals with AVED are treated with life-long vitamin E supplementation. Remarkably, the administration vitamin E in early stages of the disease seems to prevent the progression of neurological impairment, atherosclerosis, and retinopathy in these patients (Marzouki et al. 2005) and can mildly improve cerebellar ataxia (Gabsi et al 2004). A mouse model has been developed that shows late-onset head tremor, ataxia, and retinal degeneration, the neurological aspects of which resolve with supplementation of vitamin E (Yokota et al. 2001).

Currently, vitamin E is manufactured as the acetate esters of RRR-α-tocopherol by using plant materials and all-racemic-α-tocopherol by chemical synthetic methods. Even though, α-TTP preferentially packages RRR-α-tocopherol into nascent VLDL, however, some AVED individuals lacking α-TTP or with a marked defect in the RRR-α-tocopherol binding site cannot discriminate between α-tocopherol stereoisomers (Traber et al. 1993; Cavalier et al. 1998).

Cavalier et al. suggested that administration of 800 mg RRR α-tocopherol twice daily, with meals that contain fat, results in plasma α-tocopherol levels at or above the normal range (Cavalier et al. 1998).

Abetalipoproteinemia

Abetalipoproteinemia (ABL; MIM 200100) or Bassen-Kornzweig syndrome is a rare autosomal-recessive disease that is characterized by very low plasma concentrations of triglyceride and cholesterol (under 30 mg/dl) and undetectable levels of LDL and apolipoprotein (apo) B (Berriot-Varoqueaux et al. 2000). It is caused by a mutation in microsomal triglyceride transfer protein (MTP) gene on chromosome 4q22-24 (Wang

and Hegele 2000). MTP, physiologically expressed on the luminal side of the endoplasmic reticulum in intestine, is involved in the assembly of chylomicrons in the enterocytes and of VLDL particles in hepatocytes (Wang and Hegele 2000).

Despite the gold standard diagnostic test would be by sequencing the MTP gene, and a clinical diagnosis can be made for ABL based on lipid profile, blood smear, and clinical symptoms. Key clinical features in ABL patients in the first years of life are steatorrhea due to fat malabsorption, and failure to thrive. This is often accompanied by digestive symptoms, such as diarrhea, vomiting, and abdominal distension (Burnett et al. 2012).

Additionally, neurological disorders which may appear later in childhood due to profound vitamin E deficiency often have the greatest impact on quality of life especially if there has been no therapeutic intervention. Absent tendon reflexes is an early clinical sign, followed by deep sensory loss in the lower limbs and then a spinocerebellar syndrome with an ataxic gait, dysmetria, and dysarthria (Berriot-Varoqueaux et al. 2000; Kane and Havel 2001). Ophthalmological findings may include atypical retinitis pigmentosa where the presence of lipofuscin pigment in the retina suggests that vitamin E deficiency plays a central role in this retinopathy (Berriot-Varoqueaux et al. 2000, Kane and Havel 2001).

Among laboratory investigations, a blood smear may show acanthocytosis that results from either vitamin E deficiency or an altered membrane lipid composition (Kane and Havel 2001). As mentioned previously, lipid profile shows decrease of plasma levels of cholesterol and triglycerides and almost undetectable levels of apoB-containing lipoproteins including chylomicrons, VLDL, and LDL (Berriot-Varoqueaux et al. 2000; Wang and Hegele 2000). The current standard treatment consists of strict adherence to specialized diets and oral vitamin E supplementation. Total fat intake should be restricted to less than 30% of the total caloric intake which will eliminate steatorrhea and allow absorption of nutrients essential for growth and development (Berriot-Varoqueaux et al. 2000; Wang and Hegele 2000; Zamel et al. 2008).

High-dose oral vitamin E supplementation (100–300 mg/kg/day) is recommended to halt the progression of the neurological deterioration (Zamel et al. 2008). Combined oral vitamin E and A is usually administered to attenuate the severity of retinal degeneration (Zamel et al. 2008).

Hypobetalipoproteinemia

Hypobetalipoproteinemia (HBL) represents a rare co-dominant condition characterized by low plasma levels of total cholesterol, low-density lipoprotein-cholesterol (LDL-C), and apoB below the 5th percentile of the general population (Tarugi et al. 2007). Familial hypobetalipoproteinemia (FHBL; MIM 107730) is the most frequent monogenic form of HBL. It may be due to loss-of-function mutations in apoB gene (APOB-linked FHBL) or, less frequently, in PCSK9 (PCSK9-linked FHBL) (Tarugi et al. 2007; Schonfeld 2003). However, in many subjects the genetic basis of FHBL remains unexplained (Orphan FHBL) (Tarugi et al. 2007). Most APOB gene mutations lead to the formation of truncated apoB protein of various sizes

(Tarugi et al. 2007, Schonfeld 2003). Missense nontruncating mutations of the APOB gene can also cause FHBL (Burnett et al. 2003).

The best-characterized form of FHBL occurs with a dominant mode of inheritance and it has been linked to heterozygous pathogenic mutations in the APOB gene that are generally asymptomatic but often develop liver steatosis (Tarugi et al. 2007). Patients with the clinical diagnosis of homozygous FHBL are rare and they can be either carriers of homozygous or compound heterozygous mutations in APOB gene (Tarugi et al. 2007). The clinical manifestations of homozygous FHBL show great variability. They may have a similar biochemical and clinical phenotype to patients affected by ABL due to fat malabsorption and fat-soluble vitamin deficiency, particularly vitamins A and E (Lee and Hegele 2014).

Chylomicron Retention Disease

Chylomicron retention disease (CMRD; MIM 246700), also called Anderson disease, is an autosomal recessive disorder condition characterized by the accumulation of lipid droplets within the enterocytes and the selective absence of apoB-48-containing particles from plasma (Boldrini et al. 2001). CMRD is caused by homozigous and compound heterozygous mutations in SAR1B, a gene encoding Sar1b protein, which is involved in chylomicron trafficking from the endoplasmic reticulum to the Golgi apparatus (Jones et al. 2003). Until now, missense mutations have represented the majority of SAR1B mutations.

CMRD presents shortly after birth with malabsorptive diarrhea and failure to thrive, with vomiting and abdominal distension often present (Peretti et al. 2010). Vitamin E is the most affected among the liposoluble vitamins in CMRD, because its transport is highly dependent on apo B-containing lipoproteins (Berriot-Varoqueaux et al. 2000). Hepatomegaly and hepatic steatosis may develop in some patients, but in contrast to ABL and FHBL, liver cirrhosis has not been reported in CMRD (Peretti et al. 2010). The neurological complications are usually an alarm sign of vitamin E deficiency in these subjects and include hyporeflexia and loss of proprioception in adolescents and ataxia, myopathy, and sensory neuropathy in adults (Peretti et al. 2010).

In CMRD, total cholesterol, LDL cholesterol, and HDL cholesterol concentrations are low, but triglyceride levels are generally normal. An increased plasma creatine kinase concentration of up to five times the normal level may be observed from infancy (Peretti et al. 2010).

Regarding the management of CMRD patients, there are no specific recommendations for the follow-up or treatment of CMRD, even if low-fat diet regimens have shown to improve digestive symptoms in these patients (Peretti et al. 2010).

Cystic Fibrosis

Cystic Fibrosis (CF; MIM 219700) is an autosomal recessive disease caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene,

located on chromosome 7. The CFTR protein is a chloride ion channel and is expressed in many different organs (e.g., the pancreas, airways, lungs, liver, salivary glands, sweat and reproductive tract glands) (Gibson et al. 2003). CFTR protein dysfunction leads to defective ion transport across epithelial surfaces, which causes impaired mucociliary clearance. The most common manifestations in newborns and children include sinopulmonary symptoms, failure to thrive, steatorrhea, and meconium ileus (Gibson et al. 2003). However, intestinal malabsorption mediated by pancreatic insufficiency, deranged bile acid function, and enzyme inactivation by hyperacidity remains the most common feature in CF subjects (Peretti et al. 2005). Vitamin E status in these individuals has shown to be associated with hemolytic anemia (Wilfond et al. 1994), cognitive impairment (Koscik et al. 2005), and increased rate of pulmonary exacerbations (Hakim et al. 2007). Today, it has been recommended to include a dosage of 100 UI to 400 UI per day for all subjects with CF (Sinaasappel et al. 2002).

Conclusion

Vitamin E deficiency is quite rare in adult humans. It is more frequently found in children with an inherited condition that impairs their ability to absorb this vitamin.

It has been shown that vitamin E plays a vital role in various disorders through its oxidative properties, although it has also nonoxidative effects in humans. Therefore, further studies should be addressed beyond the free radical-scavenging properties of vitamin E and its metabolites.

In spite of the promising potential, the experimental analysis of tocotrienols accounts for only a small portion of vitamin E research. Hence, the current state of knowledge deserves further investigation into this lesser known form of vitamin E.

It must be emphasized that early supplementation of vitamin E could halt the disease progress and a fast progression of the disease should be avoided. However, it is well known that this vitamin is transported with lipoproteins, and therefore its plasma concentration is not indicative of whole body and peripheral tissue stores. In this context, additional markers of inadequate vitamin E status especially in newborns are needed. This would also promote the evaluation of vitamin E supplementation outcomes in terms of beneficial effects and safety.

Policies and protocols

In this chapter we described the genetic disorders associated with vitamin E deficiency in humans. Despite vitamin E deficiency is rare, it can occur as a result of genetic abnormalities in α-tocopherol-transfer protein or as a result of fat malabsorption syndromes (abetalipoproteinemia, hypobetalipoproteinemia, chylomicron retention disease, and cystic fibrosis).

- Generally, vitamin E deficiency manifests in early childhood by progressive neurologic damage and serious clinical consequences. Therefore, policies focused on the prompt recognition of individuals with vitamin E deficiency should be considered.
- The physiological role and the health consequences of vitamin E deficiency should get the desired attention in international micronutrient recommendations. In addition, public health authorities should encourage large-scale research studies to determine optimal vitamin E dosage and to evaluate the outcomes.
- As described previously, hydrogen peroxide-induced erythrocyte lysis test is used to define vitamin E status and consequently to assess vitamin E supplementation. However, when interpreting the results it is important to consider serum lipid profile components in these individuals.
- A full clinical investigation is recommended in individuals diagnosed by AVED. In addition to laboratory testing, assessment must include neurologic, ophthalmologic, and cardiac examination. Moreover, it is appropriate to perform a predictive genetic testing in at-risk families for the purpose of early diagnosis and treatment.

Dictionary of Terms

- **Tocopherols and tocotrienols** – Two main families of vitamin E. Each composed of four forms with different chemical structure.
- **Reactive oxygen species** – Highly reactive molecules produced by physiologic and nonphysiologic processes and may cause damage to cell membrane or DNA molecules.
- **Antioxidant** – Is a molecule that protects against harmful chemical reactions inside the organism.
- **Malabsorption** – Impairment in absorption of food nutrients from intestinal tract.
- **Congenital disorder** – When a baby has a disease that is present from birth. It can be inherited from mother and/or father (genetic disorder) or caused by environmental factors.

Summary

- Vitamin E is a fat-soluble vitamin that refers to a group of compounds that include both tocopherols and tocotrienols.
- Vitamin E is a potent antioxidant that acts as a peroxyl radical scavenger and can play a role in regulating cell signaling and modulating gene transcription through a nonantioxidant activity.
- Vitamin E has been shown to play a role in cardiovascular disease, cancer, chronic inflammation, and neurodegeneration.
- In humans severe vitamin E deficiency occurs as a result of genetic defects in the α-tocopherol transfer protein gene or in presence fat-malabsorption syndromes.

- Early supplementation of vitamin E may prevent and reverse clinical complications of vitamin E deficiency.
- Future research should focus on finding biomarkers of inadequate vitamin E status to optimize both diagnostic and therapeutic approaches in individuals with vitamin E deficiency.

Acknowledgments This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Low Folate Status and Relationship with Betaine and Homocysteine

87

Jose M. Colomina and Michelle M. Murphy

Contents

Abstract

Folate and betaine participate in homocysteine metabolism through the methionine synthase (MS) and betaine-homocysteine methyltransferase (BMHT) pathways, respectively. The ubiquitous MS pathway depends on 5-methyltetrahydrofolate and cobalamin as cofactors in the remethylation of homocysteine to methionine. When folate and cobalamin supply are adequate,

homocysteine remethylation to methionine is predominantly by the MS pathway. The BHMT pathway appears to play an important role in very early embryogenesis and fetal development (in animal studies) but is then limited mainly to the kidney and liver in human adults.

Low or suboptimal folate status still affects non-supplement users and low consumers of voluntarily fortified foods in populations where mandatory fortification with folic acid is absent.

Limited dietary folate and/or cobalamin intake impairs homocysteine remethylation via the MS pathway thus leading to increased blood homocysteine and reduced methionine synthesis. Evidence from in vitro and animal studies shows that the BHMT pathway is upregulated when folate status is low. Preliminary evidence supports the hypothesis that homocysteine remethylation by BHMT is enhanced when the MS pathway is impaired due to low folate status in human adults and during pregnancy. Further research is required to demonstrate that BHMT activity increases in response to low folate status and to determine the extent to which the BHMT pathway can compensate for MS pathway impairment.

Keywords

Folate · Betaine · Cobalamin · Homocysteine · Methionine synthase · Betaine-homocysteine methyltransferase · Methionine

List of Abbreviations

1C	One carbon
1CM	One carbon metabolism
5,10-CH_2THF	5,10-Methylenetetrahydrofolate
5-CH_3THF	5-Methyltetrahydrofolate
BHMT	Betaine-homocysteine methyltransferase
CBS	Cystathionine-beta-synthase
CHDH	Choline dehydrogenase
DMG	Dimethylglycine
DMGDH	Dimethylglycine dehydrogenase
FAD	Flavin adenine dinucleotide
MS	Methionine synthase
MTHFR	Methylenetetrahydrofolate reductase
NTDs	Neural tube defects
PML	Post-methionine load
PMNS	Pune Maternal Nutrition Study
SAM	*S*-adenosyl methionine
SARDH	Sarcosine dehydrogenase
SNPs	Single nucleotide polymorphisms
tHcy	Fasting total plasma homocysteine
THF	Tetrahydrofolate

Introduction

Overview of one carbon metabolism (1CM) and the roles of folate and betaine in homocysteine metabolism

The 1C network, through the intracellular transfer of 1C units to metabolic reactions, regulates purine, pyrimidine, and thymidylate synthesis as well as methionine synthesis from homocysteine. These processes lead to protein, DNA, and RNA synthesis as well as the epigenetic regulation of gene functions. The nutrients that participate in this biological process (amino acids, osmolytes, B vitamins, nitrogenous bases, phospholipids, and methyl donors) are essential for cell proliferation, metabolism, regulation, and differentiation. Amino acids, folates, the universal methyl donor *S*-adenosyl methionine (SAM), and betaine, among others, act as 1C donors in this network. These are directly supplied to the 1C network from the diet or, as in the cases of SAM and betaine, can be generated by the network (Fig. 1). Optimal performance of the network depends on adequate functioning of all relevant enzymes, plus an adequate dietary supply of all the specific micronutrient cofactors, 1C, and methyl group donors involved. Moreover, the network is strongly influenced by lifestyle factors, such as smoking, alcohol consumption, diet, and exercise.

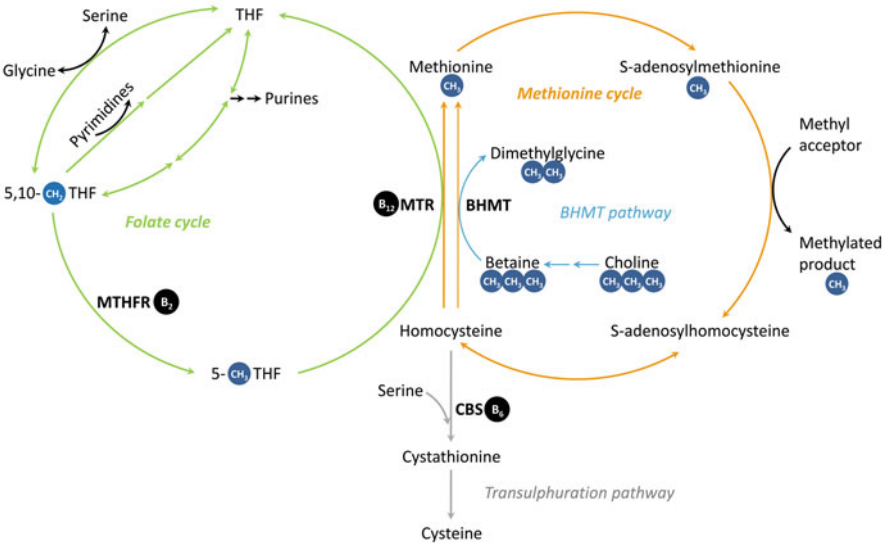

Fig. 1 Folate and methionine cycles, betaine-homocysteine methyltransferase, transulphuration and related pathways. Simplified overview to highlight interrelations between the folate cycle (green arrows), methionine cycle (orange arrows) and betaine-homocysteine methyltransferase pathway (blue arrows), and transulphuration pathway (grey arrows). Enzymes [vitamin cofactor]: BHMT, betaine-homocysteine methyltransferase; CBS, cystathionine-beta-synthase [B_6, pyridoxine]; MTHFR, methylenetetrahydrofolate reductase [B_2, riboflavin]; MS, methionine synthase [B_{12}, cobalamin]. Metabolites: THF, tetrahydrofolate; 5,10-CH_2THF, 5,10-methylenetetrahydrofolate; 5-CH_3THF, 5-methyltetrahydrofolate

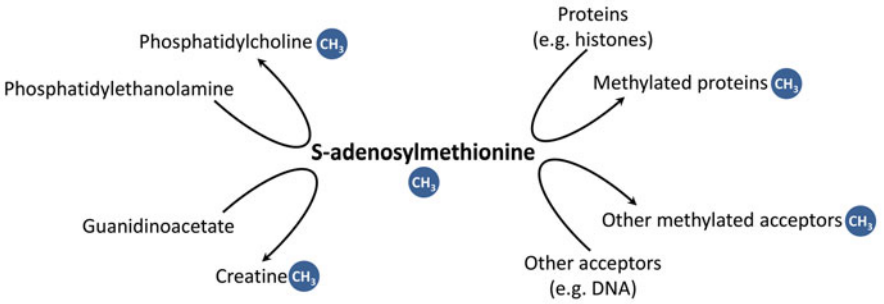

Fig. 2 Main methyl transfer reactions. Schematic representation of methyl transfer reactions with *S*-adenosyl methionine as the methyl donor

Homocysteine is an intermediate in this biological system, and a large body of evidence supports its potential as a biomarker of impaired 1C metabolism. Deficiency in folate, cobalamin, or pyridoxal phosphate, especially, leads to elevated blood homocysteine concentrations. There is also accumulating evidence to support the hypothesis that nutrient-nutrient and nutrient-gene interactions involving any of the nutrients involved in the system may lead to metabolic anomalies affecting this network as well as other metabolic processes.

Folate and betaine participate in the remethylation of homocysteine to methionine at the points of intersection of the respective methionine synthase (MS) and betaine-homocysteine methyltransferase (BHMT) pathways with the methionine cycle. The cobalamin- and folate-dependent MS pathway is ubiquitous, and the betaine-dependent BHMT pathway is limited to the liver and kidney (Finkelstein 1990) and lens (Rao et al. 1998). There are conflicting reports regarding BHMT presence in the brain (Gaull et al. 1973; McKeever et al. 1991). Status in the nutrients and metabolites that regulate the MS and BHMT pathways appears to drive interactions between these.

Methyl groups are transferred from SAM to four important methyl acceptors (Fig. 2) (McBreairty et al. 2013). The methylation of phosphatidylethanolamine and guanidinoacetate produces phosphatidylcholine (phospholipid) and creatine (osmolyte and energy storage form when phosphorylated), respectively.

The Folate Cycle and MS Pathway

Folate acts as an intermediate in the transfer of 1C units for the previously mentioned functions that are crucial for cellular proliferation and genomic stability. It also provides methyl groups for biological methylation reactions such as DNA and protein methylation that are essential epigenetic regulatory processes. Folate and cobalamin play interdependent roles in homocysteine remethylation to methionine via the MS pathway. The enzyme methylenetetrahydrofolate reductase (MTHFR) catalyzes the reduction of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate. This acts

as a cofactor and as a substrate for MS and provides the methyl group that binds to cobalamin to form methylcobalamin. Methylcobalamin is a cofactor in the MS reaction in which homocysteine is remethylated to form methionine. SAM regulates MTHFR activity by allosteric inhibition. In situations of cobalamin deficiency, intracellular 5-methyltetrahydrofolate accumulates because without cobalamin to bind the methyl group, it cannot be converted to tetrahydrofolate. Folic acid, the oxidised form of folate, is contained in vitamin supplements and fortified foods and has considerably higher bioavailability than the naturally occurring folate forms (Cuskelly et al. 1996). There are concerns that intake of high doses of folic acid, in the presence of cobalamin deficiency, may lead to the normalisation of erythrocyte size and disappearance of the symptomatic megaloblasts of cobalamin deficiency, thus masking cobalamin deficiency.

Betaine and the BHMT Pathway

Betaine is a methylamine which mainly acts as an osmolyte (Yancey et al. 1982) and in protein stabilisation (Sheikh-Hamad et al. 1994). It can also act as a methyl donor in the BHMT catalysed conversion of homocysteine to methionine. Betaine-dependent homocysteine remethylation is as important as folate-dependent homocysteine remethylation in the liver according to rat experiments (Finkelstein and Martin 1984a). Betaine supplementation of patients with homocystinuria, due to inborn errors affecting key enzymes involved in homocysteine metabolism, reduces blood homocysteine and the clinical symptoms of homocystinuria but does not normalise homocysteinemia (Garrow 1996). Therefore, it cannot compensate impairment of other regulatory pathways of homocysteine metabolism.

Dietary betaine intake recommendations have yet to be defined. Apart from dietary sources, betaine is also produced from choline oxidation (Fig. 3). In the BHMT reaction, one methyl group is transferred from betaine to homocysteine to form dimethylglycine and methionine. When dimethylglycine is converted into glycine, it donates two methyl groups to mitochondrial reactions (Wittwer and Wagner 1981). Moreover, glycine and tetrahydrofolate are converted into CO_2, NH_3, and 5,10-methylenetetrahydrofolate by the glycine cleavage system (Yoshida and Kikuchi 1970).

Choline can be obtained from the diet or synthesised endogenously by converting phosphatidylethanolamine to phosphatidylcholine via phosphatidylethanolamine *N*-methyltransferase.

Low Folate Status and the MS Pathway

Plasma folate concentration <6.8 nmol/L (measured by the gold standard *Lactobacillus casei* microbiological assay) is indicative of folate deficiency based on macrocytic anemia as an indicator (WHO 2015). Plasma folate concentration of 10 nmol/L (determined by radioimmunoassay) was proposed as the minimum cutoff concentration to

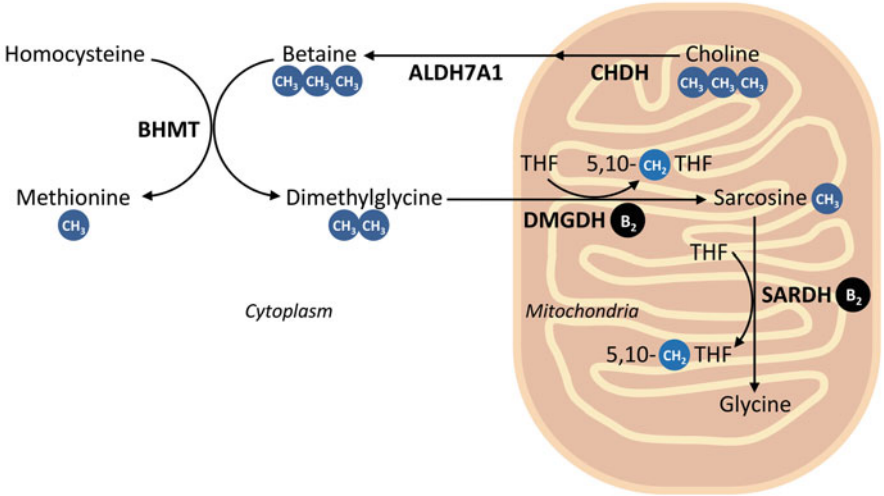

Fig. 3 BHMT pathway and related reactions. Illustration of the distribution between the cytoplasm and mitochondria of choline oxidation, methyl transfer by BHMT, and related reactions. Enzymes [vitamin cofactor]: ALDH7A1, betaine aldehyde dehydrogenase; BHMT, betaine-homocysteine methyltransferase; CHDH, choline dehydrogenase; DMGDH, dimethylglycine dehydrogenase [B_2, riboflavin]; SARDH, sarcosine dehydrogenase [B_2, riboflavin]. Metabolites: THF, tetrahydrofolate; 5,10CH_2THF, 5,10-methylenetetrahydrofolate

prevent moderately elevated fasting plasma total homocysteine (tHcy) (Brouwer et al. 1998), and concentrations below this are accepted as indicative of possible folate deficiency (WHO 2015; Bailey and Hausman 2017). Red blood cell folate concentration >906 nmol/L is optimal for protection against neural tube defect (NTD)-affected pregnancies caused by suboptimal folate status (Daly et al. 1995; WHO 2015).

Insufficient supply of folate or cobalamin to the 1C metabolic network impairs the MS pathway and leads to increased tHcy, as reported in animal and human studies. Thus, moderately elevated tHcy is an indicator of low folate and/or cobalamin status. Both folic acid and cobalamin supplementation reduce tHcy. Homocysteine remethylation via the MS pathway may also be downregulated when folate utilisation is impaired, for example, by single nucleotide polymorphisms (SNPs) associated with impaired intracellular folate metabolism, especially in the absence of mandatory fortification with folic acid or folic acid supplement use (Bueno et al. 2016). The influence of SNPs on folate metabolism is discussed below.

Low Folate Status and the BHMT Pathway

Homocysteine can be remethylated by the BHMT pathway in a reaction that does not require folate or cobalamin. Although limited to the kidneys and the liver, it may play a role in folate and cobalamin sparing, in situations of deficiency. In this case, its

role in homocysteine remethylation may be enhanced in situations of deficiency in either of these vitamins.

Evidence from in vitro, animal, and human studies suggests that 1CM nutrients interact with the BHMT pathway. Evidence from in vitro studies is summarized in Table 1. The effects of different forms of folate on the BHMT pathway have not been studied, but studies have investigated the effects of nutrients/metabolites that are likely to be replete when folate status is high, e.g., methionine and SAM. Methionine was shown to markedly inhibit rat (Finkelstein et al. 1972) and human (Szegedi et al. 2008) hepatic BHMT activity. SAM inhibited BHMT activity in rat liver (Finkelstein et al. 1972; Finkelstein and Martin 1984b) in studies using the semi-purified enzyme but not purified human hepatic BHMT (Szegedi et al. 2008). A dose-dependent

Table 1 Evidence from in vitro and animal studies for an association between folate status (or related metabolites) and the BHMT pathway

	Experiment		Effect
In vitro studies			
Finkelstein et al. 1972	Rat liver extract (semipurified BHMT)	50 μM methionine	93% lower BHMT activity
		50 μM SAM	15% lower BHMT activity
Finkelstein and Martin 1984a		224 μM SAM	32% lower BHMT activity
Castro et al. 2002; Ou et al. 2007	Human hepatoma cells with construct of *BHMT* promoter and luciferase gene; or endogenous *BHMT*	0–5000 μM SAM	SAM dose-dependent decrease in construct/*BHMT* mRNA levels
Szegedi et al. 2008	Purified human hepatic BHMT	200 μM SAM	No effect on BHMT
		200 μM methionine	15% lower BHMT activity
Animal studies			
Halsted et al. 2002	Micropigs	Folate-deficient diet	37% higher hepatic BHMT activity
Chmurzynska and Malinowska 2011	Rat dams	Folic acid-supplemented diet	Lower hepatic *BHMT* mRNA levels in offspring
Christensen et al. 2015	Mice	Excessive folic acid diet	No effect on hepatic *BHMT* mRNA
			Lower hepatic *CHDH* mRNA
Jadavji et al. 2015	Mice	Folate-deficient diet	17% lower hippocampal betaine concentration

BHMT betaine-homocysteine methyltransferase, *CHDH* choline dehydrogenase, *SAM* *S*-adenosyl methionine

reduction in BHMT expression by SAM was observed in human hepatoma cells (Castro et al. 2002; Ou et al. 2007) (Table 1).

Animal experiments suggest that the hepatic BHMT pathway is more active when folate status is low (Table 1). Micropigs on a folate-deficient diet had higher hepatic BHMT activity than pigs fed a folate-replete diet (Halsted et al. 2002). On the other hand, hepatic BHMT expression was lower in the offspring of rats fed with a folic acid-supplemented diet (5 mg/Kg diet) compared to that of rat dams fed on a control diet of 2 mg/Kg of folic acid (Chmurzynska and Malinowska 2011). A diet containing excessive folic acid had no effect on hepatic BHMT expression but was associated with lower hepatic choline dehydrogenase expression in mice (Christensen et al. 2015). In a separate study that did not measure BHMT activity, lower hippocampal betaine concentration was reported in lactating mice on a folate-deficient diet (0.3 mg/Kg diet) compared to those on an adequate folate diet 2 mg/Kg (Jadavji et al. 2015).

Various studies in humans have investigated interactions between folate and betaine status or, indirectly, between the MS and BHMT pathways (Table 2). In a study of coronary angiography patients, plasma betaine was increased by 15% following a methionine load, and there was a strong inverse correlation between post-methionine load (PML) betaine and homocysteine (Holm et al. 2004). In the same study, following random assignment to a 3-month B vitamin supplement regime, the correlation between plasma betaine and PML homocysteine was weakened, except in the placebo group. Supplementation of healthy men and women with 50–800 μg/d of folic acid led to a dose-dependent increase in plasma betaine concentrations (Melse-Boonstra et al. 2005). Furthermore, the proportional decrease in tHcy following folic acid supplementation was associated with the increase in plasma betaine concentration. As we mentioned previously, betaine's principal role does not appear to be as a methyl donor, and the authors interpreted these results as indicative of interaction between the MS and BHMT pathways. They suggested that the BHMT pathway is downregulated when MS pathway activity is optimal and that this is a potential betaine-sparing mechanism. A transversal study investigating the association between dietary betaine intake and tHcy in adult women reported an inverse association when folate status was below 400 μg/d, but there was no evidence for an independent role of dietary betaine in tHcy remethylation when folate intakes were above 400 μg/d (Chiuve et al. 2007). Betaine was a strong determinant of tHcy in adults with the *MTHFR* c.665TT genotype and low folate status (Holm et al. 2007). Before mandatory fortification of flour with folic acid was implemented in the USA, dietary betaine and choline intakes were inversely associated with tHcy in adults with low folate or cobalamin status. Post fortification, such inverse associations between choline and betaine with tHcy were not observed (Lee et al. 2010). The association between plasma betaine and tHcy was measured throughout pregnancy in a longitudinal pregnancy study carried out in the absence of mandatory fortification with folic acid (Fernàndez-Roig et al. 2013). Folic acid supplementation was most prevalent during the first trimester of pregnancy. During early pregnancy, plasma folate was strongly inversely associated with tHcy, but there was no association between plasma betaine concentration and tHcy. As pregnancy

Table 2 Summary of studies in humans that examined the association between betaine and homocysteine according to folate status

			Intake						
Holm et al. 2007	10,601 adult men and women	Transversal, observational				<10.1	TT		Betaine was inversely associated with tHcy in participants with the TT genotype and plasma folate in the lowest quartile
Lee et al. 2010	Adult men (1325) and women (1407)	Transversal, observational	Prefortification USA						Choline and betaine intake were inversely associated with tHcy, especially when folate or B_{12} status was low
			Post-fortification						No association between betaine intake and tHcy was observed
Fernàndez-Roig et al. 2013	522 pregnant women	Prospective, observational				≤11.4			Betaine was not associated with tHcy during early pregnancy but was inversely associated with tHcy by mid-

									pregnancy in women with low folate status The reduction in betaine, increase in plasma DMG (pDMG), and inverse association between betaine and tHcy were enhanced as pregnancy progressed in women with low folate status
Colomina et al. 2016	612 pregnant women	Prospective, observational				≤13.4 vs. >13.4		A allele	Carriers of the variant A allele had lower pDMG compared to the GG genotype when folate status was normal-high. pDMG did not vary between genotypes when folate status was low

[a]Mandatory fortification of flour with folic acid in the USA

MTHFR methylenetetrahydrofolate reductase, *BHMT* betaine-homocysteine methyltransferase, B_{12} cobalamin, B_6 pyridoxine, *Hcy* homocysteine, *pDMG* plasma dimethylglycine, *tHcy* fasting total plasma homocysteine

progressed, and as plasma folate status decreased, an inverse association between betaine and tHcy emerged, and by late pregnancy, the strength of the association between betaine and tHcy was similar to that of folate and tHcy, in mothers with plasma folate status below the median. This study provided indirect evidence for shifts in MS and BHMT pathway activities with changing folate status and for a possible upregulation of the BHMT pathway when the MS pathway was impaired.

In summary, evidence from both animal and human studies points toward upregulation of the BHMT pathway when folate status is low. Therefore, the roles of betaine or choline in homocysteine metabolism may be enhanced in situations of folate deficiency.

SNPs Affecting the MS and BHMT Pathways

Two non-synonymous SNPs can be regarded as the main genetic determinants of the two homocysteine remethylation pathways. The *MTHFR* c.665C>T SNP (also known as 677C>T) affects the MS pathway, and the *BHMT* c.716G>A SNP (also known as 742G>A) affects the BHMT pathway. The reported prevalences of *MTHFR* c.665 variant homozygotes range from 5% to 20% (Wilcken et al. 2003) and the prevalence of *BHMT* c.716 variant homozygotes is 10% (Fredriksen et al. 2007; Liang et al. 2014).

The MTHFR enzyme catalyzes the irreversible reduction of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, the folate form that acts as the methyl donor in the MS reaction. The variant MTHFR enzyme is thermolabile and has reduced activity (Frosst et al. 1995; Daly et al. 1999), probably due to a higher dissociation rate of the MTHFR homodimer with the subsequent loss of its flavin adenine dinucleotide (FAD) cofactor (Yamada et al. 2001). Higher homocysteine concentrations with increasing number of variant alleles have been reported in a plethora of human studies, and the *MTHFR* c.665C>T polymorphism is the most important genetic determinant of tHcy (van Meurs et al. 2013; Bueno et al. 2016). Folate appears to alleviate the defect of the variant enzyme. In vitro, 5-methyltetrahydrofolate increases the affinity of the enzyme for its FAD cofactor to a greater extent in the variant than normal MTHFR (Yamada et al. 2001). Normalisation of tHcy in the presence of the variant genotype or allele, with increasing folate status, has been reported in numerous human studies (Geisel et al. 2001; Kluijtmans et al. 2003; de Lau et al. 2010).

In the case of the *BHMT* c.716G>A polymorphism, increased affinity for homocysteine and increased (Li et al. 2008) or similar (Weisberg et al. 2003) affinity for betaine in the variant compared to normal enzyme were reported in in vitro studies. However, the effects were observed at supraphysiological homocysteine concentrations (400 or 500 μM) when rat liver concentrations were reported to be 7.6 μM (Svardal et al. 1986) and low betaine concentrations (64 μM) when rat liver betaine concentrations were reported to be 550 μM (Koc et al. 2002). The polymorphism did not affect thermostability (Weisberg et al. 2003) nor did it affect protein expression nor enzymatic activity in two separate studies that tested substrate concentrations of

64 μM of betaine and 400 μM of homocysteine (Li et al. 2008; Feng et al. 2011). No association was observed between the SNP and homocysteine in numerous human studies, but lower plasma or serum dimethylglycine (product of the BHMT pathway) concentrations were reported in the presence of the variant allele compared to the common homozygote genotype. This was observed in a Norwegian study of old adults (Fredriksen et al. 2007) and a Spanish study of pregnant women (Colomina et al. 2016). In the latter study, lower dimethylglycine in heterozygotes compared to the other genotypes was observed during early pregnancy when folate status was high. This suggests that dimethylglycine differences between the different *BHMT* c.716 genotypes may be more evident when folate status is high. Why the apparent downregulation of the BHMT pathway in the presence of the variant genotypes does not appear to affect betaine concentrations might be due to tight control of betaine supply for its principal roles as an osmolyte and in protein stabilization.

Health Consequences of Low Folate Status

The micronutrients that regulate 1C metabolism are essential in maintaining health throughout the life span. Both low folate and low cobalamin status are associated with moderately elevated tHcy. Low folate status and or moderately elevated tHcy has been associated with adverse health outcomes in adults such as chronic diseases including cardiovascular diseases (Boushey et al. 1995), cancer (Blount et al. 1997), dementia (Ravaglia et al. 2005), cognitive decline (Nurk et al. 2005), and bone disease (van Meurs et al. 2004). Low maternal folate status has been associated with increased risk of fetal malformations such as NTDs as well as preeclampsia, preterm birth, and other pregnancy complications (Murphy and Fernandez-Ballart 2011). Importantly, periconception supplementation with folic acid has been shown to protect against folate-sensitive NTD recurrence and occurrence (MRC Vitamin Study Research Group 1991), and this has led to policies worldwide aimed at ensuring adequate maternal folate status to prevent grave fetal developmental anomalies. Moderately elevated maternal tHcy has also been associated with lower weight at birth in the offspring (Murphy et al. 2004; Onalan et al. 2006; Yajnik et al. 2014). This finding was not replicated in some studies, such as a Canadian study in the post-fortification with folic acid era (Dodds et al. 2008). However, a recent meta-analysis confirmed that the inverse association between tHcy and birth weight is consistent across studies and reported an odds ratio for small for gestational age of 1.45 when maternal tHcy before or during pregnancy was above the 90th percentile (Hogeveen et al. 2012). Maternal erythrocyte folate concentration during pregnancy has also been reported to be positively associated with birth weight (Relton et al. 2005).

Some studies have shown that the association between maternal tHcy during pregnancy and health and development in the offspring extends beyond fetal life. Moderately elevated tHcy at preconception was associated with lower cognitive achievement in children at 6 years of age (Murphy et al. 2017) and late pregnancy maternal folate status was positively associated with cognitive performance in 9–10 year old children (Veena et al. 2010). In India, the thin-fat phenotype in which babies have low weight but high

adiposity has been described (Yajnik et al. 2003). The combination of elevated folate and low cobalamin status during pregnancy was associated with increased central obesity and insulin resistance in the offspring during childhood in the Pune Maternal Nutrition Study (PMNS) in India (Yajnik et al. 2008; Yajnik and Deshmukh 2012), and it has been suggested that folate-vitamin B_{12} imbalance in mothers during pregnancy may lead to babies having the thin-fat phenotype. The PMNS investigators also suggested that such imbalance may result from supplementing cobalamin-deficient mothers with folic acid.

Some studies have reported that suboptimal cobalamin status in fertile women or during pregnancy may be more widespread than expected outside of countries such as India where vegetarianism is customary (Ray et al. 2008; Solé-Navais et al. 2018). It is widely recommended that women of fertile age or with the possibility of becoming pregnant take a daily supplement containing 400 μg of folic acid and that this be continued until the end of the first trimester of pregnancy. The recommendation/composition of the prenatal supplement varies between countries. Some recommend including vitamin B_{12} and other micronutrients in the supplement, but the common ingredient in all of them is at least 400 μg/d of folic acid during the first trimester.

Policies and Protocols

In this chapter, we have described the essential role of folate in one carbon metabolism and homocysteine remethylation and some of the health consequences of low folate status. Folate deficiency is especially harmful during embryogenesis and early fetal development and has been associated with grave NTDs such as spina bifida. The adverse health and developmental outcomes associated with this condition, and others derived from grave developmental defects, have huge direct and indirect healthcare costs. Prenatal healthcare protocols around the globe include the recommendation to take 400 μg/d of folic acid during periconception and at least until the end of the first trimester of pregnancy. However, success of this recommendation requires knowledge by the mother to take the supplement (before her first prenatal visit and before knowing she is pregnant). Mandatory fortification of cereal-based products to improve the folate status of women of fertile age and reduce the incidence of NTDs was implemented in the USA in 1998 (US FDA 1996). Numerous countries around the globe subsequently introduced similar policies (see Fig. 4).

The policy led to increased serum and red blood cell folate concentrations in the USA population compared to prefortification, and low serum folate and low red blood cell folate prevalences fell from 24% and 3.5%, prefortification, respectively, to $\leq$1% post-fortification (Pfeiffer et al. 2012). Furthermore, NTD rates in the USA and Canada have fallen by 50% compared to prefortification rates (Mills and Signore 2004).

Overall, mandatory fortification has not been introduced in European countries. In some, it has been postponed due to the widespread intake of voluntarily fortified foods and concern regarding the possible adverse effects of excessive folic acid intake through combined consumption of supplements and fortified foods (Smith et al. 2008).

Fig. 4 Global distribution of mandatory fortification with folic acid. Countries highlighted in blue represent those where mandatory fortification is implemented (Food Fortification Initiative 2016; PhD thesis JM Colomina 2017)

However, in a Spanish study of non-supplement users, and where the intake of voluntarily fortified foods is low, folate deficiency affected 18.8% of adults and 30.2% of men and women of fertile age (Bueno et al. 2016).

As we also indicated in this chapter, folate and cobalamin play interdependent metabolic roles. Low cobalamin status or deficiency largely affects vegetarians (due to a deficit in intake) or old people (due to impaired uptake). We briefly mentioned the risk of masking cobalamin deficiency by high folic acid intake. Folate-cobalamin interactions are outside the scope of this chapter. However, there is some evidence that metabolic anomalies and adverse health outcomes associated with cobalamin deficiency during early and late life may be exacerbated in the presence of high folic acid intake (through combined intake from supplements and fortified foods). Further research is required to confirm these findings. Mandatory fortification is indiscriminate, and future studies should also investigate whether changes in policies, such as reduction in the content of folic acid added to cereal products or the addition of vitamin B_{12}, are required.

Dictionary of Terms

- **One carbon metabolism** – metabolic network fueled by different B vitamins, choline, betaine, and methionine that is responsible for the production and transfer of single C units (e.g., methyl groups) used for processes such as DNA synthesis and repair and methylation reactions
- **Homocysteine remethylation** – binding of methyl group by homocysteine to produce methionine either by the folate-/cobalamin-dependent reaction

(catalyzed by methionine synthase, MS) or the betaine-dependent reaction (catalyzed by betaine-homocysteine methyltransferase, BHMT)
- **Folic acid** – synthetic, oxidized folate form used in supplements and in fortified flour and foods that has greater bioavailability than the naturally occurring folate forms
- **tHcy** – fasting plasma total homocysteine concentration
- **Methylenetetrahydrofolate reductase (MTHFR)** – enzyme catalyzing the unidirectional conversion of 5,10-methylenetetrahydrolate to 5-methyltetrahydrofolate, the methyl donor in folate-/cobalamin-dependent homocysteine remethylation

Summary Points

- Nutrients involved in one carbon metabolism (including amino acids, osmolytes, B vitamins, nitrogenous bases, phospholipids, and methyl donors) are essential for cell proliferation, metabolism, regulation, and differentiation.
- Folate and cobalamin (vitamin B_{12}) play interdependent roles in the methionine synthase pathway, which is the ubiquitous homocysteine remethylation pathway.
- Homocysteine can also be remethylated by the betaine-homocysteine methyltransferase pathway, which is limited to the kidneys and the liver.
- Overall, the role of betaine as a methyl donor is relatively minor compared to folate due to its other essential roles and the limited sites of betaine-homocysteine methyltransferase.
- Folate and/or cobalamin deficiency leads to methionine synthase pathway impairment and to elevated tHcy.
- Evidence from in vitro, animal, and human studies supports the hypothesis that the betaine-homocysteine methyltransferase pathway is upregulated when folate status is low. Betaine or choline may gain importance in homocysteine metabolism in situations of folate deficiency.
- The enzyme coded by the variant allele of *methylenetetrahydrofolate reductase* (*MTHFR*) c.665C>T is thermolabile, has impaired activity, and leads to impaired folate-dependent homocysteine remethylation.
- Human studies reported no differences in fasting plasma total homocysteine concentration between *betaine-homocysteine methyltransferase* (*BHMT*) c.716G>A genotypes. However, lower plasma dimethylglycine concentration in the presence of the variant allele compared to the homozygote common genotype suggests impaired betaine-dependent homocysteine remethylation in its presence.
- Folate status interacts with the *methylenetetrahydrofolate reductase* (*MTHFR*) c.665C>T and *betaine-homocysteine methyltransferase* (*BHMT*) c.716G>A polymorphisms in their effects on the methionine synthase and betaine-homocysteine methyltransferase pathways, respectively.
- Low folate status is associated with grave fetal developmental abnormalities, pregnancy complications, and highly prevalent chronic diseases in adults.

Contents

Abstract

Folate is an essential nutrient obtained through diet and supplements. The term folate is used interchangeably with folic acid, its synthetic form. Folate is metabolized in the one-carbon pathway, and its metabolites are used for a number of biological processes. Metabolites of folate are used in nucleotide synthesis and

methylation. In fact, the one-carbon pathway produces the major methyl donor used in methylation, *S*-adenosylmethionine (SAM). Folate and DNA methylation are, therefore, closely entwined. Folate deficiency is associated with a number of diseases including congenital disabilities. In the last couple of decades, folate or folic acid supplementation is highly promoted in pregnancy because folate deficiency leads to neural tube defects with a wide range of consequences in children. Folate deficiency is also associated with gastric and colorectal cancers, cardiovascular disease, and liver disease. Alterations in global DNA methylation and disease-specific gene methylation patterns are implicated in the development and progression of these diseases. Folate is an important nutrient to understand the epigenetic regulation of disease.

Keywords

List of Abbreviations

CDC	Centers for Disease Control
CIMP	CpG island methylator phenotype
CpG Island	Cytosine–phosphate–Guanine Island
CVD	Cardiovascular disease
DHFR	Dihydrofolate reductase
DNA	Deoxyribonucleic acid
DNMT	DNA methyltransferase
dTMP	Deoxythymidine monophosphate
dTTP	Deoxythymidine triphosphate
dUMP	Deoxyuridine monophosphate
dUTP	Deoxyuridine triphosphate
5-MTHF	5-Methyltetrahydrofolate
MTHFR	Methylenetetrahydrofolate reductase
PABA	Para-aminobenzoic acid
SAM	*S*-adenosylmethionine
TET	Ten–eleven translocation proteins
THF	Tetrahydrofolate
WHO	World Health Organization

Introduction

Proper nutrition with the correct levels of vitamins and minerals are essential to lead a healthy lifestyle. Nutrient deficiency not only has the potential to make a person feel ill but may also change the epigenome, a regulatory mechanism that can alter gene expression without altering the genetic code (Choi and Friso 2010). Ramifications of changes to the epigenome can affect the individual and, with its heritable trait, subsequent generations of children. In this chapter, we will focus on

folate, an essential nutrient that when deficient leads to a host of complications and alterations in DNA methylation.

Folate

Folate or folic acid is a water-soluble vitamin B (also known as vitamin B_9) with an extensive role in human metabolism (Liew 2016). The chemical structure of folate contains a heterobicyclic pteridine ring, para-aminobenzoic acid (PABA), and glutamic acid (Lindzon and O'Connor 2007) (Fig. 1). Folate is the naturally occurring form first discovered in foliated (green leafy) vegetables. Plants and vegetables such as broccoli, asparagus, celery, lentils, beans, and Brussels sprouts have high levels of folate (NIH 2016) (Fig. 2). On the other hand, folic acid is the synthetic form of folate added to fortified foods (such as cereals, flour, grains, and bread) as of 1998 and found in supplements (Liew 2016; Crider et al. 2011; US Department of Health and Human Services FaDA 1996). The term "folate" is used interchangeably between the natural and synthetic forms.

Folate is essential for the synthesis of nucleic acids, amino acids, and methyl donors necessary for a range of biological processes from DNA synthesis to gene or epigene regulation (Liew 2016; Scaglione and Panzavolta 2014). Folate is metabolized through the one-carbon pathway; this metabolism pathway produces precursors for nucleotide synthesis and methyl donors (Bailey and Gregory 1999). In the one-carbon donor pathway, folate is converted to tetrahydrofolate (THF) and further metabolized to its biologically active form 5-methyltetrahydrofolate (5-MTHF) (Bailey and Gregory 1999). However, synthetic folic acid requires additional enzymatic steps including through dihydrofolate reductase (DHFR), an enzyme that has the potential for drug inhibition that is avoidable with natural sources of folate (Scaglione and Panzavolta 2014). Metabolism of synthetic folic acid can be inhibited by drug interactions with DHFR, potentially leading to downstream metabolite deficiencies (Scaglione and Panzavolta 2014). 5-MTHF is involved in an enzymatic reaction to convert homocysteine to methionine, which is then converted to *S*-adenosylmethionine (SAM), a major methyl-donating molecule (Liew 2016; Bailey and Gregory 1999; Blom and Smulders 2011). SAM, in turn, donates its methyl group via methyltransferase enzymes to DNA, RNA, proteins, and lipids (Shorter et al. 2015) (Figs. 1 and 3).

Folate metabolites are also involved in the production of nucleotides. In DNA synthesis, folate metabolism leads to deoxyuridine monophosphate (dUMP) methylation forming deoxythymidine monophosphate (dTMP) (Liew 2016; Stover 2009). dTMP is then converted to thymidine triphosphate (dTTP), which is one of the four deoxynucleotides needed for DNA synthesis as well as DNA repair (Liew 2016). The low availability of folate can lead to the decreased production of dTMP from dUMP and ultimately a decreased supply of dTTP available for DNA replication and repair. Excess dUMP will then be converted to deoxyuridine triphosphate (dUTP) (Scaglione and Panzavolta 2014; Bailey and Gregory 1999). Due to its inability to distinguish between dTTP and dUTP, DNA polymerases can incorrectly

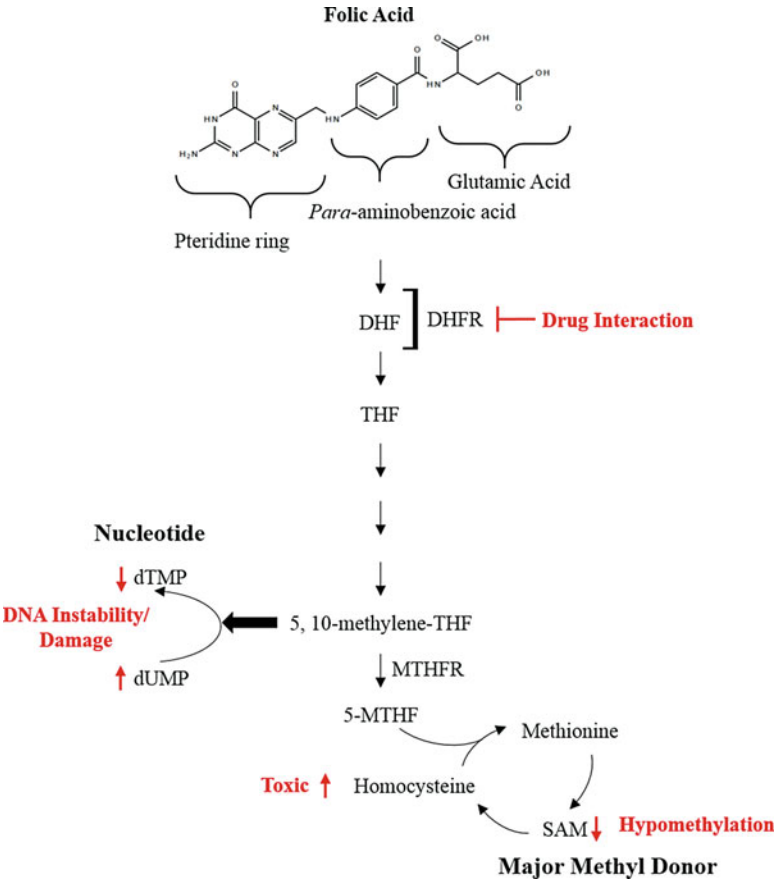

Fig. 1 Folate metabolism to metabolites involved in DNA synthesis and methylation. Folate metabolism via the one-carbon metabolism pathway. Folate is converted to DHF and then tetrahydrofolate (*THF*) by DHF reductase. THF is further metabolized to 5,10-methylene-THF which enters into nucleotide synthesis to convert deoxyuridine monophosphate (*dUMP*) to deoxythymidine monophosphate (*dTMP*) which is then incorporated as a nucleotide into DNA replication. 5,10-Methylene-THF is metabolized to 5-methyltetrahydrofolate (*5-MTFH*) by methyltetrahydrofolate reductase (*MTHFR*). 5-MTHF enters into the pathway to convert homocysteine to methionine, which can then be converted to *S*-adenosylmethionine (*SAM*). SAM is a major methyl donor in DNA methylation and other methylation processes. Figure adapted from Crider et al. (2012) with permissions

incorporate uracil in place of thymidine in the DNA synthesis, which can lead to an overabundance of uracil in the DNA (Blount et al. 1997). Excessive uracil incorporation from folate deficiency can lead to DNA instability, chromosome breaks, and increased risk for certain diseases such as cancer (Liew 2016; Blount et al. 1997; Duthie 1999) (Fig. 1). Folate deficiency is associated with a number of diseases including increased risk of certain cancers, cardiovascular disease, and neurological defects (Blount et al. 1997; Duthie 1999; Mattson et al. 2002; Ward 2001). The

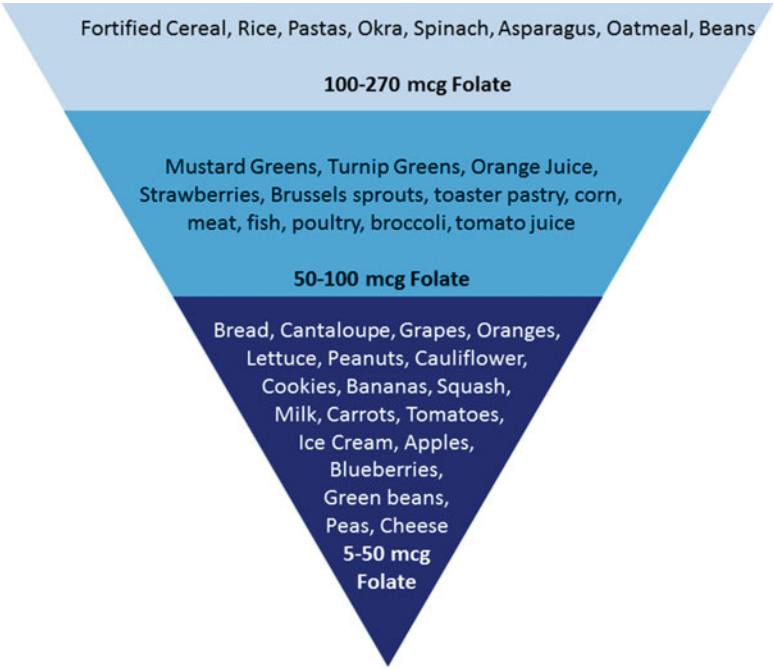

Fig. 2 Folate levels in foods. Common foods are stratified by the amount of folate or folic acid each contains. Foods are displayed by ranking of folate content in micrograms (mcg) from the USDA Food Composition Database (U.S. Department of Agriculture, Agricultural Research Service 2017). The highest folate containing foods are those supplemented with folic acid such as fortified cereals, rice, and pasta as well as some natural occurring high folate containing foods such as asparagus, Brussels sprouts, spinach, broccoli, and beans. Fruits, some vegetables, and dairy contain lower amounts of folate

mechanism underlying folate deficiency and disease risk may provide key diagnostic and therapeutic strategies in the future.

DNA Methylation

DNA methylation is one of the most studied and most well-understood epigenetic marks (Smith and Meissner 2013). It is a repressive mark leading to decreased expression of targeted genes without altering the genetic code (Choi and Friso 2010). During the process of DNA methylation, the addition of a methyl group occurs at the C5 position of the pyrimidine ring of the cytosine nucleotides via DNA methyltransferase (DNMT) enzymes (Kruman and Fowler 2014; Pacchierotti and Spano 2015). Three DNMTs have been identified as DNMT1, DNMT3a, and DNMT3b. DNMT1 is used commonly in maintaining DNA methylation patterns. Whereas DNMT 3a and 3b are involved in *de novo* DNA methylation which is the methylation of DNA during the embryonic stage of development (Qu et al. 2013;

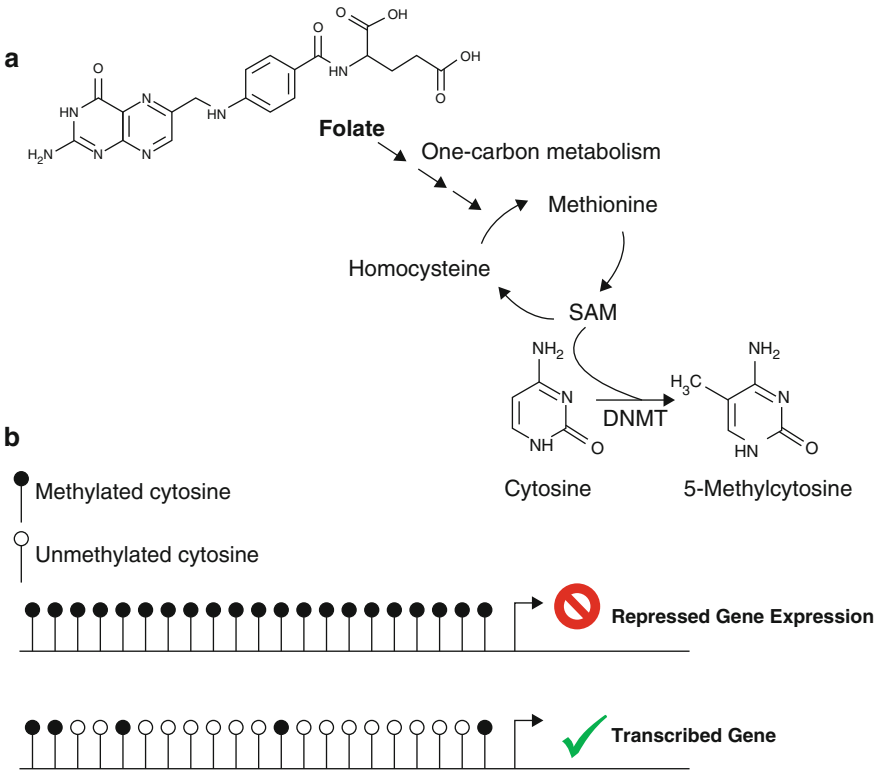

Fig. 3 Overview of DNA methylation by folate metabolite, SAM. (**a**) Folate is metabolized through the one-carbon pathway leading to the generation of SAM, a major methyl donor. DNA methylation occurs when DNMTs (DNMT1, DNMT3a, or DNMT3b) transfer a methyl group from SAM to the 5-position on cytosine generating 5-methylcytosine, a repressive mark. (**b**) Methylated cytosines (solid ball and stick) are repressive marks and prevent gene transcription. Hypomethylated genes or genomic regions where cytosines do not have a methyl group at the 5-position (open ball and stick) can be transcribed, and genes are expressed

Quintero-Ronderos and Montoya-Ortiz 2012). DNA methylation does not occur at random cytosine nucleotides. Instead, methylation occurs at CpG islands (areas of rich CG dinucleotide base pairs) near the promotor region. However, CpG islands found around transcriptional start sites of endogenous and regulatory genes often remain hypomethylated allowing for the binding of transcription factors (Kruman and Fowler 2014). Studies have also shown that methylation occurs at other CpG islands distal to the promoter region which magnifies the role of DNA methylation beyond regulation of gene expression to a more genome-wide function (Kruman and Fowler 2014; Kandi and Vadakedath 2015).

DNA methylation patterns are commonly set during development. As such, DNA methylation is stable in somatic cells, and gene expression is not rapidly altered by DNA methylation as in other epigenetic mechanisms, such as histone modifications

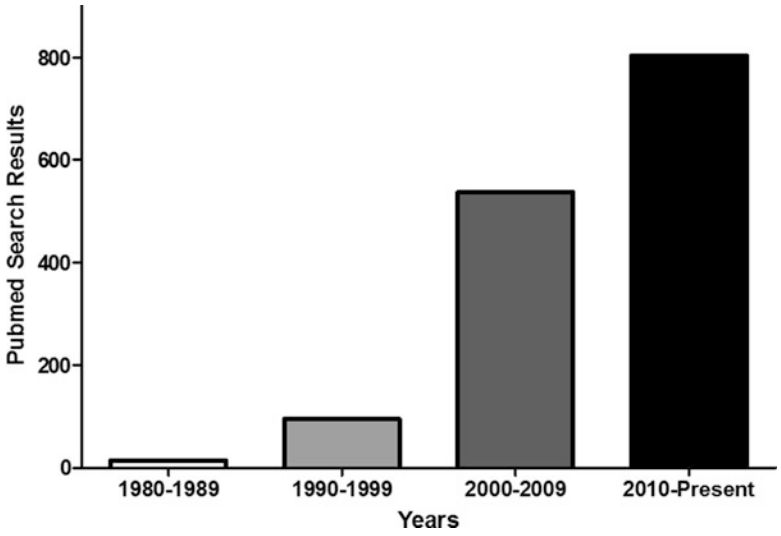

Fig. 4 Publications on folate and DNA methylation by decade since 1980. PubMed search results for the terms "Folate" and "DNA Methylation." Search results are displayed by decade from 1980 to 1989, 1990 to 1999, 2000 to 2009, and 2010 to present (2017)

(Smith and Meissner 2013; Robertson 2005). However, once DNA methylation patterns have been set during embryogenesis, they must be maintained throughout life during DNA replication. Folate is necessary to provide methyl donor pools of its metabolite SAM continually. Folate deficiency, and therefore SAM deficiency, has the potential to lead to a form of passive DNA demethylation where methylation is not maintained on newly synthesized DNA and subsequent cellular generations (Crider et al. 2012) (Fig. 3). Folate deficiency at the onset of development or later in life could have a substantial impact on the future health of the individual by altering DNA methylation patterns (Irwin et al. 2016). Thirty years ago, folate and DNA methylation research was almost nonexistent (Fig. 4). However, as the epigenetics field has emerged, studies into folate and DNA methylation also increased and is still on the rise (Fig. 4).

DNA Demethylation

DNA demethylation is also vital in certain stages of development and programming (Wu and Zhang 2014; Messerschmidt et al. 2014). For instance, DNA methylation marks are cleared from the genome in early stages of the embryogenesis and germline cells, erasing parental marks and priming the cells for pluripotent potential and new genome DNA methylation patterns (Wu and Zhang 2014). This reprogramming step is necessary to create a totipotent state that will allow for sex-determination and germ-line-specific differentiation of the embryo (Messerschmidt et al. 2014).

Although transferring a methyl group involves a covalent bond, DNA methylation is a reversible process (Wu and Zhang 2014). However, not in the same way as other epigenetic modifications such as histone acetylation and deacetylation, which is a coordinated balance between histone acetyltransferases and histone deacetyltransferases. DNA demethylation is mediated through both active and passive mechanisms. Active mechanisms of demethylation are oxidation of the 5-methylcytosine via ten–eleven translocation proteins (TET) and base excision of the methylated cytosine (Wu and Zhang 2014). When DNMT1, responsible for maintaining methylation patterns, does not methylate a strand of replicating DNA, those marks will disappear in subsequent rounds of DNA replication leading to passive demethylation (Wu and Zhang 2014). In conclusion, exploring DNA demethylation mechanisms has the potential to expand the current therapeutic knowledge of diseases.

Folate, DNA Methylation, and Disease

Folate deficiency results from either insufficient dietary intake or genetic defects in the metabolism of folate. This deficiency is prevalent in the population, and the resulting strain on the methyl donor pool may have deleterious effects on overall human health (Niculescu and Zeisel 2002). As for folate deficiency in the one-carbon donor pathway, low levels of folate results in low levels of SAM and may alter global DNA methylation patterns leading to changes in gene expression involved in various diseases including oncogenes (Liew 2016; Niculescu and Zeisel 2002) (Fig. 3).

Pregnancy Complications

Folate supplementation is imperative during pregnancy. The CDC recommends that women who may become pregnant, even before conception, take 400 micrograms of folate daily (CDC 2016). Folate is required for the proper neural tube closure during embryogenesis and development; this process occurs in the first few weeks of pregnancy (Cordero et al. 2015). Therefore, folate deficiencies during pregnancy can lead to a number of pathogeneses resulting from neural tube defects (NTD), including spina bifida (Liew 2016; Irwin et al. 2016; Pitkin 2007; Beaudin and Stover 2007). Up to 70% of neural tube closure defects are thought to be treatable with proper folate supplementation, the reason being that proper supplementation before conception ensures enough folate for neural tube formation (CDC 2016; Cordero et al. 2015). Therefore, it is recommended women who are planning to become or are pregnant take a folate supplement. Another mechanism for folate-associated pregnancy complications is accumulation of homocysteine, the precursor to methionine and SAM in the methyl donor pathway. Homocysteine levels may also affect fetal health, with an accumulation of homocysteine (a possible side effect of folate deficiency) competing for and blocking SAM binding to DNMTs leading to DNA hypomethylation (Iacobazzi et al. 2014). It is suggested that Down syndrome

where mitochondrial DNA is hypomethylated, cleft palates, and congenital heart defects are complications for imbalanced homocysteine and abnormal folate levels and metabolism (Blom and Smulders 2011) (Fig. 5).

Cancer

Alterations in DNA methylation of oncogenes and tumor suppressors can have a profound effect on cancer susceptibility (Clark and Melki 2002; Ehrlich 2002). In a hypermethylation state, tumor suppressor gene expressions are inhibited, and on the other hand during a hypomethylated state, oncogenes are overexpressed (Kandi and Vadakedath 2015). DNA methylation becomes an issue when it occurs abnormally. Anything that leads to this abnormality is of absolute importance in cancer. There

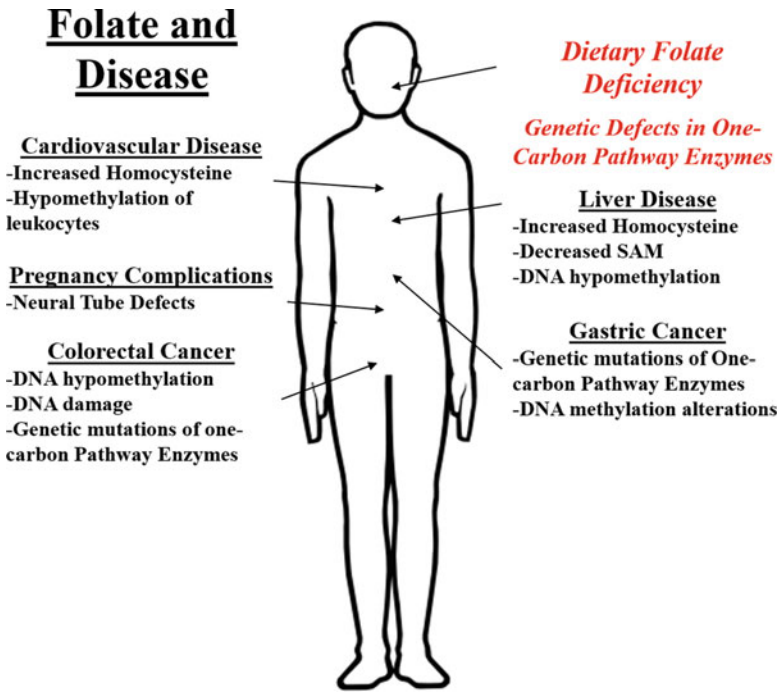

Fig. 5 Overview of folate and disease mechanisms. Folate deficiency or perturbations in folate metabolism have been linked to numerous diseases. Folate deficiency leads to increased homocysteine levels, which is toxic and detrimentally affects the cardiovascular system and liver contributing to a disease state. Folate deficiency produces less SAM, a methyl donor, which in turn results in DNA hypomethylation. DNA hypomethylation may alter oncogene and tumor suppressor gene expressions in cancers, leukocytes in cardiovascular disease, and hepatic genes that regulate liver disease. DNA damage due to DNA hypomethylation as well as nucleotide pool imbalance caused by folate deficiency is a factor in the development of cancer. While a person may take in the correct amount of dietary folate, metabolism of folate may be disrupted by polymorphisms or mutations in key enzymes in the one-carbon metabolism pathway, which contributes to cancer development

has been evidence that chemical pollutants, dietary components, and other factors are involved in changing epigenetic mechanisms such as DNA methylation (Qu et al. 2013). Folate deficiency has been shown to result in hypomethylation due to the low availability of methyl group donors, such as SAM (Qu et al. 2013). Even though methylation states of cancer cells vary, hypomethylation is common and a source of altered gene expression (Duthie 1999) (Fig. 5).

Gastric and Colorectal Cancer

Recent scientific research shows that folate deficiency either by low folate intake or due to a genetic component is associated with increased risk for gastric cancer (Gao et al. 2013; Zhao et al. 2012). Low serum folate levels have been associated with gastric cancer development and invasiveness (Lee et al. 2014). Folate deficiency has also been associated with the susceptibility of colorectal cancer by folate deficiency-induced DNA hypomethylation (Kim 2004; Pufulete et al. 2003). Although the mechanisms between folate and gastric and colorectal cancers are still being elucidated, studies suggest DNA methylation may be playing a role. As with many cancers, methylated promoter sites and aberrant methylation are present in both gastric cancer and colorectal cancer (Qu et al. 2013; Zhao et al. 2012; Bardhan and Liu 2013; Esteller 2002; Wajed et al. 2001). Diagnosis of gastric and colorectal cancers is commonly based on gastrointestinal endoscopy, colonoscopy, and fluoroscopy, which are invasive and not comfortable for the patient (Winawer et al. 2003; Pasechnikov et al. 2014). Thus, using DNA methylation as a possible diagnostic screening tool to detect cancer is becoming important. DNA methylation as a screening tool uses gastric fluids (serum or gastric washes) or biopsy specimens, and it identifies the prevalence of methylation in DNA within the specimen (Nakamura et al. 2014; Ye et al. 2010; Kalnina et al. 2015). Such DNA is the secreted product from gastric cancer cells; thus, the methylation patterns observed in the specimen are thought to be correlated with those in cancer cells (Nakamura et al. 2014; Ye et al. 2010; Kalnina et al. 2015). Numerous genes have been identified as having altered DNA methylation patterns in cancers versus normal tissue. In colorectal cancer, CpG island methylator phenotype (CIMP) is used to classify colorectal cancers (Bardhan and Liu 2013). These genes, which are hypermethylated in colorectal cancer, include MLH1, p16, MINT1, MINT2, and MINT31, common genes in DNA mismatch repair mechanisms and tumor suppressors (Bardhan and Liu 2013). CIMP panels can further be expanded to include a number of other genes, including RUNX3, IGF2, and WRN (Bardhan and Liu 2013). Furthermore, DNA methylation of serum RUNX3 and serum RASSF1A used to diagnose gastric cancer with the latter having high specificity, but low sensitivity (Qu et al. 2013). The promoters of RUNX3 and RASSF1A are hypermethylated in gastric cancer tissue compared to normal tissue (Qu et al. 2013; Chen et al. 2010; Kim et al. 2004; Waki et al. 2003; Wang et al. 2008; Ye et al. 2007) (Table 1). These hypermethylation marks can be used as biomarkers of disease risk and state. A significant difference between cancer and normal DNA is the methylation of the promoter site for gene p16, so it has become of

Table 1 Alterations in genes leading to colorectal and gastric cancer susceptibility. Changes in gene methylation or gene polymorphisms involved in colorectal or gastric cancers. Changes in DNA methylation or polymorphism increase the risk for colorectal and gastric cancers. Certain markers are used as biomarkers in disease to sub-classify cancers

Cancer	Property	Outcome or marker	References

	CIMP hypermethylation	Used to subtype	Bardhan and Liu (2013)

special interest to use this as a biomarker for gastric cancer (Qu et al. 2013) (Table 1). As for potential treatment, the idea of demethylation of tumor suppressor genes has gained much appeal since demethylation of these genes leads to cell apoptosis (cell death) (Qu et al. 2013). Folate deficiency or disruptions in the folate metabolism pathway may lead to alterations in DNA methylation patterns, and impact the development of these cancers. However, further studies into the connection between folate status, DNA methylation of these genes, and gastric and colorectal cancer is needed. Elucidating a connection between folate and DNA methylation patterns will hold diagnostic value in gastric and colorectal cancers.

Defects in the folate metabolism pathway may also markedly impact cancer development. Polymorphisms in an essential enzyme in folate metabolism, methylenetetrahydrofolate reductase (MTHFR), correlated with increased risk for gastric cancer and when associated with folate intake, decreased folate intake and further increased the risk of gastric cancer above the MTHFR polymorphism and folate deficiency alone (Gao et al. 2013) (Table 1 and Fig. 5). Deficient folate intake and the resulting DNA hypomethylation in colorectal cancer leads to damage- and mutation-prone DNA and insufficient repair mechanisms, some of which is reversible with proper folate supplementation (Kim 2004; Pufulete et al. 2003). In addition, in several cases, colorectal cancers have polymorphisms in the enzymes in the one-carbon pathway where regardless of folate intake, metabolism to methyl donors is affected due to genetics rather than environment (Zhao et al. 2012; Pufulete et al. 2003). It is thought that the reactivation of these enzymes may be possible, and whose function may trigger tumor suppression (Zhao et al. 2012) (Table 1 and Fig. 5).

Cardiovascular Disease

The evidence demonstrated a connection between DNA methylation in cardiovascular diseases (CVD) such as atherosclerosis, heart failure, myocardial infarction, and cardiac hypertrophy (Blom and Smulders 2011; Ward 2001; Li et al. 2016). Although evidence for DNA methylation and folate in CVD are at its initial stages, researchers are actively exploring the field in hopes to use epigenetics in the treatment of patients with CVD (Voelter-Mahlknecht 2016). Folate deficiency contributes to CVD in that it causes high levels of homocysteine in the body, which is damaging to the cardiovascular system (Mattson et al. 2002; Winder 1998). High levels of homocysteine are due to folate deficiency in which levels of folate are inadequate to methylate homocysteine to methionine (Mattson et al. 2002; Winder 1998; Castro et al. 2003; Rosenquist 2013). Folate supplementation lowers homocysteine levels, but its beneficial effects vary in disease states; folate supplementation has shown benefits in stroke prevention while it has shown no benefit in CVD (Voelter-Mahlknecht 2016). Although the mechanism is unknown, leukocytes in the serum of patients with vascular disease are globally hypomethylated compared to healthy controls (Kandi and Vadakedath 2015; Castro et al. 2003). This hypomethylation correlates with increased homocysteine levels in the serum; this pathway is consistent with characteristics of folate deficiency and one-carbon pathway alterations (Castro et al. 2003). Scientists speculate that the folate supplementation would help bring homocysteine levels back to safe levels, a major contributor to the development of various heart-related diseases (Li et al. 2016) (Fig. 5).

Liver Disease

Medici and Halsted demonstrated that folate deficiency is associated with the development of alcoholic liver disease through numerous mechanisms (Medici and Halsted 2013). The group showed that low levels of folate, thiamine, and vitamin B6 play a role in the development of alcoholic liver disease. It is thought that the low availability of folate and similar compounds in the human body will lead to hypomethylation of DNA and DNA instability in the liver and will cause expression of harmful liver enzymes that result in liver damage (Medici and Halsted 2013). Furthermore, folate feeds into metabolism of methionine and affects homocysteine levels, antioxidant effects, and lipid mobilization (Medici and Halsted 2013). Chronic alcohol intake disturbs the one-carbon metabolism; its hallmark effect is elevated levels of homocysteine (Kruman and Fowler 2014). Since the one-carbon metabolism is disturbed by chronic alcohol intake, it is safe to say that the effects also lead to changes in DNA methylation and subsequent gene expression, not only at the liver but multiple organs as well (Kruman and Fowler 2014). The mechanism of how chronic alcohol intake affects is not entirely understood, but it may be a result from two possible pathways: the direct interference of enzyme function from ethanol inhibition, or the decreased levels of folate due to the poor diet as seen in alcoholics (Kruman and Fowler 2014). Either way, one-carbon metabolism dysfunction leads to low levels of SAM which leads to hypomethylation of DNA (Kruman and Fowler 2014). Additionally,

increased alcohol intake strongly associates with low folate intake and colorectal cancer via mechanisms of promoter hypomethylation and elevated homocysteine levels (van Engeland et al. 2003; Giovannucci et al. 1995; Kato et al. 1999) (Fig. 5).

Conclusions

In summary, folate is an important dietary requirement, especially during pregnancy. Folate deficiency during pregnancy leads to detrimental neural tube defects, but more, folate deficiency correlates with gastric and colorectal cancer, as well as, cardiovascular and liver disease later in life. Its metabolism pathway, the one-carbon pathway, generates the methyl donor SAM for DNA and other methylation processes. Folate deficiency may be leading to unstable DNA by disrupting nucleotide synthesis and increasing susceptibility to disease. Further, folate deficiency may deplete methyl donor pools affecting DNA methylation and altering expression of genes associated with disease. Epigenetics and epigenetic regulation of disease is an emerging and fast developing field and folate's role in epigenetic regulation of disease is still unfolding. Therefore, more attention needs to be focused on the epigenetic impact of folate in human health and disease. Folate and its metabolites have potential to be used in preventative, diagnostic, and therapeutic measures in a number of diseases. Determining folate status and folate supplementation may be beneficial in treating diseases associated with elevated homocysteine levels in the blood or tissue, as in CVD and liver disease. Further, evaluating folate levels and DNA methylation in a disease context, globally or disease gene-specific, may provide valuable information on the underlying mechanism of disease, and the potential for folate supplementation in restoring proper DNA methylation. Therefore, maintaining proper folate supplementation throughout life, not just at critical stages such as pregnancy, should be evaluated in reducing the risks of developing diseases such as cancer, CVD, and liver disease.

Policies and Protocols

The World Health Organization (WHO) issued guidelines in 2015 reflecting the appropriate folate levels in red blood cells in women of reproductive age. Folate levels must exceed 400 ng/mL (906 nmol/L) in RBCs in women of reproductive age to reduce the chances of fetuses being affected by neural tube defects during development (Cordero et al. 2015). The CDC recommends women of reproductive age to consume 400 mcg of folate daily (CDC 2016).

Dictionary of Terms

- **Epigenetics** – The study of how environmental pressures, such as nutrient deficiency, alter the expression of genes without altering the genetic code.

- **DNA methylation** – An epigenetic mechanism where a methyl group is added to the 5-carbon of cysteine in CpG islands and canonically represses gene transcription.
- **DNA methyltransferase** – An epigenetic enzyme family consisting of DNMT1, DNMT3a, and DNMT3b that adds a methyl group to the C5 position of cytosine by de novo either methylation (DNMT3a and DNMT3b) or maintenance of already methylated DNA (DNMT1).
- **Folate** – An essential dietary nutrient commonly found in broccoli, celery, asparagus, beans, and Brussels sprouts and its synthetic form, folic acid, that is added to fortified foods since 1998 and found in supplements.
- **One-carbon metabolism** – Folate participates in this pathway where it is metabolized into tetrahydrofolate and undergoes further metabolism to produce nucleotides or 5-methyltetrahydrofolate, which is further metabolized into the primary methyl donor in methylation processes, *S*-adenosylmethionine.

Summary Points

- This chapter discusses the dietary nutrient, folate, and its connection to epigenetics.
- Folate is metabolized through the one-carbon metabolism pathway, and its metabolites are used in DNA synthesis and methylation processes.
- One such metabolite is *S*-adenosylmethionine, the major methyl donor in methylation processes.
- Folate deficiency leads to pregnancy complications leading to neural tube defects in children and disease such as cancer, cardiovascular diseases, and cancer in mothers and children.
- Folate deficiency may lead to insufficient methyl donor pools to maintain proper methylation of the DNA.
- Hypomethylation, or decreased methylation, of the DNA, can lead to DNA instability leading to DNA damage.
- In addition, folate deficiency and resulting hypomethylation can lead to the expression of oncogenes leading to the development of cancers such as colorectal and gastric cancers.
- Folate deficiency can also alter the balance in one-carbon metabolism to an accumulation of homocysteine, which causes damage to the cardiovascular system associated with a number of cardiovascular diseases.
- Proper supplementation of folate (400 mcg/day) has shown to prevent pregnancy complications.
- Folate levels and methylation have diagnostic and therapeutic potential; in fact, supplementation of folate has shown improvement in certain diseases.

Vitamin K Status in Nutritionally Compromised Circumstances

89

Mina Yamazaki Price and Victor R. Preedy

Contents

Abstract

Vitamin K deficiency is very rare except in neonatal populations. This is due to dietary sources, particularly plant-derived phylloquinones (vitamin K1) being abundantly distributed in nature and ubiquitously available in common foods. However, there is very little information on the bioavailability of vitamin K from foods. Furthermore, despite the increased understanding of vitamin K's biological

roles, there are difficulties in establishing a causal link between plausible biomarkers of vitamin K deficiency and reproducible health outcome measures. Additionally, with vitamin K there is the added complication that this vitamin is also synthesized in the gastrointestinal tract by gut microflora. As a result, the exact dietary requirements for vitamin K in numerical terms have not been fully established. Clinically significant vitamin K deficiency is almost nonexistence in healthy populations. However, there are states in which it is compromised in some population cohorts other than neonatal populations. This review illustrates some examples of vitamin K insufficiency states, which include eating disorders, undernourished children, inflammatory bowel disease, and chronic kidney disease. It also describes some biomarkers of vitamin K status used in recent studies.

Keywords

Vitamin K · Phylloquinones · Menaquinones · Natto · Carboxylation · Uncarboxylated · Glutamate residues

List of Abbreviations

BMI	Body mass index
ESRF	End-stage renal failure
IBD	Inflammatory bowel disease
PIVKA-II	Protein induced by vitamin K absence-II
ucMGP	Undercarboxylated matrix Gla protein
ucOC	Undercarboxylated osteocalcin

Introduction

Vitamin K is a one of four fat-soluble vitamins (the other three being vitamin A, D, and E). Vitamin K is categorized into two major forms. They are the plant-derived phylloquinones (vitamin K1) and the bacterial-derived menaquinones (vitamin K2) (Price and Preedy 2015). There are number of vitamers within each form. Some texts describe a third class, namely, menadione (sometimes denoted as vitamin K3), but it does not occur naturally (it is synthesized) and is used in animal feeds (Coombs and McClung 2017). Structurally, they have a common 2-methyl-1, 4-napthoquione ring, and the differences at the three position of the side chain separate the two major forms (phytyl side chain and prenyl side chains, phylloquinones and menaquinones, respectively) (Fig. 1).

The nomenclature of vitamin K can be somewhat challenging as they are also denoted by the number of isoprenoid units. For example, phylloquinone-1 is denoted by K-1 and menaquinone-7 is denoted as MK-7 etc. Natto, for example, (Table 1) is particularly high in MK-7. There are a number of phylloquinones and menaquinones, with different biological activities. Coombs and McClung (2017) list six phylloquinones (K-1 - K-6) and six menaquinones (MK-2 - MK-7) in terms of their bioactivity (potency). For example, K-4 is 20 times more potent than K-1. MK-5 is eight times more potent than MK-2 (Coombs and McClung 2017). There

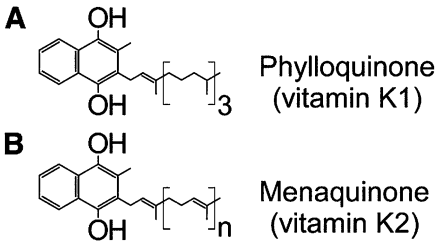

Fig. 1 Chemical structure phylloquinone (vitamin K1) and menaquinones (vitamin K2). Fig. A shows phylloquinones (vitamin K1) and B shows menaquinones (vitamin K2). (Source: Rishavy and Berkner 2012)

are probably about 20 different vitamin K isomers (both phylloquinones and menaquinones) that have been investigated or characterized in depth (see Coombs and McClung 2017).

Dietary Sources

The main dietary sources of plant-derived phylloquinone are leafy green vegetables, pulses, and certain plant oils. The phylloquinones are synthesized by chloroplasts. Phylloquinone is abundantly distributed in nature and is the primary form in the Western diet (Hayes et al. 2016). On the other hand, dietary sources of bacterial-derived menaquinones are primarily found in animal sources including dairy products and meats including processed meat products. Additionally, menaquinones are synthesized by the gut microflora in the large intestine in humans and then subsequently enter the circulation. Bacterially fermented products such as natto are a rich source of menaquinones. Furthermore, although the biological pathway is unclear, phylloquinone is converted to one form of menaquinone, i.e., menaquinone-4, in vivo which is independent of gut microflora activity (Price and Preedy 2015). Table 1 shows the vitamin K concentrations in some of the common foods consumed in the Western diet. It highlights the ubiquitous distribution of phylloquinones compared to the less common distribution of menaquinones (Schurgers and Vermeer 2000).

Biological Role

The primary or traditionally accepted role of vitamin K, established since the 1970s, is its participation in hemostasis (antihemorrhagic). It acts as a cofactor to facilitate the post-translational carboxylation of specific peptide-bound glutamate residues to γ-carboxyglutamate (in some text the Greek symbol is replaced with the term "gamma") residues in plasma-clotting proteins, namely, factors II (prothrombin), VII, IX, and X to initiate the coagulation cascade (Price and Preedy 2015).

Proteins which require vitamin K as a cofactor for the posttranslational γ-carboxylation of glutamate residues for its activation are termed as vitamin K-dependent proteins. Further discovery of a number of vitamin K-dependent proteins (a total of 16 proteins including the aforementioned 4) leads to the general consensus that the role of vitamin K extends beyond hemostasis (Price and Preedy 2015).

Table 1 Vitamin K concentrations in some of common foods consumed in the Western diet. The below values show mean values of at least three to six different samples or brands. Natto (fermented soy beans) is not commonly consumed in the Western diet but commonly consumed in Japan. It is listed as an example of extremely high content of menaquinones (Vitamin K2) in fermented foods (Source: Schurgers and Vermeer 2000)

Food group	Food	Phylloquinone (vitamin K1) concentration μg per 100 g	Menaquinone (vitamin K2) concentration μg per 100 g
Vegetables	Kale	817.0	Not detectable
	Spinach	387.0	Not detectable
	Broccoli	156.0	Not detectable
	Sauerkraut	25.1	4.8
	Natto (fermented soy beans)	34.7	1088.4
Fruits	Apple	3.0	Not detectable
	Banana	0.3	Not detectable
	Orange	0.1	Not detectable
Fat and oils	Olive oil	53.7	Not detectable

	Whole yoghurt	0.4	0.9
	Hard cheese	10.4	76.3
	Soft cheese	2.6	56.5
Meat and egg	Beef	0.6	1.1
	Chicken breast	Not detectable	8.9
	Pork steak	0.3	2.1
	Pork liver	0.2	0.3
	Salami	2.3	9.0
	Goose liver paste	10.9	369.0
	Egg yolk	2.1	31.4
Fish and shell fish	Mackerel	2.2	0.4
	Herring	0.1	Not detectable
	Salmon	0.1	0.5
	Prawn	0.1	Not detectable
Bread	Wheaten bread	1.1	Not detectable
	Sourdough bread	1.0	Not detectable

For example, vitamin K is involved in vascular and bone health by protecting against vascular calcification and bone loses, respectively. Table 2 shows a list of vitamin K- dependent proteins and their physiological roles (Berkner and Runge 2004; Booth 2009; Price and Preedy 2015). There is also increasing evidence that

Table 2 Vitamin K-dependent proteins and their biological roles. The table shows 16 vitamin K-dependent proteins. Many of biological pathways of roles listed in this table are unclear (Berkner and Runge 2004; Booth 2009)

Name of proteins	Biological role
Prothrombin (factor II)	Hemostasis/coagulation
Factor VII	Hemostasis/coagulation
Factor IX	Hemostasis/coagulation
Factor X	Hemostasis/coagulation
Protein Z	Hemostasis/coagulation
Protein S	Hemostasis/coagulation/anti-inflammatory
Protein C	Hemostasis/coagulation/anti-inflammatory
Osteocalcin	Bone health/regulates bone mineral maturation/possible role in glucose homeostasis
Gla-rich protein	Bone health/regulates extracellular calcium
Periostin	Bone health/involves extracellular matrix mineralization
Matrix Gla protein	Vascular health/inhibits vascular calcification
Gas-6	Vascular health/involves vascular smooth muscle cell apoptosis and movement
Transmembrane Gla 1	unclear/possible role in signal transduction
Transmembrane Gla 2	unclear/possible role in signal transduction
Transmembrane Gla 3	unclear/possible role in signal transduction
Transmembrane Gla 4	unclear/possible role in signal transduction

vitamin K status has a bearing on bone and cardiovascular health and well-being. Indeed, there is some evidence that supplemental vitamin K may confer a biological advantage in terms of bone health.

Dietary Requirements and Recommendations

Despite the increased understanding of vitamin K's biological roles, its exact dietary requirements in numerical terms have not been fully established. This uncertainty may be due to the difficulties in inducing vitamin K deficiency through dietary deprivation alone or finding individuals who are vitamin K deficient via classical undernutrition studies (DH 1991). Furthermore, there are difficulties in establishing a causal link between plausible biomarkers of vitamin K deficiency and reproducible health outcome measures. This is compounded by the fact that there is very little information on the bioavailability of vitamin K from foods. As a consequence, it is somewhat problematical to derive specific dietary recommendations or reference values for vitamin K (Shearer et al. 2012).

For the UK, the Dietary Reference Values consist of 3 main components as follows:

Estimated average requirements (EAR). On the population level, half will require more than the EAR and half less.

Lower Reference Nutrient Intake (LRNI). Intakes at the LRNI will only satisfy the few people in a group who have low needs (less than 3% of the population).
Reference Nutrient Intake (RNI). Intakes at the RNI will satisfy the needs of the majority of the people in a group (about 97% of the population). The risk of deficiency in the group is very small if intakes Are at the RNI or above.

Occasionally, there is not sufficient information to provide either an EAR, LRNI, or RNI. In these circumstances safe intakes have been derived for UK-based reference values. Safe Intakes are defined as "a term used to indicate intake or range of intakes of a nutrient for which there is not enough information to estimate RNI, EAR or LRNI. It is an amount that is enough for almost everyone but not so large as to cause undesirable effects" (DH 1991).

For a full explanation of these terms, their derivation, and implications for health and disease prevention, one is referred to the original report on the Dietary Reference Values (DH 1991).

In the UK, safe intakes have been derived for vitamin K dietary reference values for adults and infants (in other words and to reiterate a point, there are no EAR, LRNI, nor RNI for vitamin K). In the UK, safe intake for adults for vitamin K is 1 μg per body weight (kg) per day (DH 1991). This equates to about 69–72 and 59–60 μg/day adults, for male and female, respectively (values are calculated based on reference weight for age range between 19 and 54 years) (SACN 2015, Table 3). Safe intake for vitamin K for infants is 10 μg/day in the UK (DH 1991). These values are similar for the USA and Japan (Table 3). Both countries have only values for adequate intake, which is considered to be the UK equivalent of safe intake. In the USA and Japan, for adults, reference intakes are higher, i.e., 150 μg for both genders for the USA and 120 and 90 μg/day in Japanese men and women, respectively. For infants, they are 2.0–2.5 μg/day for the USA and 4–7 μg/day for Japan (NASEM 2016, MHLW 2015). For the definition of infants, it has to be mentioned that there is no age specification for the UK. However, they are defined as 0–12 months, for the USA, and 6–11 months for Japan, respectively (NASEM 2016, MLHW 2004).

Table 3 shows dietary reference values and definitions of the terminology for vitamin K used in the UK, USA, and Japan.

As mentioned earlier, vitamin K is widely distributed in a variety of foods. Therefore the clinical deficiency caused by dietary deficiency is extremely rare. However, there are states in which it is compromised. In the following text, we describe these compromised states pertaining to vitamin K insufficiency.

Different biomarkers have been used to define reduced vitamin K status. Table 4 summarizes the biomarkers used in studies described in the text below.

Vitamin K and its Deficiency States

Clinically significant vitamin K deficiency is almost nonexistence in healthy populations except for neonatal populations (Lee et al. 2016). Neonatal populations are particularly vulnerable to vitamin K deficiency. Underlying causes include their

Table 3 Reference values of vitamin K, definition of the terminology and current recommendation for adults used in the UK, USA, and Japan

Country	Reference values	Definition	Current recommendation or reference intakes (μg/day)
UK	Safe intake	A term used to indicate intake or range of intakes of a nutrient for which there is not enough information to estimate reference nutrient intake, estimated average requirements or lower reference nutrient intake. It is an amount that is enough for almost everyone but not so large as to cause undesirable effects	68.8–71.5 adult male 59.0–59.9 adult female 10.0 infants
USA	Adequate intakes	A recommended average daily nutrient intake level based on observed or experimentally determined approximations or estimates of mean nutrient intake by a group (or groups) of apparently healthy people. An adequate intakes is used when the recommended dietary allowance cannot be determined	120.0 adult male 90.0 adult female 2.0–2.5 infants
Japan	Adequate intake	A less well-defined value, generally the median of the population without evidence of deficiency	150.0 adult male 150.0 adult female 7.0 infants

The current recommendations or reference intakes for adults shows values 19–50 years in the UK and USA and 19–49 years in Japan. For the UK, figures are calculated based on μg/body weight (kg)/day (DH 1991) using weight for males 19–24 years, 71.5 kg; 25–34 years, 71.0 kg; 35–44 years, 69.7 kg; 45–50 years, 68.8 kg. For females, 19–24 years, 59.9 kg; 25–34 years, 59.7 kg; 45–50 years, 59.0 kg (SACN 2011). For infants, there is no age definition for the UK, for the USA, it is defined as 0–12 month old (4 μg/day for 0–6 month, 2.5 μg/day for 6–12 month); for Japan, it is defined as 6–11 months old. Sources: for the UK (DH 1991); for the USA (NASEM 2016); for Japan (MHLW 2015)

low hepatic reserve and plasma concentration of vitamin K at birth due to poor placental transport of vitamin K and low levels of vitamin K in breast milk (DH 1991; Mihatsch et al. 2016). Additionally, insufficient gut microflora colonization in the large intestine also likely contributes to endogenous deficiency (Lippi and Franchini 2011). However, some other population cohorts may also be vulnerable to vitamin K deficiency in feeding disorders, starvation, and fat malabsorption, as described below.

Eating Disorders of Anorexia Nervosa and Bulimia Nervosa

Compromised bone health (i.e., osteopenia and osteoporosis) is one of the well-recognized clinical complications of deficiency-related eating disorders and their subtype, such as anorexia nervosa and bulimia nervosa (Howgate et al. 2013). This is because of the essential role that vitamin K plays in bone metabolism

Table 4 Vitamin K biomarkers

Biomarker	Rationale
Undercarboxylated osteocalcin	Osteocalcin, a bone matrix protein is exclusively produced by osteoblasts, bone forming cells. Osteocalcin is a bone matrix protein that undergoes a post-translational carboxlylation of protein-bound glutamate residues into gamma-carboxyglutamate which requires vitamin K as a cofactor. Undercarboxylated osteocalcin has no role in bone metabolism
Undercarboxlylated prothrombin	Also called protein induced by vitamin K absence or antagonist -II (PIVA-II). Prothrombin (factor II) is one of four plasma-clotting proteins (other 3 are factor VII, IX, X). Prothrombin undergoes post-translational carboxylation of glutamate residues into gamma-carboxyglutamate which requires vitamin K as a cofactor. Undercarboxylated prothrombin is inactive/defective in blood coagulation
Undercarboxylated matrix Gla protein	Matrix Gla protein is a calcification inhibitor secreted primarily by vascular smooth muscle cells. Gamma-carboxylation of its five glutamate residues requires vitamin K as a cofactor. Undercarboxylated matrix Gla protein does not inhibit the process of vascular calcification

The above biomarkers increase in the circulation in the case of reduced vitamin K availability in vivo (Urano et al. 2015; Nakajima et al. 2011; Lee et al. 2016; Wyskida et al. 2016). These have been selected as they are mentioned in this review in the context of specific studies

(i.e., involvement by the vitamin K-dependent proteins, namely, osteocalcin, Gla-rich protein, and periostin). Urano et al. (2015) investigated vitamin K status of 54 females with eating disorders and 15 age-matched healthy controls (mean age of 28 years).

In their aforementioned study, serum undercarboxylated osteocalcin (ucOC) levels of 4.5 ng/ml or higher were defined as vitamin K deficiency. Osteocalcin is a bone matrix protein which is produced by the osteoblasts, the bone forming cells. Vitamin K is a necessary cofactor for the posttransitional carboxylation of osteocalcin. When the supply of vitamin K is insufficient or abnormal, ucOC, which has no biochemical role in bone metabolism, is released into the blood stream. UcOC is considered as a sensitive biomarker for vitamin K status (Urano et al. 2015).

The 54 subjects included 29 with anorexia nervosa and 25 with bulimia nervosa (Urano et al. 2015). The mean body mass index (BMI) of eating disorder subjects was 14.8 kg/m^2 (95% confidence interval 14.1–15.5 kg/m^2). BMI of this magnitude indicates severe thinness (BMI less than 16.0 kg/m^2) (WHO 2016). The mean BMI of the healthy subjects was 20.1 kg/m^2 (95% confidence interval 18.7–21.4 kg/m^2). All eating disorder subjects were diagnosed with osteopenia or osteoporosis, and a total of 28% of the eating disorder subjects (anorexia nervosa n = *5*, bulimia nervosa $n = 10$) were found to be vitamin K deficient. The prevalence of vitamin K deficiency within healthy subjects was not shown. However, serum levels of ucOC of bulimia nervosa subjects were statistically significantly higher than healthy subjects ($p < 0.05$), whereas differences between anorexia nervosa and healthy subjects did not reach statistical significance (Urano et al. 2015).

Interestingly, this study showed significant negative correlation between serum level of ucOC (a surrogate marker of vitamin K deficiency) and dietary vitamin K intake for both types of eating disorder ($p < 0.01$). The authors argued that the cause of vitamin K deficiency in this cohort was likely multifactorial (Urano et al. 2015). For example, complex behaviors associated with eating disorders such as severe restriction of dietary intake and vomiting/purging behaviors could cause reduction in overall vitamin K status. Regular laxatives misuse could also lead to malabsorption of dietary vitamin K. Furthermore, laxative abuse may cause alterations in the gut microflora populations which could negatively affect in vivo vitamin K synthesis (Urano et al. 2015).

The importance of mentioning the effects of anorexia nervosa and bulimia nervosa is their potential appreciation in understanding the consequence of undernutrition/starvation. In conceptual terms, these two conditions should provide us with information as to the effects of undernutrition/starvation on vitamin K status. However, as the previous text alludes, with vitamin K there is the added complication that this vitamin is also synthesized in the gastrointestinal tract.

Children and Undernutrition

There have been some studies showing positive associations between vitamin K status and childhood bone health, such as total body bone mineral content (van Summeren et al. 2008). However, in children, results are inconclusive in terms of relationships between dietary vitamin K intake and vitamin K status. This could be due to several potential reasons including the large variation in day to day vitamin K intake and difficulties in assessing bioavailability of dietary vitamin K and synthesis by gut microbial population (Cashman 2005).

Recently, Lee et al. (2016) studied 500 children of 6–8 years of age in the southern rural part of Nepal. The study found 100 children (mean age 7.3 years) to be vitamin K deficient. In this study, vitamin K deficiency was defined by plasma concentration of undercarboxylated prothrombin, also known as protein induced by vitamin K absence-II (PIVKA-II) to be more than 2 μg/L. Prothrombin (blood coagulant factor II) is a hepatic vitamin K-dependent protein and abundant in the circulation. PIVKA-II is secreted by the liver when the liver storage of vitamin K is depleted (Lee et al. 2016).

Among the 100 children identified with vitamin K deficiency, 37% and 44% were classified as stunted and underweight, respectively. However, when vitamin K-deficient ($n = 100$) and vitamin K-sufficient ($n = 400$) children were compared, the study showed no significant differences in anthropometric measurements (i.e., weight, height, BMI, and mid-upper arm circumference), prevalence of stunting and underweight. The dietary intake of certain foods (i.e., intake of milk, eggs, meat, fish, dark leafy vegetables in the past week) and most of other profiles (e.g., literacy and economics of household) were also not different between vitamin K-deficient ($n = 100$) and vitamin K-sufficient ($n = 400$) children. For example, the prevalence of underweight was 44% and 50%, in vitamin K-deficient and vitamin K-sufficient

groups, respectively. The authors hypothesized there may be diverse homeostatic responses to subclinical vitamin K status in a generally undernourished young children population (Lee et al. 2016).

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is the collective term for ulcerative colitis and Crohn's disease. IBD is characterized as a chronic relapsing and remitting inflammation of the digestive tract (Nakajima et al. 2011). Micronutrient deficiency including vitamin K as well as protein energy malnutrition is known to be commonly prevalent in patients with IBD. The prevalence of malnutrition could be as much as 85% of patients regardless of their disease status (i.e., active or remission) (Weisshof and Chermesh 2015). The degree of malnutrition depends on the disease severity including inflammatory processes and, in the case of Crohn's disease, the area of the gut affected by the disease. Therefore, the etiology of malnutrition in IBD is multifactorial. Common causes of malnutrition include failure to maintain a sufficient dietary intake (poor appetite and imposed dietary restrictions), impaired intestinal absorption (depending on the location and severity of inflammation), and nutrient loss from the inflamed and ulcerated gut (Altomare et al. 2015). Furthermore, nutritional requirements in general increase particularly in the active stages of IBD due to physiological response to inflammation. Moreover, the increased nutritional requirements during the active stages of inflammatory disease may not be coupled with increased nutritional intake for many experiencing physiological symptoms such as abdominal pain, nausea, and diarrhea (Weisshof and Chermesh 2015).

Nakajima et al. (2011) investigated vitamin K status in IBD patients. In their study, vitamin K insufficiency was defined by the comparison of serum concentration of undercarboxylated osteocalcin (ucOC) between IBD patients and healthy subjects. The cutoff value for serum concentration of ucOC to define vitamin K insufficiency was not specified (Nakajima et al. 2011).

Forty seven Crohn's disease patients, 40 ulcerative colitis patients, and 41 age- and gender-matched healthy subjects were compared (all were Japanese) (Nakajima et al. 2011). Serum ucOC level was statistically significantly higher ($p < 0.05$) in Crohn's disease patients when compared to ulcerative colitis patients and healthy subjects. However, when compared ulcerative colitis patients and healthy subjects, serum ucOC level was higher in ulcerative colitis patients compared to healthy subjects, but the differences did not reach of statistical significance.

Although this study did not examine vitamin K dietary intake, the authors argued that insufficient vitamin K intake may not be the main reason to explain the results. This is because, previously, Kuwabara et al. (2009) found vitamin K dietary intake in IBD patients exceeded the daily adequate intake level at the time the study was performed (Kuwabara et al. 2009). The mean vitamin K intake in IBD patients was 131.1 μg in this study (Kuwabara et al. 2009). At the time the adequate intake for vitamin K was 75 μg for adult male and 65 μg for adult female in Japan (MWLH 2004). The adequate intake for vitamin K in Japan was then revised to 150 μg for

adult male and female in 2015 (MHLW 2015). Rather than insufficient vitamin K dietary intake, the authors suggested that the statistically higher serum concentration of ucOC found in Crohn's disease patients compared to the healthy subjects is attributed to reduced dietary fat intake by Crohn's disease patients. In Japan, Crohn's disease patients are commonly treated with a fat-reduced diet. The absorption of fat-soluble vitamin K may be compromised in Crohn's disease patients. Finally, endogenous synthesis of vitamin K by intestinal bacteria may differ between these cohorts, as the bacterial flora composition is significantly altered, particularly in Crohn's patients, due to inflammation of the gut (Nakajima et al. 2011).

Here, we can suggest that there is a common theme in the aforementioned studies related to children with malnutrition, subjects with anorexia, and patients with IBD. Namely, the microbiological profile of the intestinal tract may complicate the understanding of the relationship between dietary intake of vitamin K and the status of vitamin K sufficiency or deficiency. However, there is little information on the exact amount of vitamin K (menaquinones) produced by intestinal bacteria. Furthermore, some have suggested de novo synthesis of vitamin K (menaquinones) may not be fully dependent on intestinal bacteria as animals lacking a gut microflora still synthesize vitamin K (menaquinones) (LeBlanc et al. 2013). Such theory adds further complication to our understanding of vitamin K homeostasis.

Chronic Kidney Disease

It is widely recognized that cardiovascular diseases are the leading cause of the mortality, morbidity, and hospitalization in end-stage renal failure (ESRF). Coronary artery calcification, a risk factor of cardiovascular disease, is commonly prevalent in ESRF patients compared to population without kidney disease (Chen et al. 2017). The link between vascular calcification, vitamin K status, vitamin K-dependent proteins, and the negative effects of commonly used medications in this cohort (i.e., vitamin K inhibitory action of warfarin) has received attention (Gallieni and Fusaro 2014).

The compromised vitamin K status of this cohort could be due to therapeutic dietary restrictions such as limiting intake of potassium and phosphorous. Commonly restricted dietary components including dairy products, legumes, fruits, and vegetables. Many of these foods contain high concentration of vitamin K as discussed previously (see also Table 1).

Wyskida et al. (2016) investigated the level of functional vitamin K deficiency and its relation to vitamin K1 (phylloquinones) intake in 153 Polish ESRF patients on hemodialysis. In their study, vitamin K status was measured using two surrogate markers, namely, plasma concentration of protein induced by vitamin K absence-II (PIVKA-II) and undercarboxylated matrix Gla protein (ucMGP). The 95% confidence interval around the mean in 20 healthy adult subjects (similar ages to ESRF patients with normal kidney function) were established as a normal, 0.37–0.66 ng/mL and 5.1–9.2 mg/mL, PIVKA-II and ucMGP, respectively. The values in ESRF patients were compared with normal ranges. ESRF patients which had surrogate

markers below normal ranges were defined as vitamin K deficient. Dietary vitamin K1 (phylloquinones) intake was assessed for the past year, using a food frequency questionnaire.

The results showed increased plasma concentration of PIVKA-II (>0.66 ng/mL) in 27.5% of ESRF patients. However, the mean plasma concentration of PIVKA-II was not significantly different between ESRF patients and healthy subjects (0.59 ng/mL and 0.51 ng/mL, respectively). The results also found significantly higher mean plasma concentration of ucMGP (17.9 mg/mL) in ESRF patients compared to healthy subjects (7.1 mg/mL, $p < 0.001$). Increased ucMGP level (>9.2 mg/mL) was found in 77% of ESRF patients (Wyskida et al. 2016).

Median vitamin K1 intake was 103 μg/day in ESRF patients. There were no significant differences between men and women. Of these109 ESRF patients, 34% subjects found to have less than the recommended values for the Polish population (at least 65 μg and 55 μg/day for adult men and adult women, respectively; (Wyskida et al. 2016).

Forty five percent of ESRF patients who showed increased plasma concentration of PIVKA-II (>0.66 ng/mL) had daily intake less than the amount recommended for the Polish population. Authors conducted further analysis of the subgroup of ESRF patients with increased PIVKA-II level > 0.66 ng/mL with the receiver operator curve analysis. ESRF patients with increased plasma concentration of PIVKA-II level > 0.66 ng/mL had lower daily vitamin K1 intake less than 40.2 μg/day, which is below aforementioned Polish daily recommendation. However, for the level of ucMGP, there was no significant difference between patient group whose vitamin K1 intake was greater than the recommendation for the Polish population and the group whose vitamin K intake was below the recommended value.

There was no correlation between plasma concentration of ucMGP and PIVKA-II and between ucMGP and daily vitamin K1 intake. The study demonstrated a correlation between plasma PIVKA-II level and dietary vitamin K intake in ESRF patients. The authors indicated PIVKA-II is superior as a surrogate marker for vitamin K deficiency compared to ucMGP.

Possible factors other than vitamin K dietary intake which could have influenced negatively in vitamin K status of ESRF patients include gut microflora composition, in vivo synthesis of vitamin K2 (menaquinones), impaired vitamin K absorption, or disturbed vitamin K metabolism (Wyskida et al. 2016).

Policies and Protocols

Readers are reminded that to ensure adequate vitamin K intake, one must have a balanced diet. However, one needs to take into account the fact that intake of vitamin K1 or K2 will depend on dietary variations. For example, vitamin K2 intake in the Japanese population is higher than that of the UK population. This is because in Japan fermented foods are an important source of vitamin K2. In the UK the majority of vitamin K comes in the form of K1 from vegetables. One also needs to consider compositional tables in context of portion size, frequency, and also concentrations

within foods. For example, natto has a vitamin K concentration of approximately 1 mg per 100 g. It is rarely consumed in the UK. So it is erroneous to say that natto is an important source of vitamin K unless the country (hence the dietary profile of that country) is specified.

In examining reference intakes, one needs to emphasize that we have only discussed values for the UK, USA, and Japan. However, other countries or bodies have different reference intakes. For example, the World Health Organization suggests 55 and 65 micrograms per day for adult women and men, respectably.

Dictionary of Terms

- **Anorexia nervosa** – A major form of eating disorders in which the patients starve themselves to induce weight loss. It is a primary psychological illness which can cause significant acute and chronic medical complications. It is not unknown for patients with anorexia nervosa to starve themselves to death.
- **Bioavailability** – The proportion of a nutrient or other substance such as a drug that enters the circulation or body system when compared with the amount ingested. A variety of processes can impact on bioavailability, such as the nature of the food matrix, transport processes in the intestine, degradation or metabolism upon entering the gastrointestinal tract, and so on.
- **Bulimia nervosa** – A major form of eating disorders. It is a psychological disorder characterized by the binge eating and purging behaviors. It is associated with a numbers of adverse health consequences including increasing suicide risk.
- **Chronic kidney disease** – A long-term condition where the functions of the kidneys are gradually impaired. The degree of impairments separates stages of diseases.
- **Crohn's disease** – A condition in which segments of the digestive system become inflamed. Unlike ulcerative colitis, it can affect any part of the gastrointestinal tract. However, most commonly Crohn's disease affects the terminal part of the ileum or the colon.
- **End-stage renal failure** – The final stage of chronic kidney disease where the kidneys are hardly functioning or not functioning at all. The patients can be treated with dialysis or kidney transplant.
- **Fat-soluble vitamins** – Fat-soluble vitamins are absorbed and transported with fats in the diet. Fat-soluble vitamins include vitamins A, E, D, and K.
  They have predominantly aromatic and aliphatic characteristics and are soluble in nonpolar solvents. They are stored in the liver and adipose tissue. The term "fat soluble" is used in contrast to "water-soluble vitamins" (such as the B vitamins, folate and vitamin C).
- **Gut microflora** – The term is often used interchangeably with gut microbiota. It is the complex communities of microorganisms (e.g., bacteria, fungi and viruses) that inhabit in the digestive tracts of all mammals. In humans, the composition, structure, diversity, and functional capacity of gut microflora are thought to be

influenced by various factors. These factors include heredity influences, diet, and medical interventions (the latter, e.g., may be the effects of antibiotics).

- **Hemostasis** – The arrest or cessation of bleeding. This involves the physiological process of blood coagulation and constriction of damaged blood vessels. The role of vitamin K within blood coagulation is the most recognized biological role of vitamin K.
- **Natto** – A fermented soybeans dish which has high concentrations of vitamin K2.
- **Ulcerative colitis** – A condition where varying amounts of the colon and almost always the rectum become inflamed. The most common symptoms include frequent diarrhea (sometime with blood and mucus) and abdominal pain.
- **Vitamin K** – Vitamin K is a fat-soluble vitamin, which has two major forms. They are the plant-derived phylloquinones (vitamin K1) and the bacterial-derived menaquinones (vitamin K2). They are abundant in nature and widely distributed in a variety of foods. Phylloquinones are commonly found in green leafy vegetables, pulses, and plant oils. Menaquinones are primarily found in animal sources such as dairy products and meats. Menaquinones are also produced by bacteria. As a consequence relatively high concentrations of menaquinones are found in fermented foods such as natto.

Summary Points

- Vitamin K is categorized into two major forms. They are plant-derived phylloquinones (vitamin K1) and bacterial-derived menaquinones (vitamin K2). There are many vitamers within each form.
- Dietary sources of vitamin K are widely distributed. The contributions of different foods will depend on the cultural significance (common or uncommon foods), portion size, and frequency.
- Phylloquinones (vitamin K1) are commonly found in leafy green vegetables. Menaquinones (vitamin K2) are primarily found in animal sources (e.g., dairy products and meat) and bacterially fermented foods and synthesized by the gut microflora in the large intestine in humans.
- The exact dietary requirements of vitamin K in numerical terms have not been fully established due to various reasons including difficulties in determining a causal link between plausible biomarkers of vitamin K deficiency and reproducible health outcome measures.
- Clinically significant vitamin K deficiency is almost nonexistence in healthy populations except for neonatal populations. However, some other population cohort may also be vulnerable. This includes undernourished children, patients with eating disorders, those with inflammatory bowel disease, and patients with chronic kidney disease.
- Compromised vitamin K deficiency status is multifactorial. These include reduced vitamin K intake, perturbations in absorption, altered de novo synthesis, and interaction with medications.

Abstract

Copper is involved in a wide range of physiological functions. In humans, copper deficiency impairs growth and reproduction and biochemical alterations and health outcomes due to copper deficiency have been reported. Biochemical or clinical copper deficiency is prevalent in infants recovering from malnutrition, children with chronic diarrhea, in some cases of malabsorption, and in some regions depending on food availability, soil concentrations, or behaviors. The effects of food choices on markers of micronutrients are still insufficiently investigated. The competitive absorption of zinc and copper is considered. The copper intake in representative samples of healthy populations has been assessed in several national dietary surveys sometimes with no concordance to copper serum concentrations. The wordwide multiplicity of dietary reference values illustrates the lack of consensus regarding requirements. The number of large-scale, high-quality studies examining the relationship between copper intakes, biomarkers of copper status, and health outcomes is still limited. None of several putative biomarkers of copper status have yet unequivocally proved to reflect changes in copper intake, in nutritional ranges. Monitoring copper status should rely on intake assessments for which several issues are reviewed here. Due to a lack of sensitive biomarkers of copper status, the question under-recognition deficiency is raised. Based on current knowledge the question of copper deficiency-related health outcomes is addressed. Policies options are considered.

Introduction

Copper (Cu) was established as an essential trace element in the 1920s. In the Western diet, decreased copper in food and diet over the last several decades has been suggested to contribute to copper inadequacy (Klevay 2011); in developing countries, malnutrition, protein-energy malnutrition, and micronutrient deficiencies continue to be major health burdens (FAO 2004). Being a transition metal, copper is a cofactor for many redox enzymes involved in several biochemical processes and physiological functions. The wide range of clinical features resulting from disturbances in the activities of cuproenzymes means that although severe copper deficiency is relatively straightforward to diagnose, identifying marginal deficiency is more difficult (Danzeisen et al. 2007). Therefore, monitoring copper status in the general population should rely on intake assessments for which several issues are reviewed here. Based on current knowledge regarding copper intake, biomarkers, and the relationship between dietary copper and health, the question of copper deficiency-related health outcomes are addressed. Policies options, including fortification, will be considered.

Copper Functions, Metabolism, and Balance

Copper Metabolism and Balance

Needed in trace amounts, copper is present in the order of approximately 110 mg Cu in the body of a healthy 70 kg human adult (10 mg in the liver, 8.8 mg in the brain, 6 mg in blood, 3 mg in the kidney, 46 mg in the skeleton, including bone marrow,

and 26 mg in skeleton muscle). Its absorption occurs mainly in the proximal part of the small intestine, where it is transported to the liver via the portal vein. The absorption rate varies between 12% and 71% depending on age, gender, food matrix, amount of dietary copper, and the use of oral contraceptives (van den Berghe and Klomp 2009). Copper absorption is consistently 10% higher in women than men, without being affected by hormone use in women and without any effect of age on fractional absorption (Johnson et al. 1992). In fully or partially breast-fed infants, limited evidence from monitoring fecal 65Cu elimination after an oral dose suggests that intestinal absorption of copper is close to 80% (Olivares et al. 2002). This estimation was not corrected for intestinal copper reexcretion; therefore, we assume that copper uptake from breast milk is almost total.

Following intestinal absorption, 75% of portal copper is taken up by the liver (Harvey et al. 2005) and the remainder flows into the peripheral circulation, mainly bound to albumin. In the liver, 20% is reexcreted back into the gastrointestinal tract and 80% is exported to the periphery, bound to ceruloplasmin (Harvey et al. 2005). An excessive intake of zinc predispose an individual to secondary copper malabsorption (Beshgetoor and Hambidge 1998).

Based on concentration in gastrointestinal fluids, an estimated 2.5 mg of copper is excreted daily in the biliary flow, and as much through other gastrointestinal secretions (including saliva, gastric juice, pancreatic and intestinal fluid secretions) (Linder et al. 1998). Most of the endogenous copper secreted into the gastrointestinal lumen is reabsorbed across the intestinal epithelium (Harvey et al. 2003; Turnlund et al. 1989, 1998, 2005). The gastrointestinal secretion of copper plays a major role in the control of copper homeostasis, with endogenous losses increasing from 0.45 to 2.46 mg per day (mg/d) for intakes increasing from 0.7 to 6 mg/d (Harvey et al. 2003).

Urinary excretion ranges from 10 to 25 μg/d (Turnlund et al. 1990, 2005, 1997) and does not seem to play a significant role in the control of copper homeostasis in response to changes in copper intake.

Sweat and integumentary losses average 42 μg/d (Milne et al. 1991), and sweat losses are believed to generally have a small overall effect on the estimated fractional losses (Snyder et al. 1975). Due to similar physiochemical properties between copper and zinc, a high intake of zinc or high molar ratio of zinc to copper has long been recognized to interfere with copper metabolism (Beshgetoor and Hambidge 1998).

Information regarding Cu flux and organ pools is summarized in Fig. 1.

Biochemical Functions

Copper is required for the function of over 30 proteins (Arredondo and Nunez 2005), involved in redox reactions in a myriad of biological processes, such as cellular respiration (cytochrome C oxidase), free radical eradication (superoxide dismutase, SOD1), connective tissue biosynthesis (lysyl oxidase), neurological development (dopamine beta-hydroxylase), iron homeostasis (ceruloplasmin), antioxidant defense, neuropeptide synthesis, regulation of gene expression, and immune

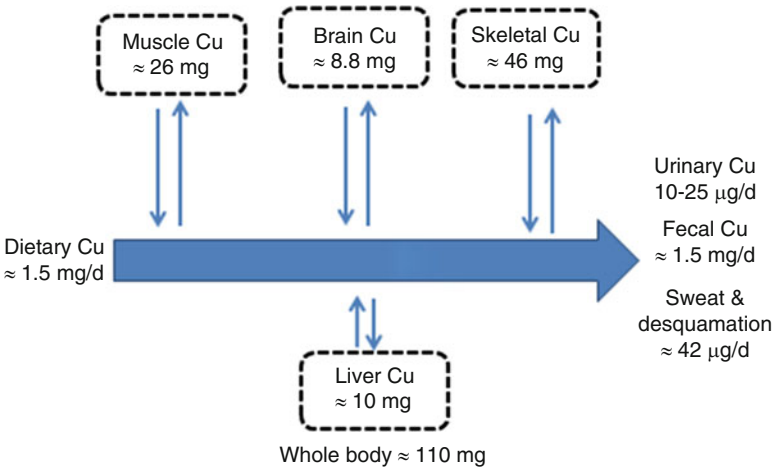

Fig. 1 Whole-body pools and flux

function (Prohaska and Gybina 2004). A deficiency of copper suppresses SOD1 activity, weakens free radical defense, and may also cause membrane damage. In SOD1, copper, as cofactor, works together with zinc, and it is the copper-to-zinc ratio, rather than the absolute amount of either metal alone, that helps the enzyme function properly. The competitive absorption of zinc and copper has to be considered. However, copper has an ambivalent role and, in its free form (as a transition metal), it can be a source of reactive oxygen species (ROS). Copper can therefore be toxic at high levels. An overload of this metal leads readily to Fenton-type redox reactions, resulting in oxidative cell damage and cell death. However, copper toxicity as a result of dietary excess is generally not considered a widespread health concern, probably as a result of the homeostatic mechanisms controlling copper absorption and excretion (Turnlund et al. 2005).

Copper Deficiencies and Health Outcomes

Biochemical alterations due to copper deficiency have been reported such as alterations in copper levels, lower hemoglobin, reduced melanin, and elevated hepatic iron content. Some of the most salient changes to organs include alterations in the hematological, cardiovascular, nervous, and immune systems. Anemia, cardiac enlargement, neuronal degeneration, and thymic hypoplasia have been observed in a number of species (Prohaska 1990). In humans, copper deficiency impairs growth and reproduction. Prolonged marginal deficiency has also been associated with alterations in cholesterol metabolism (Klevay et al. 1984; Reiser et al. 1987).

During pregnancy, deficiencies in some trace elements including copper have been described as possibly associated with complications in childbirth or fetal development (Darnton-Hill and Mkparu 2015). In utero, copper deficiency may

result in impaired development of the cardiovascular system, bone malformation and ongoing neurologic and immunologic abnormalities into infancy and beyond (Gambling and McArdle 2004; Georgieff 2007).

Lipoprotein Profile

Two cross-sectional studies (Bo et al. 2008; Ghayour-Mobarhan et al. 2005) suggest that high copper intake and status is associated with a better metabolic profile.

In a randomized control study (RCT) (Davis 2003), total and low-density lipoprotein (LDL) cholesterol did not differ between the low (0.59 mg Cu/d) and adequate (2.59 mg Cu/d) copper periods (6 weeks each). Supplementation with 2 mg Cu/d for 6 weeks (Medeiros et al. 1991) triggered an increase in total serum LDL cholesterol at 4 weeks whereas very-low-density lipoprotein (VLDL) cholesterol declined in the placebo group. The percentage of LDL increased after 6 weeks of supplementation compared with the initial baseline value, while the percentage of cholesterol as VLDL decreased compared with the baseline value in the supplemented group.

Limited results from cross-sectional studies tend to suggest that dietary copper is associated with a better lipoprotein profile. This observation is not fully supported by the results of RCTs, but the short duration of these studies may preclude the occurrence of such an effect.

Cardiac Arrhythmia

A significant increase in the number of ventricular premature discharges was observed in 3 women out of 13 after 3–12 weeks on a low copper diet (0.57 mg Cu/d for 105 days) (Milne and Nielsen 1996). In another study, 3 women out of 12 on a low copper diet (1 mg Cu/d during a 90 day controlled period) exhibited ventricular premature discharge. Although three women received supplements before the end of the study, two still exhibited an increased number of abnormal ventricular discharges. Limited evidence from the RCTs also suggests that marginal intake of copper may lead to cardiac arrhythmia but no conclusion can be drawn regarding the relationship between dietary copper and cardiac arrhythmia (Milne et al. 2001).

Neurologic Alterations

The hypothesis that copper intake is linked to cognitive decline is based on the long-recognized age-related accumulation of metal-transporting proteins and compounds in key sites of the attentional circuits (Zatta et al. 2008).

Copper concentrations have been found to be inversely associated with cognitive performance in a large cohort of elderly healthy women but not in men. Long-term and short-term recall scores are significantly lower in women with serum copper over 2.15 mg/L than women with serum copper below 0.9 mg/L. (Lam et al. 2008).

A potential role of copper in depression has been hypothesized. No significant differences have been found in serum copper concentrations between patients in a current depressive episode or in remission and healthy volunteers. Moreover, copper levels in the active stage of the disease are not correlated with clinical features of the population (Styczen et al. 2016). This study seems to be the first large-scale investigation on this topic.

An association between serum copper concentrations and sleep duration in aging men has been suggested (Luojus et al. 2015). Authors hypothesized that copper contributes to sleep regulation through pro-oxidative processes and copper-dependant N-methyl-d-aspartate receptor activity. Mechanisms underlying the relationship require further investigation.

Cancers

Two cohort studies have examined the link between copper intake and lung cancer and lymphoma.

A large cohort study (Mahabir et al. 2010) showed no relationship between total copper intake and the risk of lung cancer. In the Iowa Women's Health Study (Thompson et al. 2010), there was no link between total or dietary copper and the risk of non-Hodgkin's lymphoma, diffuse large B-cell lymphoma or follicular lymphoma. In a third cohort study in subjects aged 65 years and over (Bates et al. 2011), dietary copper intake was not predictive of cancer mortality over 14 years.

The link between copper intake and breast cancer was not demonstrated in one cross-sectional study (Dabek et al. 1994) and in one case-control study (Cavallo et al. 1991).

For other cancers, no relevant studies assessing copper intake were identified. To date, no conclusion can be drawn regarding copper intake and cancers.

Arthritis

One cohort study in women (mean age, 61.4 years) (Cerhan et al. 2003) found no link between dietary copper intake – with or without supplementation – and risk of rheumatoid arthritis. There was a weak, but significant inverse relationship between the use of copper supplements and the risk of rheumatoid arthritis, which did not persist after further adjustment for confounding factors (age and energy intake, other risk factors). Thus, no conclusion can be drawn regarding copper intake and rheumatoid arthritis.

Immunosuppression

In healthy humans, diets providing 0.38 mg Cu/d for 42 days reduces peripheral blood mononuclear cell proliferation and secretion of the interleukin-2 receptor in culture media. Neither parameter returned to baseline levels at the end of the 24 day

repletion period. Peripheral blood number of leucocytes, monocytes, neutrophils, lymphocytes or natural killer cells were unaffected by diets of 0.66, 0.38, and 2.49 mg/d Cu during 24, 42, and 90 days, respectively (Kelley et al. 1995).

A significant impact on the immune function with both leucopenia and neutropenia has been reported in specific situations where Cu malabsorption combined with low Cu intakes resulted in impaired Cu status, such as post-bariatric surgery patients (Saltzman and Karl 2013).

Together with zinc and iron, copper plays a pivotal role either in maintaining and reinforcing the immune and antioxidant performances or in affecting the complex network. The relevance of dietary copper in aging because affecting some genes related to inflammatory/immune response is suggested despite sensitive biomarkers are missing to assess marginal or moderate copper deficiency in aging of genes involved in encoding proteins for a correct inflammatory/immune status (Mocchegiani et al. 2012).

Keratoconus

Copper has been called into question in relation to keratoconus (KC). A hypothesis linking the entire putative pathway of KC development suggests that copper imbalance in corneal tissue may be an independent risk factor for the disease. Current evidence suggests that, in the vast majority of patients, the development of KC depends on the interplay between genetic and environmental factors. Copper deficiency may be an unrecognized factor increasing susceptibility to the disease (Dudakova et al. 2015). It has been hypothesized that lower plasma levels of copper in males compared with females could explain a higher prevalence of KC (Johnson et al. 1992). The assessment of copper levels and its distribution in keratoconic corneas warrants further investigation (Dudakova et al. 2015).

Copper Requirements and Dietary Reference Values

Requirements for Adults

To set nutritional requirements in adults, calculation of nutrient balances requires a thorough assessment of nutrient losses. For copper, four balance studies are available (Harvey et al. 2003; Milne et al. 1990; Turnlund et al. 1998, 2005). Copper balance values are reported to be positive for intakes greater than 2.4 mg Cu/d and negative for intakes less than 0.8 mg Cu/d (Harvey et al. 2003; Turnlund et al. 1998).

Fractional copper absorption has been measured using extrinsic meal labelling with 65Cu and fecal copper monitoring for several days to accurately quantify the amount of absorbed copper reexcreted in fecal matter (Harvey et al. 2005; Harvey et al. 2002, 2003). The results allow considering the true fractional absorption of copper as being close to 50%, and constant for copper intakes ranging from 0.7 mg/d to 6.0 mg/d.

Table 1 Copper requirements and dietary reference values (DRV) (mg Cu/d) according to several public health authorities

	ANSES (2017)	D-A-CH (2013)	EFSA (2015)	IOM (2001)	NHMRC (2006)	NCM (2012)
Men						
EAR	1	–	–	0.7[a]	ND	0.7
DRV	2.0 1.5 (51–65 year)	1.0–1.5	*1.6*	0.9	1.7	0.9
Women						
EAR	0.8	–	–	0.7	ND	0.7
DRV	1.5	1.0–1.5	*1.3*	0.9	1.2	0.9

[a]Based on variations in copper status estimated from copper in serum, ceruloplasmin, SOD in erythrocytes in depletion/repletion studies

These data suggest that the minimal amount of dietary copper required to achieve a null balance lies somewhere between 0.8 and 2.4 Cu mg/d. Consequently, there is no consensual requirement value and, depending on the public health authority, this requirement has been set based on balance studies available or other types of data. Some of these values are summarized in Table 1.

Requirements for Children

In infants, copper requirements can reach 40–80 μg Cu/kg body weight (bw)/d. Copper stored in the liver of the fetus and delivered by the mother during the last trimester of pregnancy is essential to cover this requirement (Afssa 2001). Therefore in pregnant women, copper intake should be increased of 0.2–0.5 mg/d.

Human breast milk usually contains 300–400 μg/L of copper (Dorea 2000) and, typically, initially provides 50 μg/kg bw/d, declining to approximatively 13 μg/kg bw/d after 6 months of lactation (Casey et al. 1989). Copper balance has been reported in infants receiving 27 μg/kg/d of copper from breast milk (Aggett et al. 1983).

Therefore, the World Health Organization (WHO) has proposed that all infants (0–6 months of age) not given breast milk should receive cow's milk-based or other formula diet providing at least 50 μg/kg bw/d of copper. This intake may have to be increased in formulae where the bioavailbility of copper is likely to be reduced (e.g., soy-based formulae).

The UK Committee on Medical Aspects of Food Policy (DH 1991) set a requirement for infants based on a factorial approach. In the UK, requirements of 47, 39, and 36 μg/kg bw/d were set for successive 3-month periods of infancy.

In the Nordic Nutrition Recommendations (NNR 2012), for infants aged 6–11 months and children, copper requirements were extrapolated from adult requirements, taking into account an allowance for growth, in line with the Institute of Medicine (IOM 2001).

Clinical and biochemical studies monitoring copper intakes in children are very rare. Data on copper intakes required to establish equilibrium between input and

output differ widely, ranging from 35 to 2000 μg/kg bw/d (Alexander et al. 1974). Although most suggest that copper balance can be reached at intakes in the range of 50–100 μg/kg/d, most datasets also reflect the difficulty of interpreting copper balance studies when the copper status of experimental subjects has not been previously defined.

The IOM (2001) extrapolated the copper requirement for children from the requirement for adults using allometric scaling (body weight to the power of 0.75), owing to the absence of data for children. The choice of this scaling approach was justified by the structural and functional role of copper in many enzymes and because it resulted in higher values than extrapolation based on isometric scaling (i.e., linear with body weight).

Dietary Reference Values (DRVs)

DRVs are established for each nutrient and target population based on scientific data of various types (biochemistry, epidemiology, etc.). The methods of "construction" to establish these values vary depending on the nature of nutrients and the data available. For copper, due to the lack of appropriate balance data, a few institutions (Anses 2016; IOM 2001) have derived a recommended dietary allowance (RDA) based on requirement estimations. Other authorities (e.g., NHMRC, EFSA, DASH) therefore proposed recommended values based on observed intake (adequate intakes, AI). Some of the proposed values are summarized in Table 1.

To date, at the international level, the multiplicity of values illustrates the lack of consensus regarding nutritional requirements and reference values for copper.

Copper Intake and Assessment of Copper Status

The calculation of the prevalence of inadequacy must take into account both copper content in food, intake frequencies, and food composition data to calculate copper intakes compared with DRVs.

Dietary Sources of Copper

Copper content in food varies with regional specificities, which explain some of the differences between composition tables among regions or countries. Naturally low soil copper concentrations are responsible for low contents in food and drinking water. Use of copper compounds as bactericides or fungicides on many crops also affects its content in cereals, fruits, and vegetables and, to a lesser extent, meat and animal products (Olivares et al. 2004).

The most bioavailable source of copper is meat and the major storage is in the liver, primarily bound to metallothioneins (MT) (Hartmann et al. 1993). Food groups such as offal (7–20 mg/100 g), nuts (1–2 mg/100 g), shellfish (1–3 mg/100 g), and, to

a lesser extent, cereals and fruits (0.5–2 mg/100 g) can be regarded as good sources of copper, while milk and dairy products contain low amounts (<1 mg/100 g) (Ciqual, ANSES 2016). The largest contributors to intake in the French adult population are bread and bread products (14.1%), vegetables (7.8%), offal (7.4%), fruits (6.1%), and potatoes (5.5%).

Copper density in a vegan diet has been shown to be twice that of an omnivorous diet (2.0 ± 0.34 mg/1000 kcal vs 0.7 ± 0.29 respectively) (Abdulla et al. 1981). Daily copper intake has been reported to be 27% higher in vegetarians than in omnivorous adolescent females (Donovan and Gibson 1996). The higher copper content of a plant-based diet has been consistently shown to compensate for its slightly reduced bioavailability resulting from the presence of phytates and fibers, suggesting that diets low in animal does not cause copper deficiency (Hunt and Vanderpool 2001; Turnlund 1983, 1985).

Dietary Intakes and Nutritional Status

The copper intake in representative samples of healthy populations has been assessed in several national dietary surveys (Table 2).

Similar levels of copper intake have been reported in European countries for adults and the elderly (Table 2), according to recent reviews of representative national dietary surveys and total diet studies (Sadhra et al. 2007; Vinas et al. 2012) and in the US adult population (US Department of Agriculture 2012).

Several methods are used for calculating the prevalence of inadequacy which require knowledge on intake and DRVs values. Nutritional status is mostly assessed

Table 2 Mean copper intake in adults and the elderly in various European countries according to representative national dietary surveys.

Country	Study – years	Method	Men		Women

[a]*FFQ* food frequency questionnaire

using the estimated average requirement (EAR) cut-point method. Because biological status is rarely measured due to technical or methodological reasons, the interpretation of prevalence of inadequacy must be made with caution.

A Greek cross-sectional epidemiological study showed wide variation in copper intakes across age. The prevalence of inadequacy assessed using the EAR cut-point method showed inadequacies ranging from 1.9% to 8.4% in children from 9 to 13 years old, 18.3% and 37.5% in 40–60 years old, respectively, males and females (Manios et al. 2014). For the authors, the significant age-related increases are consistent with previous studies conducted in Greece as well as in other developed countries.

In Chile, copper intake inadequacy assessed using the EAR cut-point method was observed to be most common in adult males (33.3%) and in women (21.1%).

In Nordic countries, referring to an EAR of 0.7 mg/d, the percentage of the population over 65 years at risk for inadequate dietary intakes of copper from food alone was 14% for men and 18% for women (ter Borg et al. 2015).

Data from the literature have shown that biochemical or clinical copper deficiency is prevalent in infants recovering from malnutrition or children with chronic diarrhea (Araya et al. 2003). The early introduction of cow's milk as a primary nutrient source leads to the development of copper deficiency, particularly in low-birth-weight and premature infants (Naveh et al. 1981). Case studies (Levy et al. 1985) also describe signs of deficiency in two 6-month-old male infants who were neither premature nor seemingly malnourished but were fed cow's milk since birth. These studies suggest that deficiency during the first year of life in infants fed with a cow's-milk-based diet may not be that uncommon and, unfortunately, may often go undiagnosed.

In some cases, sufficient intake can be even associated with low copper serum concentrations as observed in Mexico, where serum concentration below 65 μg/dl has been reported for 30.6% in children from 1 to 11 years old and 14.1% in adolescents (Morales-Ruan Mdel et al. 2012). The meaning is not quite understood and authors speculate that copper absorption is inhibited by a high intake of absorption antagonists, abundant in the Mexican diet. This study illustrates the limits of basing conclusions on the relationship between intake and a marker of biological status.

Copper deficiency is also commonly observed in formerly obese patients after gastric bypass surgery, with prevalence ranging from 10% to 15% in cross-sectional studies and 4–18% in longitudinal studies (Jaiser and Winston 2010; Gletsu-Miller et al. 2012). Its prevalence is higher after Roux-en-Y gastric bypass and Biliopancreatic diversion with duodenal switch compared to other types of bariatric surgery and is a consequence of both reduced copper intake and malabsorption resulting from decreased hydrochloric secretion in the remnant stomach and duodenal bypass (Gletsu-Miller et al. 2012).

Overall, data on intakes alone are not sufficient to determine prevalence of nutrient inadequacy. Dietary inhibitors and enhancers of absorption influence copper bioavailability and, hence, determines absorption efficiency (IOM 2001). Further, fractional absorption and excretion depends on its availability in the diet and subjects can adapt to intake below levels set by requirements. Therefore, insufficiencies identified by dietary assessment need to be confirmed by complementary parameters

that are seldom included in protocols (clinical, biochemical, and functional). The effects of dietary behavior on markers of micronutrients are still insufficiently investigated. Nevertheless, when trace element levels are inconsistent with medical evaluations, a test for activity of the suspected enzyme(s) may lend support to the differential diagnosis.

Biomarkers of Copper Exposure

Although serum and plasma copper are often used as markers of copper status (Harvey et al. 2009), they show no variation for copper intake values ranging from 0.57 to 6 mg/d in controlled studies. For other putative biomarkers, either their specificity and sensitivity is too low or the quality and number of studies examining their link with copper intake is insufficient to support their use in the evaluation of copper exposure.

Even being available, erythrocyte and extracellular SOD, leucocyte copper, platelet cytochrome c oxidase, or serum lysyl oxidase (Klevay 2011) is less frequently used. The protein-metal speciation analysis has also been proposed as an added value for a precise diagnosis of nutrient deficiency or overload, and subsequently provides a more complete picture for defining correct individual supplementation (Mocchegiani et al. 2012).

Additionally, using only biochemical parameters may be misleading because of a nonspecific increase in serum concentration of ceruloplasmin during acute-phase response against various infections and inflammatory conditions (Muataz Elsiddig and Elmuataz 2008). A Cu:Zn ratio exceeding 2 indicates a severe infection (Hua-Dong et al. 1999).

The lack of a suitable biomarker for copper intake and status highlights the need for high quality RCTs in healthy subjects evaluating the responsiveness of putative new biomarkers of copper status over wide copper intake ranges (Bost et al. 2016). Generally speaking, more informative biomarkers are needed to assess copper status at the population level. To date, information on circulating levels in the general population and children is still scarce. Therefore, data are lacking to accurately estimate the copper status in the populations.

Discussion

The number of large-scale, high-quality studies examining the relationship between copper intakes, biomarkers of copper status, and health outcomes is still limited. It remains difficult to assess the links between copper intake and health and copper requirements. To date, none of several putative biomarkers of copper status have yet unequivocally proved to reflect changes in copper intake within the range of nutritional intakes. The question could be raised of whether deficiency is under-recognized due to a lack of sensitive biomarkers of copper status.

The weakness of food composition tables in providing a clear nutrient composition of all individual food items is also among methodological limitations in assessing the actual dietary intake in studies.

Additionally, the prevalence of inadequacy depends on the chosen EAR value, which varies among countries. International projects, such as the European micronutrient RECommendations Aligned (EURRECA) project have the potential to lead to a standardized way of estimating the adequacy of micronutrient intake in populations, including copper which is considered as one of the top 10 priorities (Cavelaars et al. 2010).

The unresolved issues of copper intake and inadequacy assessment raise the issue of the relevance of copper fortification.

In Europe, few data are available on the contribution of dietary supplements to daily copper intake (Flynn et al. 2009). In the USA, dietary supplements contribute significantly to daily copper intake (50% in male supplement users and 60% in female users) (Bailey et al. 2011). Although the use of dietary supplements results in a small but significant reduction in the prevalence of copper inadequacy in the adult population, it also leads to an increasing risk of intake above the upper intake levels (UL) in children 2–8 years old (7.7% vs. 39% for nonusers and users, respectively) (Bailey et al. 2012). Because fortification with micronutrients should be safe for the whole population, unacceptably large intakes of micronutrients from all sources should be prevented. As voluntary food fortification expands, careful scrutiny and monitoring of this practice is needed (Sacco et al. 2013) to avoid excessive intakes. Among trace elements, copper intake is not frequently assessed in Europe (Novakovic et al. 2013), and the need for an increase in copper intake has not been clearly demonstrated.

High interindividual genetic variability, interactions between dietary habits and genetic factors and the unreliability of specific biomarkers for testing zinc, copper, iron status together contribute to the poor success of supplementations (Klevay 2011). Regarding the heterogeneity of intake data, and considering the risks related to both deficiency and excess, it is judicious to consider restricting the addition of micronutrients to cases in which health benefits are demonstrable. This consideration includes zinc fortification, because the well-known competitive absorption between copper and zinc which can alter copper status under zinc fortification.

Copper has an ambivalent role and may demonstrate U-shaped exposure-response relationships due to toxic responses occurring as a result of both excess and deficiency (Milton et al. 2016). Rather than focus entirely on a single optimal intake level, it may be more appropriate to consider an acceptable range of copper intake, allowing for uncertainties in the data and interindividual variability in the response.

Conclusions

Fortification policies aiming at reducing inadequate nutrient intakes in the general population need to be weighed against the risks of intakes above the UL in other parts of the population. The scientific evidence needed to support fortification policies requires a dedicated risk/benefit assessment.

In the case of copper, uncertainties regarding concentration in foods and the lack of accurate biomarkers of copper status may lead to misclassification in terms of copper exposure and confuse the link between copper intake and health. To understand the public health significance of copper malnutrition and identify the most appropriate measures to prevent it, the number of unresolved issues and uncertainties calls for studies with a more complete and precise assessment of copper exposure based on reliable biomarkers of copper status. The physiological role and the health consequences of copper-deficient diets have to be better understood to establish criteria for defining the degree of malnutrition, and to develop prevention and control strategies.

Policies and Protocols

Policies

Dietary Copper Intakes and Nutritional Status Display Heterogeneous Scenarios that Need Differentiated Approaches Regarding Regions and Populations

- Governments have to encourage research to better understand the physiological role and the health consequences of copper-deficient diets
- The estimation of copper intake in populations has to be standardized at an international level
- The right answer to copper deficiency when occurring in the population has to target the affected population
- Criteria for defining the degree of malnutrition, and to develop prevention and control strategies has to be established by the public health authority
- If considered, fortification policies need to be weighed against the risks of excessive intakes in the nonaffected parts of the population
- Fortification policies require a dedicated risk/benefit assessment in the whole population

Protocols

Assessment of the Responsiveness of Putative new Biomarkers of Copper Status

Uncertainties regarding concentration in foods and the lack of accurate biomarkers of copper status may lead to misclassification in terms of copper exposure and confuse the link between copper intake and health. Intake is insufficient to determine prevalence of nutrient inadequacy and need to be confirmed by complementary information to be included in clinical, biochemical, and functional protocols. This review highlights the need for a more complete and precise assessment of copper exposure based on reliable biomarkers of copper status at the population level and in healthy subjects. The link between biomarkers and

copper intake are insufficiently established to support their use in the evaluation of copper exposure. Specific and sensitive markers have to be identified or developed – using high quality RCTs – to be specific and sensitive over wide copper intake ranges.

Dictionary of Terms

- **Cuproenzyme** – enzyme in which copper is bound in an active site and used as a cofactor.
- **Biomarker** – substance contained in tissues (mainly blood serum or hair) that can be accurately and reproducibly measured. It is supposed to objectively reflect a physiological state.
- **Estimated average requirement (EAR)** – average daily need within the population, as estimated from individual intake data in relation to a criterion of nutritional adequacy in experimental studies
- **Adequate intake (AI)** – average daily intake of a population or subgroup whose nutritional status is considered adequate.
- **Dietary reference value (DRV)** – daily intake that covers the requirement of almost the entire population considered, as estimated from experimental data. The DRV is usually derived from the EAR or an AI by default.
- **Nutritional adequacy** – comparison between nutritional intakes and requirements in order to assess population risk of inadequate intakes. The prevalence of nutrient inadequacy can be assessed by the probability approach or using the estimated average requirement (EAR) cut-point method.
- **EAR cut-point method** – defines the prevalence of inadequate intakes as the proportion of the population with intakes below the median EAR.
- **Fortification** – addition of vitamins, minerals, or other substances that has a nutritional of physiological effect in common foods. Fortification can be voluntary, at the initiative of the industrial, or mandatory, as a public health intervention.

Summary Points

- This chapter focuses on dietary copper which is an essential trace element naturally present in soils and water.
- Copper is involved in many biological functions, thus low copper intake may have various health effects, such as alterations in the hematological, cardiovascular, nervous, or immune systems.
- Due to the lack of putative biomarkers, monitoring copper status mainly relies on dietary intake data that may confuse exposure measure and the assessment of the link between intakes and health.

- The lack of high quality studies examining the relationship between copper intakes, biomarkers of copper status, and health outcomes leads to the absence of consensual requirement values.
- The unresolved issues concerning copper intake and health makes difficult to suggest appropriate policies and to assess their efficiency.

Contents

Abstract

Chromium is a micronutrient found in several oxidation states, being trivalent chromium and hexavalent chromium the most prevalent. Although it is present in several foods in small quantities, there is still no recommended average requirement. Studies show that during the various life stages, there are

different needs of ingestion of this mineral. Despite the low molecular weight, there is a small absorption capacity of chromium and its absorption occurs in the intestine by passive transport. Along with other metallic ions, its transport is related to the performance of transferrin, and there may be competition for sites that bind to iron and other minerals. Chromium is related to changes that encompass carbohydrate and lipid metabolism. Therefore, some studies indicate that chromium-deficient diets may favor insulin resistance, with consequent development of type 2 diabetes. This mineral is also present in nutritional supplements featuring various structures such as chromium picolinate, chromium histidinate, chromium chloride, and chromium nicotinate. Trivalent chromium demonstrated an important role in gene expression, mainly in hepatocytes, insulin activity, and adiposity. Studies have investigated the effects of chromium supplementation on diabetes, obesity, and dyslipidemia, but the results are still incipient for the development of guidelines recommending supplementation in risk groups.

TTP	Tocopherol transfer protein
UCP 1	Uncoupled protein 1
UL	Tolerable upper intake levels
VLDL	Very low-density lipoproteins
WHO	World Health Organization
μg	micrograms

Introduction

Since its discovery in the eighteenth century, chromium has had several uses as dyes in the textile industry, manufacture of refractories, and metal alloys due to its corrosion capacity (Ensminger et al. 1990; Zelicoff and Thomas 1998). In the twentieth century, the scientific community obtained important findings about the role of chromium in carbohydrate metabolism through the potentiation of insulin signaling (Jeejeebhoy et al. 1977; Vincent 1999). Due to the importance of this micronutrient in the diet, this chapter aims to present the nutritional needs and the main dietary sources of this element, the processes involved in digestion, absorption, transport, and mechanisms of action of chromium in metabolism and its relation with the modulation of gene expression. Because of the increasing use of chromium as a nutritional supplement, this chapter further discusses its effects on type 2 diabetes mellitus and obesity, as well as adverse reactions and toxicity.

Studies indicate a relationship between chromium, health, and disease. But it is still necessary to better understand this micronutrient, such as food, nutritional, biochemical, and public health aspects in order to enable the findings to determine nutritional recommendations for healthy individuals and support guidelines for chromium supplementation in vulnerable groups.

Nutritional Requirements and Food Source

Chromium is a micronutrient present in nature in various valence states, being trivalent (Cr^{3+}) and hexavalent (Cr^{6+}) the most common. Cr^{3+} is the most stable oxidation state and, possibly, the most common form present in the diet, due to the reducing action of food substances (IOM 2001).

In foods, Cr^{3+}can be found, originally identified in brewer's yeast (Schwarz and Mertz 1959). Despite being found in various foods, its amount in most of them does not exceed 2 μg per serving (Roussel et al. 2007) (Table 1).

Cr^{3+} is an important nutrient in the diet, but in the absence of scientific evidence, the Estimated Average Requirement (EAR) of its daily intake has not been established yet. Adequate Intake (AI) (Table 2) is the only establishment to date. The Tolerable Upper Intake Level (UL) has also not been defined, since only a few serious adverse effects were found as a result of its high intake (IOM 2001).

Table 1 Chromium content of foods

Foods	Cr content (μg/serving)
Radish	2.61
Beef steak	2.88
Grapefruit juice	2.94
Grilled chicken	3.83
Pork rib	4.20
Broccoli gratin	4.40
Leek	5.18
Kiwi	5.09
Orange	6.22
Apple	6.80
Boiled potatoes	10.20
Dark chocolate	14.28

Roussel et al. (2007)

Table 2 Daily adequate intake (AI) of chromium (μg)

		Female		
Age	Male		Pregnancy	Lactation
0–6 months	0.2	0.2		
7–12 months	5.5	5.5		
1–3 years	11	11		
4–8 years	15	15		
9–13 years	25	21		
14–18 years	35	24	29	44
19–30 years	35	25	30	45
31–50 years	35	25	30	45
51–70 years	30	20		
>70 years	30	20		

IOM (2001)

Considering life stages, healthy individuals do not represent risk groups for chromium deficiency. Thus, the AI of chromium was based on the average of food consumption. In this case, for children from 0 to 6 months of exclusive breastfeeding, the nutritional recommendation was based on the content of chromium in breast milk, and for children from 7 to 12 months, the quantity of this mineral present in breast milk and in healthy complementary foods was considered (IOM 2001).

For people from 1 to 50 years, there appears to be no increased nutritional requirements of chromium; therefore, the AI of this mineral was based on the average of chromium present in an adequate diet (IOM 2001). For individuals above 51 years, the AI of chromium was also determined from the average amount of this nutrient found in a balanced diet, within the energy requirement for this age group (IOM 2001). There is not sufficient scientific evidence to prove a greater

requirement for chromium in this age group for the prevention of diseases, such as diabetes mellitus type 2 (Mccormick 2012).

In the case of pregnant women, there are no studies that confirm the requirement for chromium supplementation during pregnancy (IOM 1990). Therefore, to obtain the AI of chromium, the recommendation for a nonpregnant woman, of the same age group, added to the requirement for this mineral to fetal supply was considered (IOM 2001). For lactation, the AI of chromium was based on the AI for women of the same age group added to the amount of chromium required for replacement of chromium found in breast milk (IOM 2001).

For individuals with chronic diseases such as diabetes, several studies used additional doses in order to verify the effects of chromium in humans and generate evidence for supplementation recommendations. However, the current evidence does not support a positive effect to the supplementation with chromium in the treatment of diabetes (Abdollahi et al. 2013).

Digestion, Absorption, and Transportation

Although Cr^{3+} is the most stable oxidation state, its absorption is low because it presents difficulty in crossing the plasma membrane (Mertz 1992). As for Cr^{6+}, it has strong oxidative capacity, mainly in acid media, and is linked to oxygen in the form of chromate (CrO_4^{2-}) or dichromate ($Cr_2O_7^{2-}$), which are the easiest compounds to absorb by the plasma membrane. During transport through the membrane, Cr^{+6} is detoxified to Cr^{+3} and reacts with protein components and nucleic acids inside the cell (Pechova and Pavlata 2007).

Specifically during ingestion, the Cr^{+6} dichromate is mixed with saliva and in the stomach it is reduced in Cr^{+3} by hydrochloric acid and thermosensitive-reducing agents present in the gastric juice (Kirman et al. 2013). An enzyme of great importance in the process of chromium reduction is pent gastrin, which stimulates gastric secretion, and Cr^{6+} is reduced into Cr^{3+} by hydrochloric acid, especially in individuals who remain in prolonged fasting (Stollenwerk and Grove 1985).

An in vitro study also demonstrated the conversion of Cr^{6+} to Cr^{+3} by the enzyme glutathione (GSH). By means of the spectrophotometric analysis, it was observed that the excess of the GSH enzyme accelerated the conversion reaction of Cr^{6+} to Cr^{+3}. It has also been shown that this reaction is strongly pH-dependent, being slower in pH 7.4 solutions than at pH values below 5.0 (Wiegand et al. 1984).

The absorption of chromium occurs in the intestine by passive transport, along with other metal ions, mainly in the portion of the jejunum and, to a lesser extent, in the ileum and duodenum, as demonstrated in an experiment with rats (Chen et al. 1973). In humans, there is also evidence that the absorption of chromium begins in the jejunum (Ducros 1992). Chromium in foods has increased absorption by the presence of amino acids, ascorbic acid, high levels of carbohydrates, oxalate, and aspirin in the diet, while phytates and antacids (sodium hydrogen carbonate, magnesium hydroxide) reduce Cr concentrations in the blood and in others tissues (Stoecker 1999).

Inorganic chromium compounds exhibit low absorption, less than 3%, regardless of the dose or chromium status. On the other hand, chromium complexes in the diet are more available than simple chromium salts (Fairweather-tait 1992), that is, the organic sources of Cr^{+3} are better absorbed (Ohh and Lee 2005).

In nutritional supplements, studies on the bioavailability of chromium are controversial; some show that chromium chloride has less bioavailability (0.1–0.4%) than chromium picolinate (2.8%) (Commission 2002). However, due to the toxic effect of picolinate in inducing renal insufficiency, anemia, and hemolysis, the nicotinate compound of chromium has shown greater bioavailability and lower toxicity (Bagchi et al. 2002). More recently, the soluble and ionic forms of chromium phenylalaninate [Cr (D-Phen3), Cr (L-Phen3)] and chromium hydrochloride (CrCl3) have been found to be better absorbed than the organic chromium trispicolinate (CrPic3), chromium nicotinate (CrNic2), and chromium propionate (CrProp) compounds (Laschinsky et al. 2012).

After absorption, chromium is transported in the blood by transferrin and can compete with binding to iron and other minerals (Quarles et al. 2011). The transferrins are proteins (molar mass ~ 80 kDa) that bind reversibly to metal ions, exhibiting greater selectivity for Fe^{+3}. However, the binding of Cr^{+3} to the Fe^{+3} sites of the carrier protein may be related to the detoxification process, more than the transport of an essential trace element (Levina et al. 2016).

The affinity of transferrin to metal ions varies according to environmental conditions, especially pH (Brock 1985). The binding of transferrin to chromium occurs similarly to its attachment to iron. The chromium binds to transferrin's two sites. When each chromic ion binds to the tyrosine residues of transferrin, changes occur in the ultraviolet spectrum of the protein, which was detected by means of Raman resonance (Aisen et al. 1969; Ainscough et al. 1980).

Chromium in Glucose and Lipid Metabolism

Chromium is postulated with functions that mainly cover carbohydrate metabolism. Increased plasma glucose levels stimulate insulin secretion, which binds to the α subunit of its trans membrane receptor and favors the transport of Cr^{+3} through the chromo-transferrin (Cr-Tf) complex. In the intracellular medium, four chromium atoms bind to a protein called apo-chromodulin which becomes active in the form of holo-chromodulin (Fig. 1). Holochromodulin binds to the β subunit of the insulin receptor, amplifies the signal, and activates the kinase activity of the receptor (Vincent 2000). However, the European Food Safety Authority (EFSA) by the Scientific Opinion on Dietary Reference Values for Chromium suggests there is insufficient evidence on chromium's action mechanism that supports its essentiality on glucose metabolism (EFSA 2014).

Intracellular signaling of insulin begins with its binding to the α subunit, which promotes conformational change and β subunit auto-phosphorylation, with a consequent increase in receptor kinase activity. Activation of the insulin

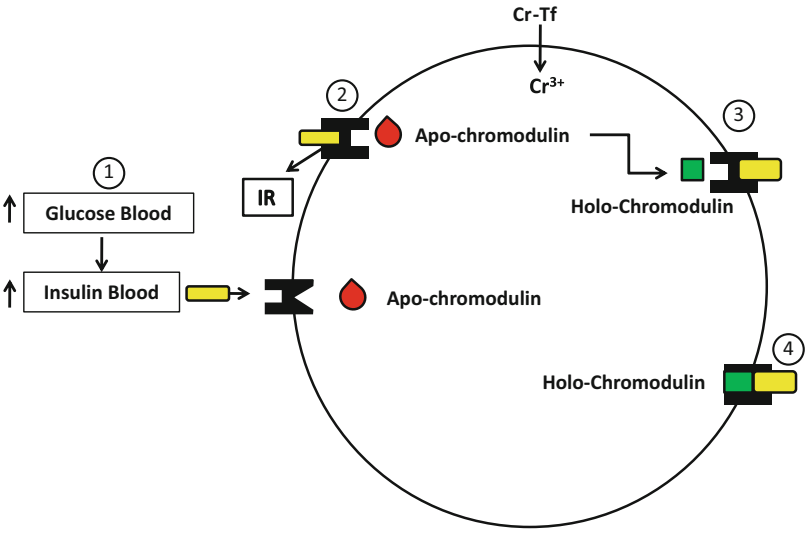

Fig. 1 Action of chromium in glucose metabolism. ◯: Increased glucose and insulin secretion that bind to the α subunit of its receptor, ➔ ▬, ◯: The insulin receptor (*IR*) becomes active through insulin binding and promotes conformational change in the β subunit (▬) and favors the entry of Cr^{+3} into the cell through the chromo transferrin complex (*Cr-Tf*), ◯ to ◯: conversion of the inactive form apo-chromodulin (●) to the active form holochromodulin (■), ◯: Final active form holo-chromodulin attaches to the site at the insulin receptor (▬) (Adapted from Vincent 2000)

receptor kinase triggers a cascade of intracellular phosphorylation. Initially, phosphorylation of its intracellular protein substrates (IRS-1 and IRS-2, respectively) phosphorylates the p85 regulatory subunit and activates the p110 subunit of phosphatidylinositol-3-kinase (PI3k), favoring the conversion of phosphatidylinositol-4,5 -phosphate (PI3k -inactive) in phosphatidylinositol-3,4,5-triphosphate (PI3k-active) (White and Kahn 1994).

Active PI 3-kinase is important in regulating mitogenesis, cell differentiation, and insulin-stimulated glucose transport. It promotes phosphorylation of protein kinase B (AKT) and other phosphoinositois kinase-dependent (PDKs) (White and Kahn 1994; Myers and White 1993).

The phosphorylation mechanism of the p110 subunit of PI3K is stimulated by the chromium present in the cytosol of the cell. Chromium also activates AKT, which stimulates the translocation of the glucose transporter (GLUT4) to the membrane, which is important for the glucose uptake process (Whiteman et al. 2002). The activated AKT phosphorylates other pathways assisting in the conduction of glucose transport (Wang et al. 2006; Dong et al. 2008). Chromium still inactivates PTP-1B which is a protein phosphatase considered to be a negative regulator of insulin signaling (path not shown in the figure) (Goldstein 2002; Sreejayan et al. 2002).

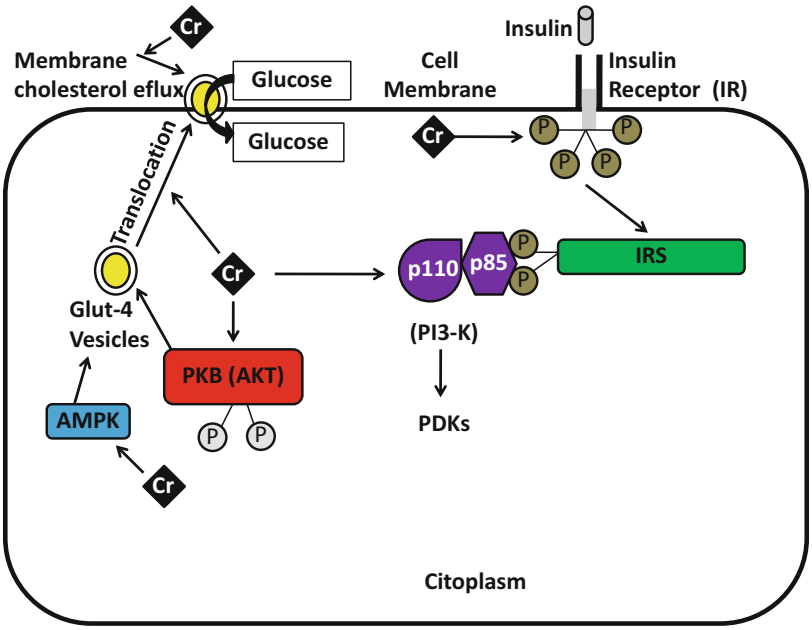

Fig. 2 Putative mechanisms by which chromium augments cellular glucose uptake. Chromium (*Cr*) showed increased kinase activity via phosphorylation of the insulin receptor β (*IR-β*), which was associated with the downstream insulin receptor (*IRS-1, IRS-2* respectively), which was phosphorylated thereby the p85 regulatory subunit and p110 subunit of the phosphatidylinositol 3-kinase (*PI3K*) protein and phosphoinositde-dependent kinases (*PDKs*). Chromium also assists in the signaling and phosphorylation of protein kinase B (*AKT*) leading to translocation of vesicles of glucose 4 (*Glut4*). The transient upregulation of cyclic adenosine monophosphate-activated protein kinase (*AMPK*) leads to increased uptake of glucose. Chromium mediates cholesterol efflux from membranes causing Glut4 translocation and glucose uptake (Adapted from Hua et al. 2012)

The transient positive regulation of AMPK by chromium leads to a higher uptake of glucose, that is, chromium favors the cholesterol efflux of membranes, which causes GLUT4 translocation and consequently glucose uptake (Fig. 2) (Chen et al. 2006).

Although chromium is involved in various mechanisms of glucose metabolism, it was found that chromium nicotinate supplementation did not promote increased insulin sensitivity and reduce blood glucose in diabetic subjects (Guimarães et al. 2013; Abdollahi et al. 2013).

There are also studies that report the relationship of chromium with lipid metabolism. Elevated blood cholesterol levels and aortic plaque formation were observed in rats fed a chromium-deficient diet, but not in animals supplemented with chromium chloride (Schroeder 1969). Later, a reduction in atherosclerotic plaque was observed in rabbits when they received potassium chromate injection (Abraham et al. 1980).

In humans, evidence on the importance of chromium in lipid metabolism has occurred from analyses of aortas of people who died of cardiovascular disease. They had less chromium than aorta from healthy people who were victims of an accident (Schroeder et al. 1970). Later, it was found that people with cardiovascular disease

had lower serum chromium concentrations when compared with healthy people (Newman et al. 1978; Simonoff et al. 1984).

Studies on the effect of chromium supplementation on improving lipid disorders are controversial. Press et al. (1990) have shown the potential of chromium picolinate in improving the lipid profile of people aged 25–80 years; however, Amato et al. (2000) found no promising effect of chromium picolinate on dyslipidemia in the elderly. In a study performed with diabetic subjects who received chromium supplementation by means of brewer's consumption, it showed a decrease in the levels of triglycerides and low-density lipoprotein (LDL-c) (Sharma et al. 2011). However, another study with diabetic subjects showed no change in total cholesterol, LDL-c, high-density lipoprotein (HDL-c), and triglycerides after 90 days of supplementation with chromium nicotinate (Guimarães et al. 2013).

Status, Toxicity and Adverse Chromium Effects

As previously discussed, chromium is a potentiating agent for insulin signaling (Vincent 1999; Chen et al. 2011). Thus, it is assumed that their dietary deficiency may contribute to the development of type 2 diabetes mellitus (IOM 2001). Most of the patients with diabetes mellitus have low concentrations of serum chromium (Guimarães et al. 2013), which makes clear the inverse relationship between HbA1c and serum levels of chromium (Rajendran et al. 2015). Thus, hyperglycemia may lead to a decrease in serum chromium concentrations and increase its urinary excretion, worsening diabetes (Gaméz et al. 2002). In healthy subjects, urinary excretion of chromium did not differ after high glycemic index diets compared to low glycemic index diets (Hajifaraji and Leeds 2008). Regarding age, there is a decrease in serum chromium levels in healthy individuals (Rocha et al. 2016). Table 3 shows studies on chromium status in health and disease.

Regarding obesity, serum chromium levels among obese and eutrophic children did not differ (Azab et al. 2014). The relationship between serum chromium and obesity was also not observed in obese women (Yerlikaya et al. 2013). Despite this, the relationship between obesity and insulin resistance is well established (Zhang et al. 2015). In this sense, chromium status in adults with visceral obesity plays an important role in insulin resistance, due to the inverse relationship between capillary chromium level and HOMA-IR (Kim and Song 2014). The chromium status of the toenails was also inversely associated with the incidence of metabolic syndrome, as a function of its relationship with blood lipids (Bai et al. 2015).

Regarding the deficiency diseases, the majority of anemic children due to iron deficiency presented chromium deficiency (Angelova et al. 2014). Despite the antagonistic effect of chromium on iron, by competing for the binding to apotransferrin (Quarles et al. 2011), insufficient intake of iron from the diet can be accompanied in many cases by borderline or insufficient intake of other micronutrients. On the other hand, in vitamin A deficiency, children with nocturnal blindness presented high levels of chromium in biological samples (blood, scalp, and urine (Afridi et al. 2011).

Table 3 Chromium status in health and disease

Reference	Study design	Sample characteristics	Sample size	Results
Healthy individuals				
Rocha et al. 2016	Cross-sectional study	Healthy individuals 18 to 74 years old	240	There was no difference in serum and urinary levels of chromium between the sexes. Serum chromium levels decreased with age.
Metabolic syndrome				
Bai et al. 2015	Cohort	American adults, aged 20–32 years	3648	Higher toenail chromium levels in young adulthood were associated with lower incidence of metabolic syndrome.
Prediabetic individuals				
Rafiei et al. 2014	Cross-sectional study	Prediabetic patients	132	In the group with a normal level of Cr, serum chromium levels decreased with age.
Type 2 diabetes				
Rajendran et al. 2015	Cross-sectional comparative study	Newly diagnosed type 2 diabetes mellitus patients without any pre-existing complications	42	Mean serum chromium concentration was significantly lower in uncontrolled type 2 diabetic patients. There is a decrease in serum chromium levels with age. The decrease in serum levels of chromium is greater after 40 years old.
Harani et al. 2012	Cohort	Adults aged 40 to 60 years	278	Serum chromium levels vary according to glycemic control in subjects with type 2 diabetes. Individuals with poor glycemic control had chromium levels 33% lower than healthy individuals. Serum chromium levels correlated strongly with insulinemia and HOMA-IR.
Guimarães et al. 2013	Randomized double-blind clinical trial	Adults with type 2 diabetes	42	Serum chromium deficiency was observed in 72% of individuals with type 2 diabetes.

(*continued*)

Table 3 (continued)

Reference	Study design	Sample characteristics	Sample size	Results
Enteral nutrition				
Santos et al. 2017	Prospective observational study	Patients aged 26–95 years that underwent percutaneous endoscopic gastrostomy	129	The majority (94%) of individuals with long-term dysphagia due to head and neck cancer or neurological dysphagia had normal serum levels of chromium. None of the patients who had low levels of serum chromium had diabetes or glucose intolerance. Low levels of serum chromium were not related to gender, glycemia, body mass index, serum albumin or transferrin.
Parenteral nutrition				
Capone et al. 2017	Cross-sectional comparative study	Preterm infants receiving parenteral nutrition therapy	706	Chromium supplementation via parenteral nutrition promoted better glucose tolerance and calorie delivery during the first week of life, especially in very low birth weight infants.
Anemia				
Angelova et al. 2014	Cross-sectional study	Children younger than 3 years with iron deficiency anemia	30	Low serum chromium in 73% of children.

High levels of chromium are generally observed in individuals who are submitted to occupational exposure (Scheepers et al. 2008). Inhalation of dust, mist, or vapor and dermal contact of products containing Cr^{+6} are the major routes of occupational exposure to chromium. In humans, there is sufficient evidence for the carcinogenicity of chromium VI compounds. Cr^{+3} compounds, found in foods, were not classifiable as to their carcinogenicity (IARC 2012).

Chromium is also present in nutritional supplements such as chromium picolinate, chromium histidinate, chromium chloride, and chromium nicotinate. The toxicity of supplements containing Cr^{+3} compounds depends on the binder. Study showed chromium picolinate as a mutagenic (Stearns et al. 2002), but the National Toxicology Program's technical report found no evidence of carcinogenic activity of chromium picolinate monohydrate (NTP 2010). Chromium picolinate,

chromium histidinate, and chromium chloride in high concentrations did not result in oxidative damage to DNA, in situations of oxidative stress induced by hydrogen peroxide (Hininger et al. 2007). However, when compared to chromium bound to niacin, chromium picolinate showed higher production of harmful superoxide anion and increased DNA fragmentation. Despite this, Cr^{+3} compounds are relatively nontoxic and exhibit less oxidative stress and DNA damage when compared to Cr^{+6} (Bagchi et al. 2002). The genotoxic effects of Cr^{+3} are unlikely to occur in humans or animals when exposed to the physiological or moderately elevated level of ingestion (Eastmond et al. 2008).

In addition to genotoxicity, adverse effects were reported during studies with chromium supplementation, such as dizziness, headache, nausea, constipation, flatulence, watery stools (Suksomboon et al. 2014), and itching in the palm of the hands (Guimarães et al. 2013). However, short-term chromium supplementation at usual doses of 150–1000 mcg does not increase the risk of adverse effects when compared with placebo. Even so, the safety of long-term supplementation is not established (Suksomboon et al. 2014).

The Role of Chromium in Modulating Gene Expression

Cr^{+3} has been presenting important effects on gene expression. Changes in hepatic cells, insulin activity, and obesity have already been observed (Peng et al. 2010; Rink et al. 2006; Wang et al. 2016).

Regarding hepatic cells, an in vitro study with Cr^{+3} noted improvement in oleic acid-induced steatosis, as it led to a reduction in the accumulation of lipids, fatty acid content, and the amount of triglycerides. This occurred because chromium blocked the transport of oleic acid excess inside the cells to suppress the mRNA and proteins expressed by the gene cluster of differentiation 36 (CD36); and also to downregulate the expression of diacylglycerol acyltransferase 2 (DGAT2) (Wang et al. 2016). CD36 genes express membrane glycoproteins that help in the capture of chylomicrons, VLDL, and long chain free fatty acids by cells (Iqbal and Hussain 2009) as well as stock and secretion of triglycerides in the liver (Kennedy et al. 2011). In turn, the DGAT2 genes express proteins that help to modulate the synthesis of triglycerides, and their excess can lead to the accumulation of this substance in the liver, and, consequently, liver steatosis (Yen et al. 2008).

As for the effect of chromium on the activity of insulin, an in vitro study demonstrated that the use of chromium picolinate (CrPic), complex of chromium chelated with small peptides (CrSP) and chromic chloride (CrCl3), potentiates the insulin action. In the presence of chromium, insulin increased the expression of insulin-like growth factor 1 (IGF-1) gene, responsible for protein synthesis, and reduced levels of ubiquitin mRNA, responsible for protein degradation (Peng et al. 2010).

Finally, the effect of chromium on obesity was observed with supplementation of niacin-bound chromium (NBC), which acted on adipose tissue by *upregulating* the expression of calsequestrin 1 (CASQ1), tropomyosin-1 (TPM1), enolase 3 (ENO3),

and glucose phosphate isomerase1 (GPI1) genes and downregulating the expression of Cell-death-induced DNA fragmentation factor (CIDEA), thermogenic uncoupled protein 1 (UCP1), and tocopherol transfer protein (TPP) genes (Rink et al. 2006). CASQ1 expressed proteins related to stocks of calcium in the sarcoplasmic reticulum of cells, which may reduce the levels of free calcium inside the cells, thus promoting better insulin signaling in fat cells (Beard et al. 2004; Lau et al. 2008). As for the protein tropomyosin, expressed by TPM1 gene, when their levels are reduced, there is an increasing differentiation of preadipocytes into adipocytes; therefore, the presence of this protein reduces the amount of fat in adipocytes (Lau et al. 2008). ENO3 and GPI 1 genes express key enzymes for glycolysis (Lau et al. 2008; Rink et al. 2006). However, CIDEA and UPC1 genes act on the increase in brown adipose tissue; in addition, a study reported that mice deficient in CIDEA are slim and have better resistance to the development of obesity and diet-induced diabetes, because it presented a higher metabolic rate and lipolysis (Lau et al. 2008; Zhou et al. 2003). TPP gene is involved in the transport of α-tocopherol that will be incorporated into LDL-c; therefore, the reduction in the expression of this gene can reduce levels of this lipoprotein. The increased expression of TPP can also increase the antioxidant defense of adipocytes, making breakage of adipose tissue (Lau et al. 2008; Rink et al. 2006).

Thus, chromium supplementation appears to have beneficial effects regarding the modulation of gene expression and liver health, obesity, and diabetes. Despite these results, further studies are needed to generate scientific evidence, since the studies already carried out were in vitro and in animals.

Policies and Protocol

According to the World Health Organization (WHO), the formulation of a guideline follows the steps to identify the issues and priority outcomes for public health, to observe and evaluate the evidence, so that recommendations and implementation for the prioritized issue solution can be formulated (WHO 2010). The WHO considers some micronutrients deficiency in specific population groups to the proposition of guidelines such as the fortification of multiple micronutrients (sachet containing iron, vitamin A, and zinc and other vitamins and minerals that the country regards necessary) to children aged between 6 and 23 months (WHO 2011) and the daily supplementation of iron and folic acid for pregnant women (WHO 2012). Thus, it appears that the health authorities recommend micronutrient supplementation, whose deficiency in risk groups is well consolidated by the scientific literature.

In the case of chromium, so far, no policies, programs, and guidelines recommend this mineral supplementation for risk groups. The evidence is insufficient to support the use of chromium to improve glycemic control in diabetic subjects. The results of the studies with chromium supplementation are conflicting and confused, due to differences in dosage, micronutrient levels achieved with the initial status of chromium supplementation, and methodologies used (Evert et al. 2013). Thus, although clinical trials are already suggesting that chromium supplementation helps in

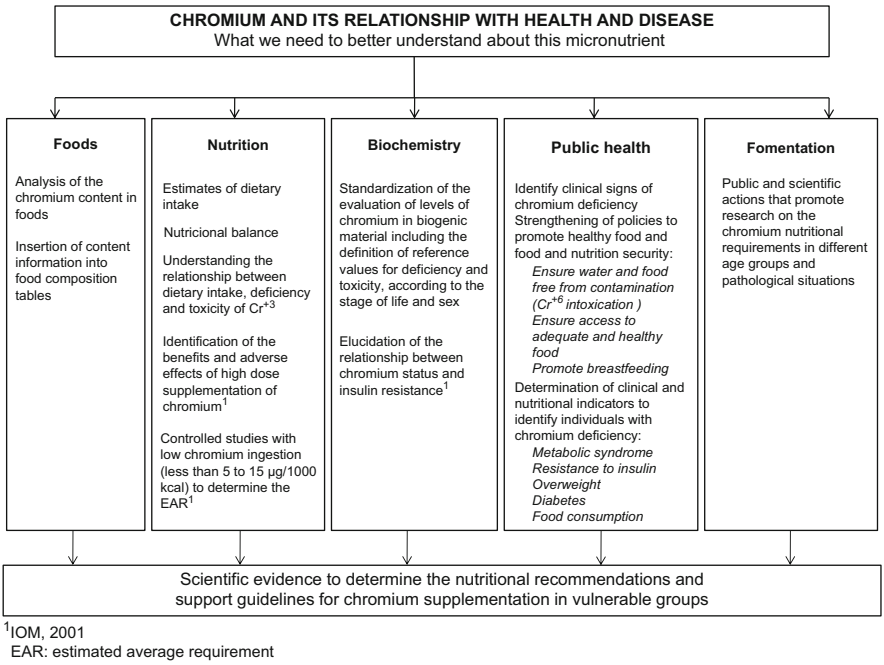

Fig. 3 Research protocol on chromium, health, and disease

controlling diabetes, obesity, and dyslipidemia, the results are still incipient (Onakpoya et al. 2013).

Therefore, chromium still does not meet the requirement of consolidated scientific evidence to develop a guideline recommending supplementation in high-risk groups. More studies are needed on the use of this mineral (Fig. 3), which evaluate the benefits and safety of use in the short, medium, and long term and showing more consistent results, so that it forms part of a policy or program of supplementation for the prevention and/or treatment of both deficiency diseases as chronic. The policies for the promotion of healthy eating and food and nutritional security can be effective initiatives for the prevention of micronutrient deficiencies, including chromium, and for coping with chronic diseases.

Dictionary of Terms

- **Nutritional requirements** – sufficient intake levels to get nutrient requirements in healthy individuals.
- **Adequate intake (AI)** – reference value used when there is insufficient information to determine Recommended Dietary Allowance (RDA).
- **Upper intake levels (UL)** – daily intake limit of the nutrient with no adverse health effects for the majority of the population.

- **Estimated Average Requirements (EAR)** – estimate of daily intake to get needs, indicator, or criteria in half of healthy individuals of a given sex or stage of the life cycle.
- **Recommended Dietary Allowance (RDA)** – daily consumption level that gets the nutrient requirement for almost all healthy individuals at a given stage of life and gender.
- **Bioavailability** – ratio of drug or nutrient concentration to concentration of drug or nutrient at the locus of action.
- **Chromodulin** – low-molecular-weight chromium-binding substance. A 1,5 kDa peptide, composed of four glycine, cysteine, glutamate, and aspartate residues, presenting a tetranuclear characteristic linked to four trivalent chromium ions, being important for insulin signaling.
- **Insulin resistance** – condition where the physiological response induced by insulin is lower than expected considering insulin concentration.
- **Modulation of gene expression** – mechanisms that regulate the synthesis of proteins or other biomolecules by controlling the transcription of genes responsible for the production of these substances.

Summary Points

- Chromium is an important nutrient in food but, because of the lack of scientific evidence, the estimated average requirement (EAR) of its daily intake and the tolerable upper intake levels (UL) have not yet been established.
- Chromium in foods has increased absorption by the presence of amino acids, ascorbic acid, high levels of carbohydrates, oxalate, and aspirin in the diet, while phytates and antacids (sodium hydrogen carbonate, magnesium hydroxide) reduce the absorption of chromium.
- Chromodulin, a low-molecular-weight chromium-binding substance, participates in the mechanism of amplification of insulin-cell signaling.
- Chromium is present in nature in different states of oxidation, with trivalent chromium and hexavalent chromium being the most common forms.
- Chromium is absorbed in the small intestine by passive transport. Due to difficulties in traversing the plasma membrane, the absorption of trivalent chromium is low.
- Hexavalent chromium has strong oxidative capacity and its absorption occurs more easily through the plasma membrane.
- Chromium is transported by ferritin and there may be competition with other metals, such as iron.
- Chromium is present in nutritional supplements in various forms such as chromium picolinate, chromium histidinate, chromium chloride, chromium nicotinate.
- Serum chromium levels vary according to glycemic control in subjects with type 2 diabetes. Serum chromium deficiency appears to be greater in uncontrolled diabetic subjects.

- Serum chromium levels decreased with age in healthy subjects.
- Although chromium is involved in several mechanisms of glucose metabolism, the evidence is not sufficient for long-term therapy in diabetic subjects.
- High levels of chromium are generally observed in individuals who are submitted to occupational exposure.
- In humans, there is sufficient evidence for the carcinogenicity of Cr^{6+} compounds. Cr^{3+} compounds, as found in foods, were not classifiable as to their carcinogenicity.
- Policies to promote healthy eating and food security and nutrition initiatives can be effective for the prevention of micronutrient deficiencies, including chromium, and for coping with chronic diseases.

Abstract

Iodine is an essential micronutrient for normal growth and development and essential component of the thyroid hormones synthesized in the thyroid gland. Iodine deficiency (ID) is one of the most common nutritional disorders. The global efforts to control ID have been very successful, largely because of universal salt iodization

(USI) programs and the number of countries where ID is a public health problem has decreased over the last two decades. Initial assessment and regular monitoring of the iodine status of a population is crucial to develop optimum public health policies and to monitor the outcomes of ID control programs. For this purpose, it has been recommended that the iodine status of a population should be assessed every 3–5 years in surveys that use valid and well-described methods. Generally, four major methods are recommended for the assessment of a population's iodine status: urinary iodine concentration (UIC), total goiter rate (TGR) (assessed by palpation or ultrasound), thyroid-stimulating hormone (TSH) levels in neonates, and serum or dried blood spot (DBS) thyroglobulin (Tg). Currently, the median UIC in spot urine specimens from a representative sample is the most common measure used to assess a population's iodine status. In conclusion, UIC is the universal, well-validated, readily applicable, cost-effective indicator of population iodine status.

Introduction

Iodine deficiency (ID) is one of the most common nutritional disorders and, yet, it is an easily preventable cause of mental impairment worldwide (Zimmermann 2008). This mental impairment has an immediate effect on children's learning capacity, women's health, the quality of life of communities, and economic productivity

(World Health Organization (WHO) et al. 2007). Pregnant women, newborns, infants, and young children are sensitive to the effects of ID. Health consequences of ID including endemic goiter, cretinism, intellectual impairments, growth retardation, neonatal hypothyroidism, increased pregnancy loss, and infant mortality are collectively termed as iodine deficiency disorders (IDD) (WHO et al. 2007; Zimmermann 2009).

It is estimated that approximately one-third of the world's population lives in iodine-deficient areas (Andersson et al. 2012). ID is particularly common in countries in the Eastern Mediterranean region, Asia, Africa, and large parts of Eastern Europe (Ramakrishnan 2002). Although the populations in inland areas, especially mountainous areas such as the Alps, the Himalayas, and the Andes, are particularly vulnerable to having high levels of ID, ID can also occur in coastal areas and on islands (Zimmermann 2009).

In 1991, the World Health Assembly adopted the goal of eliminating ID worldwide as a public health problem. In order to prevent and treat IDD globally, in 1993, universal salt iodization (USI) was recommended by the United Nations Children's Emergency Fund (UNICEF) and the WHO (UNICEF-WHO 1994). This strategy has been approved and implemented in most countries where ID is a public health problem, and elimination of IDD has been an essential part of many nutritional intervention programs (Zimmermann 2008). The global efforts to control ID have been very successful, largely because of USI programs, in line with the recommendations by the WHO and the International Council for Control of Iodine Deficiency Disorders (ICCIDD) (WHO et al. 2007) (Fig. 1). The number of countries where ID is a public health problem has decreased over the last two decades, making the control of ID a major public health success. Despite the changes in data coverage,

Table 1 Changes in number of countries in iodine status from 1993 to 2016

Iodine intake	1993	2003	2007	2011	2016
Insufficient intake	113	54	47	32	15
Sufficient intake	8	67	76	105	102
Excessive intake	–	5	7	11	10
Countries with data	121	126	130	148	127
No data	62	66	63	45	67

Sources: Andersson et al. 2005, 2012; de Benoist et al. 2008; Gizak et al. 2017; http://www.ign.org/scorecard.htm

from 1993 to 2016, the number of iodine-deficient countries decreased from 103 to 15, and the number of iodine-sufficient countries increased from 8 to 102 (Andersson et al. 2005; de Benoist et al. 2008; Andersson et al. 2012; Gizak et al. 2017) (Table 1). However, these achievements are fragile and sustainability is absolutely critical for ID control programs. As ID is a nutritional deficiency that is primarily the result of permanent ID in soil and water, when control programs are interrupted, ID can return at any time after their elimination (Li et al. 2006).

Iodine Cycle and Dietary Considerations

Iodine is an essential micronutrient and it is obtained solely via exogenous dietary sources. As distinct from other essential dietary nutrients, iodine status is not linked to socioeconomic development but rather to geographical location (Rohner et al. 2014). Iodine (as iodide) is widely but unequally distributed across the earth's environment. Most of the iodide is found in the oceans. Iodide ions in seawater are converted into elemental iodine, a volatile form that is evaporated into the atmosphere, and the iodine is returned to the soil by precipitation. However, in many regions, the iodine cycle is slow and incomplete. Additionally, many other factors including geological formation, glaciation, flooding, and soil erosion impact the natural iodine content of the soil. As a result, the iodine in soil and groundwater becomes insufficient (WHO et al. 2001). The iodine content of local foods is dependent on the soil and water iodine content, and therefore, low iodine concentrations in the soil and water result in an iodine-deficient biological environment (Rohner et al. 2014). ID in populations residing in these areas will persist until iodine enters the food chain via foods produced in iodine-sufficient regions or until the addition of iodine to foods (the methods of proven value for mass use are iodized salt and iodine supplementation) (Zimmermann 2009). The natural iodine content of most foods and beverages is low. In general, commonly consumed foods provide 3–80 μg per serving (Haldimann et al. 2005). Foods of marine origin have higher iodine content because marine plants and animals concentrate iodine from seawater. The main sources of dietary iodine are iodized salt, saltwater fish, seaweed, and grains (Zimmermann 2009).

Table 2 Recommendations for daily iodine intake by age and population group

Age/population group	Iodine intake (μg per day)
Children aged 0–59 months	90
Children aged 6–12 years	120
Adolescents (above 12 years)	150
Adults	150
Pregnancy	250
Lactation	250

Source: Reproduced from reference WHO et al. 2007 with permission

Table 2 shows the UNICEF, ICCIDD, and WHO recommendations regarding iodine requirements by age group and for pregnant and lactating women (WHO et al. 2007). As shown in Table 2, the daily iodine requirement during pregnancy increases from 150 μg to 250 μg due to (1) the increase in maternal thyroid hormone production to maintain maternal euthyroidism, (2) transfer of thyroid hormones and iodine to the fetus to cover its needs, and (3) the increase in renal iodine clearance (Glinoer 1997, 2006).

ID is the main cause of endemic goiter, but other substances termed "goitrogens" can interfere with thyroid metabolism and potentiate the effect of ID (Vanderpas 2006). Most goitrogens can cause a major clinical effect when there is coexisting ID (Zimmermann 2008). Iodine absorption can be reduced by the presence of goitrogens in certain foods (including cabbage, broccoli, cassava, lima beans, sweet potato, soy, and millet) and by deficiency in other micronutrients (such as selenium and iron) (Köhrle 1999; Zimmermann 2010). Industrial pollutants, such as perchlorate and disulfides from coal processes, are also important goitrogens. In infants, particularly during periods of exclusive breastfeeding, thyroid function depends solely on iodine in the maternal milk. Maternal smoking during breastfeeding is associated with reduced iodine concentrations in breastmilk, and it dose-dependently reduces breastmilk iodine content up to about half of the normal content and, consequently, may expose the infant to an increased risk of ID (Lauberg et al. 2004).

Iodine Biology

Iodine is an essential component of the thyroid hormones tri-iodothyronine (T3) and thyroxine (T4) synthesized in the thyroid gland. Thyroid hormones, and therefore iodine, are crucial for the regulation of metabolism and for normal physical and neurological development (Zimmermann 2009). The human body contains ~15–20 mg of iodine, of which 70–80% is concentrated in the thyroid gland (WHO 2004). To maintain the normal concentration of iodine in the body, humans require exogenous sources in any of the following chemical forms:

- Iodide, which is rapidly and almost completely (>90%) absorbed in the intestine
- Iodate, which is widely used in salt iodization and is reduced in the gut and absorbed as iodide
- Organically bound iodine (Alexander et al. 1967)

Like iodate, dietary iodine is converted into iodide in the gut lumen, and, as mentioned above, >90% is rapidly absorbed in the stomach and upper small intestine. Fifteen percent of ingested iodine is retained by the thyroid gland (European Food Safety Authority (EFSA) 2006). A sodium/iodide symporter transfers iodide into the thyroid at a concentration gradient of 20–50 times the concentration in the plasma (Eskandari et al. 1997). In individuals with chronic ID, the fraction of iodine absorbed by the thyroid can exceed 80% (Wayne et al. 1964). The half-life of plasma iodine is about 10 h, but this time is reduced in individuals with ID.

The thyroid gland uses iodine for the synthesis of the hormones T4 and T3. T3, the active hormone, is essential for the maintenance of the body's metabolic rate (as it helps to control energy production and oxygen consumption by cells), normal growth, and neural and sexual development (Larsen et al. 1981). T4 is converted to T3 in peripheral tissues by deiodinases (by removing an outer-ring iodine from the T4 molecule). More than 99% of the T3 and T4 circulating in the blood is bound to proteins, and it is only the small amount of free (unbound) thyroid hormone that is bioactive (Rohner et al. 2014). The iodine released when T4 is converted to T3 enters the plasma iodine pool and can it be taken up again by the thyroid or excreted by the kidney. Approximately 90% of ingested iodine is ultimately excreted in the urine (Zimmermann 2008). Thyroglobulin (Tg) is a key precursor in the production of thyroid hormones. The production and release of thyroid hormones are regulated by thyroid-stimulating hormone (TSH), which is released from the pituitary gland into the circulation. This regulation is maintained by feedback inhibition (Ristic-Medic et al. 2009).

Elimination of ID and the Biomarkers to Assess Population Iodine Status

In nearly all countries, the best strategy to control ID is iodization of table salt because salt is widely available and consumed in regular amounts throughout the year, and the cost of salt iodization is quite affordable (WHO et al. 2007; WHO 2014a). When access to iodized salt is inadequate or absent in iodine-deficient areas, temporary iodine supplementation should be considered to ensure optimal iodine intake among vulnerable groups (WHO Secretariat et al. 2007). Giving priority (regarding iodine supplementation) to pregnant and lactating women should be considered until the salt iodization program is scaled up. Additionally, for infants aged 7–24 months, either iodine supplementation or the use of iodine-fortified complementary foods could be considered as temporary public health measures

(WHO et al. 2007). However, in countries or regions in which USI program covers >90% of households and has been sustained for =>2 years, and the monitoring studies indicate iodine sufficiency in the population (within last five years), pregnant and lactating women do not require iodine supplementation (WHO Secretariat et al. 2007; WHO et al. 2007; Zimmermann 2010).

There are three major components of a sustainable program to eliminate IDD:

- Political will and support
- Administrative and legislative arrangements
- Baseline assessment and monitoring systems (WHO et al. 2001, 2007)

Initial assessment and regular monitoring of the iodine status of a population is crucial to develop optimum public health policies and to monitor the outcomes of ID control programs (WHO et al. 2007). For this purpose, it has been recommended that the iodine status of a population should be assessed every 3–5 years in surveys that use valid and well-described methods (WHO Secretariat et al. 2007; WHO et al. 2007).

The most frequently assessed population group that is used to indicate the iodine status of a population is school-age children (SAC), as this group is easy to survey and the iodine status of SAC usually reflects the iodine status of the general population. When SAC are not available for surveys, preschool children and other populations may also be used for population surveys (WHO et al. 2007).

Generally, four major methods are recommended for the assessment of a population's iodine status: urinary iodine concentration (UIC), total goiter rate (TGR) (assessed by palpation or ultrasound), TSH levels in neonates, and serum or dried blood spot (DBS) Tg (WHO et al. 2007) (Table 3). These indicators are complementary because changes in the TGR reflect long-term iodine nutrition (months to years), UIC is a sensitive indicator of recent iodine intake (days), and Tg is associated with an intermediate response to iodine intake (weeks to months) (Zimmermann 2009, 2010).

Urinary Iodine Concentration

UIC is a sensitive, widely accepted, readily applicable, and cost-effective indicator of a population's iodine status. As >90% of ingested iodine is excreted in the urine, UIC is considered a sensitive marker of recent dietary iodine intake, and it is often used for monitoring iodine interventions (Gibson 2005; Nicola et al. 2009). Although UIC does not provide direct information on thyroid function, a low value indicates that a population is at higher risk of developing thyroid disorders (Zimmermann 2010). UIC can be expressed as a concentration (μg/L), in relation to creatinine excretion (μg iodine/g creatinine), or in terms of a 24-h excretion rate (μg/day). An individual's UIC can vary diurnally and day-to-day. Therefore, UIC is not recommended for the diagnosis and monitoring of individuals. However, the variation tends to even out across populations, so UIC can provide a useful measure of the

Table 3 Summary of indicators of iodine status by age and population group

Biomarker	Age group	Advantages	Disadvantages	Rationale/recommendation	Assessment
Median urinary iodine concentration	School-age children (aged 6–12 years) Pregnant women	Spot urine samples are easy to collect Low cost Cut-off points for classifying population iodine status are available Iodine status categories are well established External quality-control program in place	Assesses iodine intake only over the past few days Meticulous laboratory practice is required to avoid contamination with iodine A sufficiently large number of samples must be collected to allow for varying degrees of subject hydration and other biological variation among individuals Not useful for individual assessment	As >90% of ingested iodine appears in the urine, UIC is considered a sensitive marker of recent dietary iodine intake The median UIC from a representative sample of spot urine collections from different population groups is the most common way to classify a population's iodine status	Table 4
Goiter rate assessed by palpation	School-age children	Simple and rapid screening test Requires no specialized equipment	Responds slowly to changes in iodine repletion (months to years) High interobserver variation Specificity and sensitivity are low	Goiter can be used as a baseline assessment of iodine status and as a long-term indicator of the success of an ID elimination program	Table 5 Table 6
Goiter rate assessed by ultrasound	School-age children	More quantitative measurement than palpation Safe and non-invasive International reference values for thyroid volume in schoolchildren are available	Expensive equipment and a source of electricity is needed A specially trained operator is necessary Responds slowly to changes in iodine repletion (months to years)	Goiter can be used as a baseline assessment of iodine status and as a long-term indicator of the success of an ID elimination program	Table 6

TSH	Newborns	Measures thyroid function at a vulnerable age Low costs if a newborn screening program is in force Sample collection and storage on filter paper is simple Blood spots can be stored for several weeks in cool, dry conditions at room temperature	Requires a standardized, sensitive assay Not useful if iodine antiseptics are used during delivery Sampling time should be at least 48 h after birth	TSH is a sensitive indicator of iodine status in newborns For countries and regions that already have a system of neonatal screening in place, the data can be analyzed	A frequency in a population of <3% of individuals with TSH >5 mIU/L Indicates iodine sufficiency
Thyroglobulin	School-age children	Sample collection and storage on filter paper is simple Blood spots can be stored for several weeks in cool, dry conditions at room temperature Can measure improvement of thyroid function within weeks to months after iodine repletion An international reference range has been established	Expensive immunoassay Requires laboratory infrastructure Standard reference material is available, but there is wide interassay variation	Measurement of DBS Tg in school-age children is a sensitive indicator of iodine status in a population and can be used to monitor improving thyroid function after iodine repletion	The Tg reference interval for iodine-sufficient school-age children is 4–40 μg/L

Source: WHO et al. 2007; Reproduced with permission

iodine status of a population. As UICs tend not to be normally distributed, the median is the preferred measure of central tendency (WHO et al. 2007). As it is impractical to collect 24-h samples in population studies, UIC can be measured in spot urine specimens from a representative sample of the target group, and expressed as the median, in μg/L (WHO et al. 2007).

In 1990, UIC was recommended as an effective biochemical indicator of a population's iodine status, and a median UIC of ≤50 μg/L was established as the cut-off value for ID (WHO et al. 1990). Thereafter, in a consultation held by the WHO in 1992, the cut-off value for ID was raised to a median UIC of <100 μg/L, and cut-off values were defined for classifying ID as mild, moderate, or severe (WHO et al. 1994). Importantly, all these cut-off values are based on the median UIC among SAC (WHO 2013).

Table 4 Epidemiological criteria for assessing iodine nutrition based on median urinary iodine concentrations by age group

Age/population group Median urinary iodine concentration (μg/L)	Iodine intake	Iodine status
School-age children		
< 20	Insufficient	Severe ID
20–49	Insufficient	Moderate ID
50–99	Insufficient	Mild ID
100–199	Adequate	Adequate iodine nutrition
200–299	Above requirements	May pose a slight risk
≥300	Excessive	Risk of adverse health consequences (iodine-induced hyperthyroidism, autoimmune thyroid disease)
Pregnant women		
<150	Insufficient	
150–249	Adequate	
250–499	Above requirements	
>500	Excessive	
Lactating women[a]		
<100	Insufficient	
≥100	Adequate	
Children aged < 2 years		
<100	Insufficient	
≥100	Adequate

ID iodine deficiency
[a]For lactating women, the figures for the median urinary iodine concentration are lower than the iodine requirements because of the iodine excreted in breastmilk

Iodine requirements are greatly increased during pregnancy and lactation due to metabolic changes. During pregnancy, the transfer of T4 and iodine from the mother to the fetus is essential for fetal brain development and thyroid function (Glinoer 1997). During lactation, the rate of production of thyroid hormones and urinary iodine excretion returns to normal. However, iodine requirements remain elevated, as the iodine is concentrated in the mammary glands for excretion in breastmilk (WHO Secretariat et al. 2007). Additionally, children <2 years of age are also at a high risk of ID because of their continuing high iodine demands, as high levels of iodine are necessary to support brain and thyroid development (UNICEF 2008). Therefore, the cut-off values for assessing iodine nutrition based on the median UIC in vulnerable populations such as pregnant and lactating women and children <2 years of age are different from those of the general population (WHO et al. 2007; WHO Secretariat et al. 2007). Despite this, UIC cut-offs for vulnerable groups are still in need of validation using functional biomarkers in field studies (Rohner et al. 2014). Epidemiological criteria for assessing iodine nutrition based on the median UIC in different age groups and pregnant and lactating women are presented in Table 4.

Thyroid Size and Total Goiter Rate

The thyroid gland is not visible when the neck is in a normal position, and the lateral lobes are often barely palpable on both sides of the trachea. The term "goiter" refers to a thyroid gland that is enlarged (Perez et al. 1958). Goiter is an adaptive process that occurs in response to low iodine intake, and chronic ID is the primary cause. However, goiter is sometimes the result of a combination of low iodine intake along with additional goitrogenic factors. When dietary iodine intake is insufficient for thyroid hormone synthesis, serum T4 decreases. This stimulates the pituitary gland, which releases more TSH. As a result, TSH induces the growth and metabolic activity of the thyroid follicular cells, leading to the enlargement of the thyroid gland (Zimmermann and Andersson 2012).

Goiter is often a reflection of chronic ID, and the level of goiter in a population can be used as a baseline assessment of a region's iodine status and as a sensitive long-term indicator of the success of an ID elimination program. However, changes in goiter prevalence lag behind changes in iodine status and, therefore, goiter cannot be relied upon to accurately reflect current iodine intake (WHO et al. 2007).

Two methods are available for assessing goiter: neck inspection with palpation and thyroid ultrasonography. Assessment of thyroid size by inspection and palpation is the time-honored method of assessing the prevalence of IDD. Ultrasonography provides a more precise and objective method, for grading goiter (WHO et al. 2007). Although the highest prevalence of goiter occurs during puberty and childbearing age, SAC is the preferred group for goiter surveys, as it is easily accessible. Goiter is also common and responds well to the iodine replacement in this age group (WHO et al. 2007; Zimmermann and Andersson 2012).

Table 5 Classification of goiter by palpation

Grade	Examination findings
0	No palpable or visible goiter
1	A goiter that is palpable but not visible when the neck is in a normal position. Thyroid nodules in a thyroid that is otherwise not enlarged fall into this category
2	A swelling in the neck that is clearly visible when the neck is in a normal position and which is consistent with an enlarged thyroid when the neck is palpated

Table 6 Epidemiological criteria for evaluating the severity of ID based on the prevalence of goiter in SAC

	Degree of ID, expressed as a percentage of the total number of children surveyed			
Indicator	None	Mild	Moderate	Severe
TGR by palpation	0.0–4.9	5.0–19.9	20.0–29.9	≥30
Thyroid volume > 97th Percentile (as assessed by ultrasonography)	0.0–4.9	5.0–19.9	20.0–29.9	≥30

Source: WHO et al. 2007; WHO 2014b. Reproduced with permission
ID iodine deficiency, *SAC* school-age children, *TGR* total goiter rate

Assessing Thyroid Size by Palpation

When using the palpation method, a goiter is diagnosed when "each of the lateral lobes of the thyroid gland has a volume greater than the terminal phalanx of the thumb of the person being examined" (Perez et al. 1958). The palpation method is quite simple and, since 1960, it has been used in most epidemiological studies of endemic goiter (WHO et al. 2007). However, the palpation method has several limitations including high interobserver variation and reduced sensitivity and specificity, so the use of ultrasound is necessary if increased diagnostic precision is required (Delange et al. 2001; Zimmermann et al. 2003).

Goiter assessed by inspection and palpation is graded according to the classification system presented in Table 5. The prevalence of goiter can be quantified using the TGR, which is equivalent to the number of goiters of grades 1 and 2 detected in a population divided by the total number of individuals examined (WHO et al. 2007). A TGR >5% among SAC is recommended by the WHO as an indicator of a public health problem (WHO et al. 2007). Table 6 shows the epidemiological criteria for assessing ID severity based on the prevalence of goiter among SAC.

Assessing Thyroid Size by Ultrasonography

The introduction of the use of ultrasonography to visualize the thyroid gland has been an important development. Ultrasonography is a safe, noninvasive, and specialized technique that can be used to measure thyroid volume more precisely and

objectively than palpation (WHO et al. 1994, 2007). It does not take much time (2–3 min per subject) and is feasible (using portable equipment) even in remote areas (WHO et al. 2007).

The major disadvantages of this method are its high cost, the need for well-trained/experienced technicians, and the inter-rater variability in its application and interpretation (Zimmermann and Andersson 2012). The thyroid is visualized transversely and longitudinally in order to determine the gland's dimensions, and these measurements are used to calculate the thyroid volume (WHO et al. 2007). International thyroid volume reference values for goiter screening have been established (as a function of age, sex, and body surface area) among SAC (Zimmermann et al. 2004). Table 6 shows the epidemiological criteria for assessing ID severity based on the TGR in terms of a thyroid volume > 97th percentile (as assessed using ultrasonography) among SAC.

Thyroid Stimulating Hormone

TSH is secreted by the anterior pituitary gland, and it regulates thyroid hormone synthesis and secretion. Testing for serum TSH is the principal screening test for thyroid dysfunction. Serum TSH concentrations increase when thyroid hormone concentrations are low (hypothyroidism) and decrease when thyroid hormone concentrations are high (hyperthyroidism) (Rohner et al. 2014).

In newborns, the thyroid has smaller iodine stores and a higher iodine turnover than in adults. This high turnover, which is increased in newborns with ID and in fetuses with mild ID, can compromise the neonatal thyroidal secretion of T4, causing increased TSH secretion by the pituitary gland. Hence, in iodine-deficient populations, TSH levels are increased among newborns in the first few weeks of life, a condition known as transient hyperthyrotropinemia (Zimmermann 2010). This fact underpins the use of newborn TSH screening for indicating a population's iodine status. The neonatal period is the only setting in which TSH can provide a useful index of population iodine status (Delange 1997; Zimmermann 2010). Moreover, newborn TSH screening is an important test because it reflects iodine status during a period when the developing brain is particularly sensitive to ID. In older children and adults, although serum TSH may be slightly increased by ID, values are usually in normal range. Therefore, TSH is an insensitive marker for detection of ID in older children and adults, and its routine use in school-based surveys is not recommended (WHO et al. 2007).

When a sensitive TSH assay is used on samples collected 3–4 days after birth, the prevalence of neonatal TSH levels >5.0 mIU/L should be <3% for a region to be classed as an iodine-sufficient region (Zimmermann et al. 2005). In contrast, the TSH levels among other age groups cannot be used to discriminate between iodine-sufficient and iodine-deficient populations (Rohner et al. 2014).

In most developed countries, routine neonatal TSH screening is carried out to detect congenital hypothyroidism (CH) (Pearce and Caldwell 2016). After the pioneering studies were conducted, in addition to its role in diagnosing individual

neonates with CH, neonatal TSH screening was recommended for monitoring population iodine status (Thilly et al. 1978; Kochupillai et al. 1986; Delange 1998, 1999). Subsequently, neonatal TSH screening started to be used as a tool to assess the severity of ID and monitor the outcomes of iodine prophylaxis programs in countries and subnational regions. Although conflicting results have been reported by some studies, especially regarding appropriate cut-off values (Rajatanavin 2007; Burns et al. 2008), many countries have developed successful models (Tylek-Leman'ska et al. 2003; Zimmermann et al. 2005; Gyurjyan et al. 2006; Charoensiriwatana et al. 2008). In Thailand, the use of a geographic information system in the neonatal TSH screening program has enabled the identification of ID at the subdistrict level (Charoensiriwatana et al. 2008). A study conducted in Poland indicated that with the reintroduction of iodized salt in 1992, the prevalence of neonatal TSH levels >5 mIU/L dropped from above 20% in 1991 to just above 5% between 1995 and 2000 (Tylek-Leman'ska et al. 2003). Another study conducted in Switzerland demonstrated that a 25% increase in the concentration of iodine in iodized salt resulted in a reduction of the prevalence of neonatal TSH levels >5 mIU/L from 2.9% to 1.7%, and the iodine status among children and pregnant women has increased from "borderline" to "sufficient" (Zimmermann et al. 2005).

However, the use of neonatal TSH as a biomarker has several limitations. Factors other than ID (including prematurity, birth weight, mode of delivery, maternal or newborn exposure to iodine-containing antiseptics, type of collection paper used for the blood spot, and TSH assay methodology) can affect newborn TSH levels and lead to misinterpretation of the results (Li and Eastman 2010). Evidence shows that the mean serum TSH level sampled from neonates less than 24 h after birth is significantly higher than that sampled from neonates after the first 24 h (Lott et al. 2004). Thus, as a result of the physiological surge in serum TSH in the first 24 h after birth, the appropriate sampling time point for CH screening is between 2 and 4 days after birth (American Academy of Pediatrics et al. 2006).

In conclusion, when a neonatal TSH screening program is in force, the data can be used to assess iodine status at the population level (WHO et al. 2007). However, the implementation of a neonatal TSH screening program requires technical experience and financial resources. Therefore, using this type of program solely to assess community iodine status is not cost-effective and therefore not recommended (Delange 1999; WHO et al. 2001; Ristic-Medic et al. 2009).

Thyroid Hormone (T4 and T3) Concentrations

Elevated serum TSH combined with normal serum T4 and T3 is termed subclinical hypothyroidism, while unchanged or increased serum T3 and TSH combined with decreased serum T4 is termed overt hypothyroidism, which tends to occur in iodine-deficient populations (Delange et al. 1972). An increased T3 concentration is an adaptive response of the thyroid to ID (while, in contrast, fasting and malnutrition are associated with low T3 concentrations). Among individuals with

hypothyroidism, T3 concentrations may not decrease until the disease has progressed to a great extent, because increased TSH concentrations stimulate T3 release from the thyroid (Rohner et al. 2014). Usually, these changes are within the normal range, and the overlap between thyroid hormone concentrations in iodine-deficient and iodine-sufficient populations is large enough to make thyroid hormone concentrations poor indicators of iodine status (WHO et al. 2001, 2007; Zimmermann 2009). Serum concentrations of the thyroid hormones are not recommended as an indicator of population iodine status due to impracticability, high cost, and less sensitivity (WHO et al. 2007).

Thyroglobulin Concentration

Tg is a highly abundant intrathyroidal protein comprising two 330-kDa protein chains, and it is synthesized only in the thyroid gland (van de Graaf et al. 2001). When iodine intake is sufficient, small amounts of Tg are secreted into the circulation, and serum Tg is normally <10 μg/L (Spencer and Wang 1995). The thyroid hyperplasia and goiter that are characteristic of ID both increase the amount of Tg that is released into the blood (in response to TSH stimulation) (WHO et al. 2007; van de Graaf et al. 2001).

Tg can be measured in serum or dried blood spots (DBSs). The implementation of DBS technology is a significant development, as it makes sampling practical even in remote and resource-poor regions (Zimmermann et al. 2006). The measurement of DBS Tg among SAC is recommended as a sensitive indicator of the iodine status of a population, and DBS Tg can be used to monitor improvements in thyroid function after iodine repletion (WHO et al. 2007).

An international reference range for DBS Tg was established in a multicenter study of healthy 5- to 14-year-old children that can be used for monitoring iodine status (Zimmermann et al. 2006). According to this study, the DBS Tg reference range for iodine-sufficient SAC is 4–40 μg/L (Zimmermann et al. 2006; WHO et al. 2007). This is similar to the reference range for adults, which is reported to be 3–40 μg/L (Baloch et al. 2003). In 1994, the WHO, ICCIDD, and UNICEF proposed that a median Tg concentration < 10 μg/L could be used to indicate adequate iodine nutrition among SAC. In another cross-sectional study, reference ranges for DBS Tg were established among 6- to 12-year-old primary SAC in 12 countries (Zimmermann et al. 2013). On the basis of the findings of this study, Tg was proposed as a sensitive indicator of both low and excess iodine intake. It was recommended that a median Tg level < 13 μg/L and/or <3% of Tg levels >40 μg/L could be used to represent iodine sufficiency among primary SAC (Zimmermann et al. 2013). Tg reference ranges for population iodine sufficiency have not been established for other age groups or pregnant women (Pearce and Caldwell 2016).

Tg holds promise as a biomarker for ID, and it is increasingly being used as an index of population iodine status (Ma and Skeaff 2014). In prospective studies, DBS Tg has been shown to be a sensitive measure of iodine status, and it reflects intermediate response (weeks to months) iodine repletion (Zimmermann et al. 2006). However, there are some limitations associated with the use of Tg, and

several questions need to be resolved before Tg can be widely adopted as an indicator of iodine status (Zimmermann 2008). One disadvantage of the use of Tg as a biomarker of iodine status is the fact that it cannot be reliably measured in people with detectable anti-Tg antibodies (Spencer and Wang 1995). In addition, despite the development of a standard reference material for serum Tg, laboratory assay results for this biomarker remain highly method dependent (Schlumberger et al. 2007).

Policies and Protocols

The elimination of IDD is an important developmental indicator, and it should be a priority for governments and international agencies. In order to prevent, treat, and eliminate IDD, USI remains the key strategy recommended by the WHO, UNICEF, and ICCIDD. Moreover, national policies regarding salt iodization and the reduction of salt intake to <5 g/day are both essential, and they should be implemented with close collaboration. An effective ID control program should involve the following processes (as recommended by the WHO):

- Baseline assessment of the population iodine status
- Dissemination of findings
- Planning
- Achieving political will
- Implementation
- General program monitoring and evaluation

Sustainability is a critical issue in ID control programs. To be sustainable, programs must have an effective monitoring system that ensures that basic information is regularly collected regarding the iodization of salt and the population iodine status. It is recommended that population iodine status is assessed regularly in surveys that use universally accepted, practical, and cost-effective methods. Additionally, specific target groups (including pregnant women, nursing mothers, and newborns) should not be neglected, and so they should be included in the monitoring studies. UIC is a sensitive and universal indicator of iodine status in SAC and pregnant women. Also, serum or DBS Tg values can be used as population indicator of iodine status in SAC. For countries and regions that already have a system of neonatal TSH screening in place, neonatal TSH data can be analyzed as a supplementary assessment method (in addition to regular UIC screening), as the only additional costs incurred would be for the data analysis.

Dictionary of Terms

- **Goiter** – A thyroid gland that is enlarged.
- **Iodine** – A natural chemical element of the earth. It is an essential micronutrient for normal growth and development and essential component of the thyroid hormones produced by the thyroid gland.

- **Iodine Deficiency** – One of the most common nutritional disorders.
- **Iodine deficiency disorders** – Collective terminology of health consequences of ID including endemic goiter, cretinism, intellectual impairments, growth retardation, neonatal hypothyroidism, increased pregnancy loss, and infant mortality.
- **Screening** – An important concept in public health medicine and application of a specific diagnostic procedure in a population to detect asymptomatic disease.
- **Thyroglobulin** – Intrathyroidal protein synthesized only in the thyroid gland.
- **Thyroid-stimulating hormone** – Secreted by the anterior pituitary gland and it regulates thyroid hormone synthesis and secretion.
- **Thyroxine (T4) and tri-iodothyronine (T3)** – Thyroid hormones produced by the thyroid gland.
- **Total Goiter Rate** – Equivalent to the number of goiters of grades 1 and 2 (assessed by palpation) or thyroid volume $>$ 97th percentile (assessed by ultrasonography) detected in a population divided by the total number of individuals examined.
- **Universal Salt Iodization** – Iodization of all salt for human and animal consumption according to the internationally agreed recommended levels.
- **Urinary Iodine Concentration** – A sensitive indicator of recent iodine intake (days).

Summary Points

- ID is one of the most common nutritional disorders and, yet, it is an easily preventable cause of mental impairment worldwide.
- The global efforts to control ID have been highly successful, largely due to USI programs.
- In order to prevent and treat IDD, the best strategy has been the iodization of salt because it is widely available, consumed in regular amounts throughout the year, and also cost-effective.
- Baseline assessment and regular monitoring of population iodine status is crucial for effective surveillance of USI programs.
- The iodine status of populations should be assessed in surveys conducted every 3–5 years using valid and well-described methods.
- Four major methods are recommended to assess and monitor the iodine status of a population: UIC, total goiter rate (by palpation or ultrasound), serum Tg, and TSH levels in neonates.
- As $>$90% of ingested iodine is excreted in the urine, UIC is considered a sensitive biomarker of recent dietary iodine intake.
- Currently, the median UIC in spot urine specimens from a representative sample is the most common measure used to assess a population's iodine status.
- The median UIC is also recommended for assessing the iodine status of pregnant women (using specific cut-off values).
- TSH is a sensitive indicator of iodine status in newborns.

- For countries and regions that already have a system of neonatal TSH screening in place, as a supplementary assessment method, the data can be used to assess iodine status at the population level.
- Tg holds promise as a biomarker for ID, and it is increasingly being used as an index of population iodine status.
- The measurement of DBS Tg among SAC is recommended as a sensitive indicator of iodine status in a population, and DBS Tg can be used to monitor improvement in thyroid function after iodine repletion.
- In conclusion, UIC is the most universal, well-validated, readily applicable, cost-effective, and recommended indicator of population iodine status (including improvements in the iodine status after iodine repletion).

Effects of Iron Deficiency on the Oropharyngeal Region: Signs, Symptoms, and Biological Changes

93

Preeti Tomar Bhattacharya and Satya Ranjan Misra

Contents

Abstract

Iron is the most abundant essential trace element inside human body. Iron deficiency anemia is the most common nutritional deficiency worldwide. It reportedly causes reduction in working capacity, hampers mental development in growing children and young adults, and significantly worsens the quality of daily life. Nonpregnant women in reproductive age group and pregnant women are equally vulnerable to iron deficiency. Apart from systemic signs and symptoms

like pallor, fatigability, palpitations, koilonychia, light headedness, and shortness of breath, oropharyngeal region can also provide important diagnostic clues to this systemic condition. Moreover, other oral conditions such as aphthous ulcers and burning mouth syndrome; premalignant conditions such as Plummer Vinson syndrome, oral lichen planus, and oral submucous fibrosis; and malignant disease such as oral squamous carcinoma have been associated with iron deficient state. This review appraises various signs and symptoms encountered within oropharyngeal region in the iron deficient state and underlying biological changes responsible for those clinical manifestations.

Introduction

Iron is the most abundant essential trace element in the body and it is critical for the growth and differentiation of all cells. Around 3–5 g of iron is stored in the body with majority being in blood and rest in liver, bone marrow, and muscles in the form of heme. About 1–2 mg of iron is lost every day, through skin, enteric desquamation and minor blood losses. Intestinal absorption balances this loss. Iron plays an imperative role in oxygen transport, electron transfer, and serves as a cofactor in many enzyme systems, such as peroxide-generating enzymes and nitrous oxide-generating enzymes that are vital for immune cells to function normally (Bhattacharya et al. 2016b).

The status of iron inside body can vary from iron overload to normal iron status, to iron deficiency with no apparent signs, and finally to iron deficiency with anemia (World Health Organization recommendations 2001).

Iron deficiency can be defined as a condition in which there are no mobilizable iron stores and in which signs of a compromised supply of iron to tissues, including the erythron, are noted. The more severe stages of iron deficiency are associated with anemia. The mild to moderate level of iron deficiency may not result in clinically evident anemia but the cells are still functionally impaired. According to the World Health Organization criteria, men with Hb < 13 g/dL and women with Hb < 12 g/dL are defined as having Hb deficiency or anemia (WHO 2001). Additionally, as per Shine (1997) patients with serum iron level < 60 mg/dL are defined as iron deficient.

Iron deficiency anemia (IDA) is the most common, easily diagnosed and treated anemia and with women being more frequently affected than men. The prevalence of iron deficiency anemia varies widely with age, sex, and race. About 2% of adult men, 9–12% of white adult females, and roughly 20% of black adult women were found to be suffering from IDA in the study conducted by Johnson-Wimbley and Graham (2011). Similarly study by Shaw et al. (1999) found the incidence of iron deficiency in Taiwan to be 2.1% in males and 10.7% in females out of which only 0.2% males and 2.1% females were suffering from IDA.

Patients with IDA may have characteristic systemic symptoms such as pallor, fatigue, weakness, lightheadedness, exertional dyspnea, tachycardia, palpitations, postural hypotension, and neuropathy. Oral symptoms and signs may include mucosal pallor, atrophic glossitis, generalized oral mucosal atrophy, anemic stomatitis, angular cheilitis, tenderness or burning sensation of oral mucosa, various types of oral candidiasis, lingual varicosities, recurrent aphthous ulcers, dry mouth, and dysgeusia. Severe prolonged iron deficiency may result in Plummer Vinson Syndrome (Fig. 1).

Burning mouth syndrome has been described as the clinical condition characterized by burning sensation of the oral mucosa without any apparent mucosal changes. Burning mouth syndrome may also be associated with deficient iron status.

Apart from iron deficiency anemia, the role of iron deficiency in oral premalignant conditions has been extensively studied and the results suggest that deficient nutritional iron status may predispose to the development and progression of Oral lichen planus, and Oral submucous fibrosis. Low iron levels can result in increased oxidative stress thus playing some role in development of oral cancer.

The authors aim at discussing biological changes, signs, and symptoms associated with iron deficiency in relation to oropharyngeal region.

Signs and Symptoms of Iron Deficiency

Anemia

Per Benoist et al. (2008), WHO data (1993–2005), globally, anemia affects 1.62 billion people which corresponds to 24.8% of the population with highest prevalence noted in preschool-age children and lowest in men. Various reasons of iron

deficiency include an increased demand for red blood cells (RBC) production during childhood growth spurts and during pregnancy; a decreased intake of dietary iron due to low socioeconomic status or negligence; reduced absorption of iron in patients with total gastrectomy or celiac sprue and chronic blood loss associated with excessive menstrual flow, gastrointestinal diseases, such as peptic ulcer, diverticulosis, or malignancies (Neville et al. 2009). Patients with IDA may have characteristic systemic symptoms such as fatigue, weakness, lightheadedness, shortness of breath, and palpitations. Oral signs of iron deficiency anemia include a myriad of conditions such as mucosal pallor, general mucosal atrophy, stomatitis, atrophic glossitis, cheilosis, lingual varicosities, angular cheilitis, oral lichen planus, various forms of candidiasis, and aphthous ulcers as outlined by Wu et al. (2014) The recommended daily dietary intake of iron in various countries has been listed in the Table 1.

Atrophic glossitis is a term used for "flattening of the tongue papillae" leading to a smooth and reddish tongue that may mimic geographic tongue or migratory glossitis. The bald appearance of the tongue dorsum results from the atrophy or loss of filiform papillae initially as they are most susceptible to nutritional deficiency followed by fungiform papillae. The circumvallate and foliate papillae on the posterior third of the tongue are spared. Samad et al. (2015) described the condition as being reversible on proper nutritional supplementation and regeneration of the lost papillae occurs in reverse order. In more severe cases, the tongue may be tender. Long et al. (1998) also reported cheilosis (dry scaling of the lips and corners of the mouth) as a common finding in patients of iron deficiency anemia (Fig. 2).

Angular cheilitis is a protean condition with several predisposing factors such as nutritional deficiency of vitamins and iron, lip-sucking, dehydration, overclosure of

the jaws, improper vertical dimension in artificial dentures, and mixed bacterial and fungal infections (Shafer et al. 2003). This lesion is characterized by wrinkling of epithelium at the corners of the mouth unilaterally or bilaterally which over the time becomes macerated, more pronounced to from one or more deep fissures which later ulcerate with or without exudative crusting. These fissures characteristically terminate at the mucocutaneous junction and do not involve the mucosal surface of the commissures of the mouth. With time, these fissures tend to get infected with bacterial and fungal strains such as staphylococci, streptococci, and candida species (Fig. 3; Shafer et al. 2003).

Shin-Yu Lu (2016) found in his study that iron deficiency led to a high incidence of Candida infection among the patients and resulted in a variety of clinical forms such as angular cheilitis, pseudomembranous candidosis, erythematous candidosis, median rhomboid glossitis, chronic mucocutaneous candidosis, papillary hyperplastic candidosis, and cheilocandidosis. Impaired cellular immunity along with epithelial changes may result in one or more types of candidal lesions. Candidiasis is an opportunistic infection caused commonly by yeast like fungus *Candida albicans* apart from other species such as C. tropicalis, *C. glabrata, C. parapsilopsis, C. guilliermondii, C. pseudotropicalis*, *C. stellatoidea*, and *C. krusei*. Acute and chronic forms of pseudomembranous candidiasis are the most common and characterized by the soft, white, elevated, curd-like scrapable plaques on buccal mucosa, gingivae, tongue, and floor of the mouth (Fig. 4). In erythematous form of candidiasis, the clinical manifestation is of red lesion involving palatal mucosa, buccal mucosa, and tongue (Fig. 5 and 6). When erythematous candidiasis involves tongue, it is referred to as median rhomboid glossitis (Fig. 5). Chronic mucocutaneous candidiasis presents with firm, white, nonscrapable plaques usually on the lips, tongue, and cheeks. The papillary hyperplastic candidiasis is the third stage of denture stomatitis. The first stage consists of numerous palatal petechiae and a

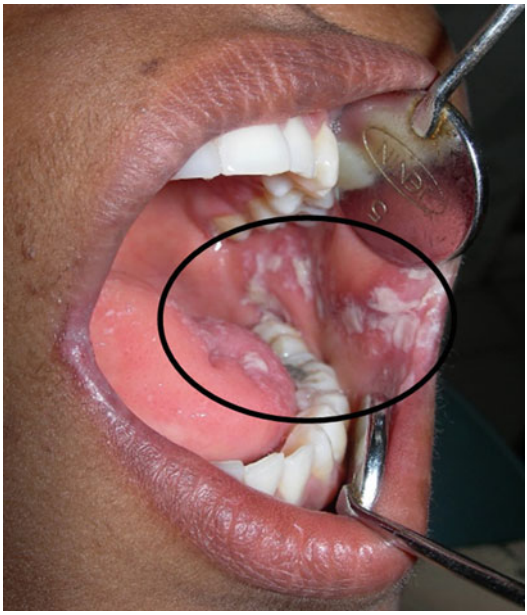

Fig. 4 Pseudomembranous candidiasis on left buccal mucosa and tongue. Photo shows white curd-like deposits on left buccal mucosa and tongue which are scrapable in an anemic patient (Source: Personal collection)

diffuse erythematous involvement of the denture-covered mucosa is seen in the second stage. The third stage shows the development of tissue granulation or nodularity (papillary hyperplasia) commonly involving the central areas of the hard palate and alveolar ridges (Greenberg et al. 2008).

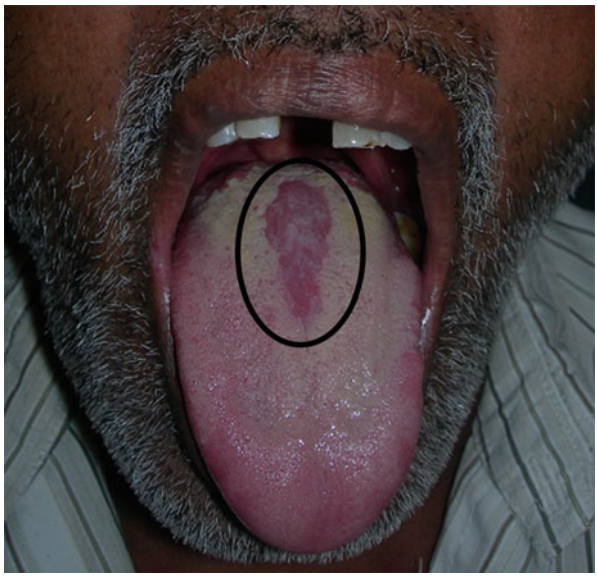

Fig. 5 Median rhomboid glossitis or erythematous candidiasis of tongue. Photo showing red rhomboidal shape lesion, i.e., median rhomboid glossitis on dorsum of tongue posteriorly is a type of erythematous candidiasis (Source: Personal collection)

Fig. 6 Erythematous candidiasis on palate. Photo showing red lesion with few white components is a manifestation of erythematous candidiasis (Source: Personal collection)

Other miscellaneous oral manifestations found in patients of iron deficiency anemia in various studies include hyperpigmentation, recurrent oral ulcers, lingual varicosities, and oral lichen planus (Wu et al. 2014; Samad et al. 2015; Lu SY 2016). Varicosities are abnormally dilated and tortuous veins that are often found on the ventral surface of the tongue in aged individuals due to the age-related loss of connective tissue tone supporting the veins (Neville et al. 2009). Oral lichen planus (OLP) is characterized as presence of radiating white or gray, velvety, thread-like papules in a linear, annular, or retiform manner forming a typical lacy reticular patch known as Wickham striae or papules over the buccal mucosa, lips, tongue, and palate which may or may not be associated with erosion or ulceration (Fig. 7). Pica, a

Fig. 7 Papular oral lichen planus on right buccal mucosa. Photo shows nonscrapable white granular lesion or oral lichen planus on right buccal mucosa in an anemic patient (Source: Personal collection)

behavioral disturbance comprising abnormal consumption of dirt or mud, also referred to as geophagia, is seen in iron deficiency patients (Louw et al. 2007). This results in poor oral hygiene; inflamed, erythematous gingiva; and staining of teeth.

Oral symptoms as outlined by Wu et al. (2014) chiefly due to atrophic mucosa and fungal infections included burning sensation of oral mucosa, pain, dry mouth, numbness of oral mucosa, recurrent ulcers, bad taste, and dysfunction of taste. The reason behind symptoms in iron deficiency anemia patients has been described in details under the biological changes section of the chapter.

Plummer Vinson Syndrome (PVS)

Also, known as Paterson Kelly syndrome or sideropenic dysphagia is a triad of microcytic hypochromic anemia, atrophic glossitis, and esophageal webs or strictures. Apart from these findings koilonychia or spoon-shaped nails and atrophic changes in the conjunctiva have also been associated with this syndrome.

PVS was first described by Paterson and Kelly in 1919. PVS is associated with iron deficiency anemia and has become increasingly rare due to early diagnosis and treatment of deficient iron status. Postmenopausal women are more commonly affected. One or more signs and symptoms of iron deficiency anemia may be present along with the above-mentioned triad. Apart from these, koilonychia or spoon-shaped nails of brittle nature are also noted. Dysphagia due to esophageal strictures is a characteristic finding in these patients. PVS is a potentially malignant disorder with the risk of development of squamous cell carcinoma of the esophagus due to the post cricoidal webs that are formed as described by Samad et al. (2015).

Burning Mouth Syndrome

Burning mouth syndrome (BMS) is a condition characterized by a burning sensation of the oral mucosa in the absence of clinically noticeable mucosal changes. BMS is described by 2–3% of adults and 14% of postmenopausal women. The prevalence is reported to have been more in advanced age, women, and Asians as compared to males and Caucasians, respectively. Lopez-Jornet et al. (2010) reported BMS as one of the most common disorders encountered in oral mucosal disease clinics. Systemic factors which predispose to BMS include iron deficiency anemia and PVS apart from others. The tip and lateral borders of the tongue are commonly involved.

Premalignant Conditions

Oral submucous fibrosis (OSMF) is an insidious, chronic, and debilitating condition encountered in South Asian population and has a malignant predisposition and can affect any part of the oral cavity and sometimes the pharynx (Jayasooriya et al. 2011). Epithelial atrophy characterizes OSMF along with changes in the connective tissue fibers of the lamina propria and deeper parts leading to stiffness of the mucosa causing trismus and inability to eat. Globally, estimates of OSMF shows a confinement to Indians and Southeast Asians, with an overall frequency of about 0.2–0.5% in India from 20 to 40 years' age range (Reddy et al. 2011). Angadi and Rao (2011) suggested strong association of OSMF with a risk of OSCC with a malignant transformation rate of 7.6% over a period of 17 years.

Interestingly, Bhattacharya et al. in 2016a described a very rare case of onset and subsequent treatment of OSMF secondary to iron deficiency anemia which supports the hypothesis that iron deficiency may have some role in the initiation and progression of this premalignant condition.

Oral lichen planus and Plummer Vinson syndrome as discussed earlier are potentially malignant conditions and have been associated with the iron deficient state.

Oral Cancer

Oral cancer is a disfiguring, potentially fatal disease that continues to rise in incidence among younger and older people alike. The annual incidence of oral and pharyngeal cancer is approximately 615,000 worldwide as reported by Mignogna et al. (2004). More than 90% of oral cancer is oral squamous cell carcinoma (OSCC). Richie et al. (2008) outlined cigarette smoking, chronic alcohol consumption, and low dietary nutrition as the major risk factors for onset of oral squamous cell carcinoma. Negri et al. in 2000 and Petridou et al. in 2002 found significant risk of oral cancer with decreased dietary intake of iron whereas Gupta et al. in 1999 found no significant association between oral premalignancy and low iron intake in Indian women. Nevertheless, in a case controlled study conducted by Richie et al. (2008), a significant association between low iron body stores and an increased risk of

oral cancer was appreciated. The possible reason of this association has been described in detail in the further biological changes section.

Biological Changes

Iron deficiency has profound effect on important bodily functions which has been demonstrated in numerous studies and was also observed by Camaschella (2015). Various biological changes underlying the iron deficient state have been outlined in Fig. 8.

Iron deficiency is the result of long-term negative iron balance within the human system. With decreased dietary intake or increased iron loss from the body, the stores of iron namely hemosiderin and ferritin are progressively reduced. This results in the compromised supply of iron to the transport protein apotransferrin. The overall condition leads to diminished saturation of transferrin and an increase in transferrin receptors in the circulation and on the surface of cells, including the erythron. Hence there is deficient supply of iron to all the tissues including erythron. Enhanced expression of transferrin receptors on cell surfaces is in proportion to actual iron need of the same. Consequently, insufficient supply of iron to all other tissues ensues due to compromised supply of iron to the erythron. Thus, lack of mobilizable iron stores in due course cause a demonstrable change in classical laboratory tests, such as measurement of hemoglobin, mean corpuscular hemoglobin concentration, mean corpuscular volume, total iron-binding capacity, transferrin saturation, and zinc-erythrocyte protoporphyrin.

All physiologic effects of iron deficiency are dependent on the severity of anemia, decreased oxygen transporting capability of the blood and the iron-containing

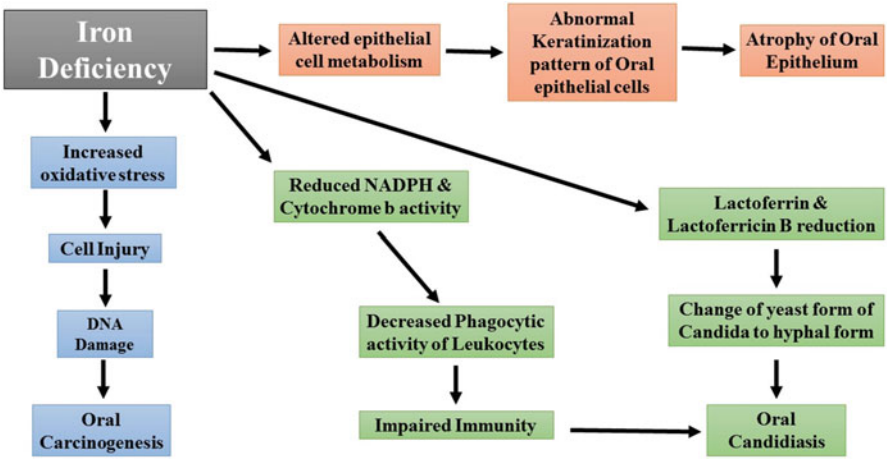

Fig. 8 Biological changes and clinical manifestations. Flowchart shows the most important biological changes and the resultant clinical manifestations in iron deficient status (Source: Personal collection)

proteins (Wu et al. 2014). Many reviews have described atrophy of the oral and gastric epithelium and nail changes in individuals as the foremost nonerythroid changes in humans and animals. The oral changes are the most prevalent and significant, with atrophic glossitis, angular cheilitis, and Plummer Vinson syndrome characterized by postcricoid dysphagia being the most common. Iron is an essential trace element for the growth and maturation of all cells. Rennie et al. (1982) in their study on the buccal epithelial cells in iron deficient subjects stated that a decidedly significant reduction in the total epithelial thickness and predominantly the thickness of the maturation compartment, along with low enzyme levels in the buccal epithelium, was noted. Richie et al. (2008) also confirmed similar findings by observing that the histological examination of the oral mucosa in iron deficiency anemia revealed epithelial atrophy with thinning of the lamina propria of the connective tissue. Sustained decreased levels of iron within blood result in reduced hemoglobin levels carrying inadequate supply of oxygen to oral mucosal tissues and finally leading to mucosal atrophy (Rennie et al. 1982; Wu et al. 2014). The biological changes in the blood profile, oral epithelium, defense cells, and enzymes system involving iron result in innumerable manifestations is evident in iron deficiency anemia. Per Montes et al. (2014) papillary atrophy of the tongue or atrophic glossitis results as a consequence to abnormalities in keratinization patterns and cellular structure of oral epithelium secondary to changes in the metabolism of oral epithelial cells. The thinned or atrophied oral mucosa is susceptible to ulcer formations.

Pigmentation in iron-deficiency anemia is evident due to excessive tyrosine formation which leads to abnormal melanosis. Ghosh K in 2006 elucidated the role of iron in melanin metabolism. Accordingly, enzymes phenylalanine hydroxylase and homogentisic oxidase are dependent on iron for their action on homogentisic acid and melanin quinines. In the scenario of iron deficiency, homogentisic acid cannot be metabolized and hence ensue excessive tyrosine formation.

There is no biological explanation for pica indulgence. Other miscellaneous clinical findings such as lingual varicosities and oral lichen planus have been reported in iron deficient cases without any logical explanation for the same.

The gastrointestinal tract is susceptible to iron deficiency; rapidly losing the iron-dependent enzymes because of its high cell turnover, causing degeneration of the mucosa, and predisposing to web formation (Chisholm 1974). Also, the resultant epithelial atrophy, changes in cell kinetics, and decreased repairing capacity of the mucosa amplify the effects of carcinogens and cocarcinogens and consequently predispose the oropharyngeal area to malignant transformation as described by Dinler et al. (2009). Dantas (1993) correlated the reason of dysphagia to decreased gastric motility in iron deficiency.

Iron has a significant role in immune-surveillance, due to its properties of promoting growth and differentiation inducing properties for leukocytes interfering with cell-mediated immunity and chemical mediators of inflammation as observed by Oppenheimer (2001). Iron deficiency adversely affects the normal defense system of the body as it compromises the body's immune system to act against pathogens. Iron deficiency also negatively influences the normal defense systems against infections. Ribonucleotide reductase is an iron-dependent enzyme required for DNA synthesis, hence Doherty

(2007) elucidated that in iron deficiency T lymphocyte formation is decreased thereby impairing the cell-mediated immunity. Besides, in iron deficiency even the phagocytic activity of the neutrophils is impaired thereby decreasing host defense against pathogens.

Loiarro et al. (2010) expounded the role of iron dependent co-enzyme nicotinamide adenine dinucleotide phosphate hydrogen oxidase and cytochrome b in immunity and illustrated that the activation of above mentioned enzymes does not occur in the iron deficient state and consequently the formation of free hydroxyl radicals within the leukocyte and the respiratory burst are affected thus decreasing the phagocytic capability of neutrophils. In a very noteworthy study, Soukka et al. (1992) found that lactoferrin, an iron binding glycoprotein, and lactoferricin B (LFcin B), an LF-derived antimicrobial peptide, inhibit the growth of Candida species, strains, not only in yeast form but also in hyphal form, and hence are important for the pathogenesis of this fungus. Therefore, the atrophied oral epithelium is colonized by the opportunistic candida species, normal commensals in the oral cavity, especially the tongue, and there is hyphal invasion of the stratum corneum.

The role of iron in collagen synthesis is well-documented. Iron is essential for collagen synthesis by enzymes proline hydroxylase and peptidyl lysine hydroxylase during hydroxylation of proline and lysine, respectively. Iron is a cofactor along with molecular oxygen alpha-Ketoglutarate and ascorbic acid that is used by peptidyl proline hydroxylase in this process. Ganapathy et al. (2011) reestablished that in oral submucous fibrosis there is iron deficiency as there is extensive uncontrolled collagen production which requires iron among other nutrients. Besides due to ulceration and epithelial atrophy patient is unable to chew adequately hence the deficiency is aggravated.

Per Lin et al. (2013), untreated dry mouth and iron or vitamin B12 deficiency over a period may lead to partial atrophic changes in the epithelium of the tongue as described earlier. In BMS patients, this change is so indiscernible that it is difficult to appreciate the same on clinical visual inspection. Thus, the spicy salivary components may diffuse through the atrophied oral tongue epithelium into the subepithelial connective tissue and irritate the free sensory nerve endings persuading burning sensation, pain, or numbness of the tongue.

Iron deficiency has been implicated in the pathogenesis of oral cancer as it induces oxidative stress. There is an equilibrium between the prooxidant and the antioxidant systems in the body; when the prooxidant systems predominate favoring oxidation, they cause direct oxidative damage to cellular molecules like the deoxyribonucleic acid (DNA) which is referred to as oxidative stress. Reactive oxygen species and free radicals are produced in iron deficiency which contribute to oxidative stress leading to cell injury (Vives Corrons et al. 1995; Halliwell 1994).

Policies and Protocols

The developed as well as developing nations need to draft strong policies and follow protocols vigorously to eradicate iron deficiency from the population especially in low socioeconomic areas.

Government of India has taken significant steps to achieve the same and laid National Guidelines for Control of Iron Deficiency Anaemia with following four purposes:

1. To bring to attention of program managers of health and health-related activities the serious negative consequences of anemia for the health and physical, mental, and economic productivity of individuals and populations
2. To layout iron and folic acid supplementation protocols across the life cycle (preventive strategy)
3. To define a minimum standard treatment protocol for facility-based management of mild, moderate, and severe anemia segregated by levels of care (curative strategy)
4. To broadly identify platforms of service delivery and indicate roles of service providers

Identification Nutritional anemia is a major public health problem in India and is primarily due to iron deficiency. The National Family Health Survey-3 (NFHS-3) data suggests that anemia is widely prevalent among all age groups, and is particularly high among the most vulnerable – nearly 58% among pregnant women, 50% among nonpregnant nonlactating women, 56% among adolescent girls (15–19 years), 30% among adolescent boys, and around 80% among children under 3 years of age.

Delivery Per Kapil and Bhadoria (2014) National Iron + Initiative will reach the following age groups for supplementation or preventive programming:

- Biweekly iron supplementation for preschool children 6 months to 5 years
- Weekly supplementation for children from 1st to 5th grade in Govt. & Govt. Aided schools
- Weekly supplementation for out of school children (5–10 years) at Anganwadi Centers
- Weekly supplementation for adolescents (10–19 years)
- Pregnant and lactating women
- Weekly supplementation for women in reproductive age

Monitoring

- Provision of iron and folic acid tablets to pregnant women will be during routine antenatal visits at subcenter/Primary Health Centre/Community Health Centre/ District Hospital.
- Accredited social health activist (ASHA) to ensure provision of IFA supplements to pregnant women who are not able to come for regular antenatal check-ups through home visits. She will also monitor compliance of IFA tablets consumption through weekly house visits.

Accountability The Ministry of Health and Family Welfare took a policy decision to develop the National Iron + Initiative and to take cognizance of ground realities,

evaluate the programs in various centers, and review the implementation on a monthly basis by program reports from the state health departments.

Recent Developments Food fortification programs to supplement nutrition with iron have not been very successful. One alternative solution is iron biofortification. Biofortification of crops is an interesting approach towards increasing the concentrations of bioavailable mineral elements such as iron in food crops. Two methods have been tried namely first involves application of mineral fertilizers and/or improving the solubilization and mobilization of mineral elements in the soil and second development of crops with increased ability to acquire mineral elements and accumulate them in edible tissues (White and Broadley 2009).

Dictionary of Terms

- **Accredited social health activist (ASHA)** – Community health workers instituted by the government of India's Ministry of Health and Family Welfare as part of the National Rural Health Mission (NRHM).
- **Anaemia** – Abnormally low level of hemoglobin in the blood.
- **Anganwadi Centre** – A shelter providing the basic health care in Indian villages.
- **Atrophy** – Decrease in the size of an organ or tissue.
- **Candidiasis** – A fungal infection due to any type of Candida (a type of yeast).
- **Epithelial cell** – A cell which lines various organs/structures in the body.
- **Iron deficiency** – Depleted/decreased of iron concentration in the body.
- **Phagocytosis** – Process by which a cell engulfs pathogens, debris, or foreign bodies.
- **Premalignant** – An altered condition of tissues which are more prone to develop cancer.
- **Protoporphyrin** – Chemical intermediate that combines with iron and protein to form hemoglobin, myoglobin, and certain respiratory pigments.
- **Stomatitis** – Inflammation of mouth mucosa.
- **Total iron binding capacity** – Measure of the binding capacity of transferrin for iron.
- **Transferrin receptor** – It is a carrier protein for transferrin.
- **Transferrin** – Protein synthesized in the liver that transports iron in the blood. It can bind two molecules of ferric iron.

Summary Points

- Iron is essential nutrient required for the functioning of various physiologic processes, which includes electron transfer reactions, binding and transport of oxygen, gene regulation, and regulation of cell growth and differentiation.
- Hemoglobin values below 80 g/L have been associated with impaired physical work capacity, reproductive efficiency, and cognitive and psychomotor development.

- Maternal hemoglobin concentrations at either the low or high end of the distribution during pregnancy (usually in the first or second trimester) are markers of increased risks of low birth weight and perinatal mortality.
- Iron deficiency has significant effect upon the oral mucosa.
- Oral effects of iron deficiency on oropharyngeal region varies from mucosal pallor, atrophic glossitis, generalized oral mucosal atrophy, anemic stomatitis, angular cheilitis, tenderness or burning sensation of oral mucosa, to various types of oral candidiasis, recurrent aphthous ulcers, dry mouth, and dysguesia. Severe prolonged iron deficiency may result in Plummer Vinson Syndrome.
- Atrophic changes in iron deficiency anemia are observed in the middle layers (progenitor compartment) of the epithelium.
- Impaired cellular immunity along with epithelial changes may lead to fungal infections within oral cavity.
- Burning mouth syndrome and premalignant conditions are other noticeable changes associated with iron deficiency.
- Increased oxidative stress has been suggested as a predisposing factor in initiation and progression of premalignant conditions and oral cancer.
- Regular iron screening of the vulnerable population and closely monitored iron supplementation in diet or tablet form are effective tools in combating ill effects of iron deficiency.

Abstract

The treatment of iron deficiency depends on correct diagnosis of iron deficiency with hemoglobin, ferritin, transferrin, sTfR estimations, the treatment of the reasons of iron deficiency, and the choice of effective iron preparations.

There are causes for iron deficiency in nonpregnant women like hypermenorrhea. The volume of blood loss is correlated with hemoglobin and ferritin values. Iron deficiency and anemia in pregnancy and postpartum are associated with maternal and fetal morbidity and mortality.

Beside the iron intake in the diet (daily requirement 2 mg) for treatment of iron deficiency, oral and intravenous iron preparations can be used. For parenteral iron treatment, three preparation types must be contemplated with different pharmacokinetics, toxicity, and side effects.

Keywords

Anemia · Fetal morbidity · Ferritin · Hemoglobin · Hemoglobinopathies · Hypermenorrhea · Iron deficiency · Iron dextrin · Iron hydroxide gluconate · Iron Hydroxide-sucrose complex · Iron therapy · Maternal morbidity · Transferrin

Introduction

Iron deficiency is known to be among the commonest nutritional deficiency states worldwide, with the physical sequelae and symptoms depending on the duration and severity of the iron deficiency. While countries with chronic malnutrition have a high prevalence of people with iron-deficiency anemia (50–80%), iron deficiency states without anemia are frequently found in countries with normal nutrition (prevalence up to 20%) (Milman 2011). Successful iron therapy depends, on the one hand, on correct diagnosis of the iron deficiency and, on the other hand, on the choice of effective iron preparations and treatment of the causes of the iron deficiency. Women naturally have a much higher risk of iron deficiency states than men. Women with regular periods have a prevalence of iron deficiency that is about ten times higher than men of the same age; in addition, it can be shown that among blood donors, for example, it is nearly always only women who have empty iron stores. The reason for this is the regular blood or iron losses during menstruation at the same time as often inadequate or insufficient daily iron intake in the diet (Akabas and Dolins 2005; Fraser et al. 2015).

Gynecological Bleeding as a Cause of Iron Deficiency and Iron-Deficiency Anemia

Gynecological bleeding causing iron deficiency includes recurrent hypermenorrhea, menorrhagia, or metrorrhagia. They all come under the heading heavy menstrual bleeding. It has been shown for many years that the rate of anemia significantly

increases with increasing menstrual blood loss. It has been shown that if menstrual blood loss is 61–80 mL per cycle, the rate of anemia is 10.3%, while the rate is 50% with menstrual blood loss of between 151 and 240 mL. A further study showed that with one definition of iron deficiency (hemoglobin less than 12 g/dL and a ferritin level less than 16 μg/L), the prevalence of iron-deficiency anemia was 0% with blood loss of less than 20 mL, while if blood loss was 60–80 mL, the prevalence was 17% and with blood loss of over 100 mL, the prevalence was 26%. Gynecological bleeding caused by diseases such as adenomyosis, uterine fibroids, or endometrial hyperplasia frequently results in considerable iron-deficiency anemia. In registration studies for a hormonal treatment of hypermenorrhea, in the baseline groups of 231 patients with hypermenorrhea, blood loss of a mean of 640 mL was demonstrated using the very specific alkaline-hematin method in a 90-day reference period. The amount of blood loss correlated well with low hemoglobin and ferritin levels (Akabas and Dolins 2005; Fraser et al. 2015; Gao et al. 1992).

Pregnancy and Postpartum

Anemia in pregnancy and the puerperium is associated with increased maternal and fetal morbidity and mortality depending on the severity and possible additional complications. It is among the commonest risk factors in obstetrics and perinatal medicine. According to the WHO, the estimated worldwide prevalence of anemia in pregnancy is 30–50%, depending on geographical area. Especially in developing countries, postpartum anemia continues to be among the commonest causes of death in women who have just given birth; in Europe, approximately 10% of women in the puerperium have moderate to severe anemia, adequate treatment of which without recourse to allogeneic blood is a current problem (Allen 1997; Bencaiova et al. 2012; Breymann et al. 2011).

Symptoms of Iron Deficiency

Symptoms of iron deficiency causing the woman considerable suffering are the main reason for the use of iron therapy. The therapeutic use of iron preparations for correction of low iron stores alone without symptoms should be rejected. Symptoms in iron deficiency (fatigue, headache, hair loss, poor concentration, reduced physical performance in general) are, among other things, a consequence of the iron deficiency in various enzyme systems such as oxidoreductases, mono-oxidases, dioxygenases, and especially decreased mitochondrial activity in the body cells (Milman 2011; Akabas and Dolins 2005; Hercberg et al. 2001; Munoz et al. 2011; Murray-Kolb 2012). Various placebo-controlled studies have shown a positive influence of iron administration on specific symptoms. In this context, the effect of iron does not correlate directly with the amount of iron administered or the ferritin level, which is a measure of iron stores. It is important to note that certain symptoms, such as fatigue, may only suggest iron deficiency but are not proof that it is present.

People without iron deficiency may have the same degree of fatigue as people with iron deficiency. The sensitivity of the symptom "chronic fatigue" for iron deficiency (ferritin <15 μg/L) is only 20%. Thus, if iron deficiency is suspected as the cause of certain problems, this always needs to be confirmed by specific tests (Beglinger and Breymann 2010).

Consequences in Pregnancy

Iron deficiency is known to influence several body functions such as physical and intellectual performance, enzyme functions (e.g., electron transport chain), thermoregulation, muscular functions, immune response, and neurological functions. Only a few of these possible effects have been specifically studied in iron-deficiency anemia. In general, iron-deficiency anemia leads to many symptoms such as fatigue, decreased physical and work capacity, increased cardiovascular stress (tachycardia, fall in blood pressure), reduced thermoregulation, and increased susceptibility to infection. In pregnant women, tolerance to peripartum blood losses is greatly reduced. Depending on the severity of iron-deficiency anemia, maternal mortality is increased. The reasons for this are an increased rate of cardiovascular insufficiency, a higher risk of hemorrhagic shock, higher infection rates in the puerperium, and poorer wound healing. Maternal morbidity is pos sibly linked to further factors such as socioeconomic status, medical care, nutritional state, etc. A general problem when interpreting the available studies is that maternal and fetal outcome are related to the severity of the anemia but not to the duration and time of first appearance of the anemia or severity, duration, and start of iron deficiency. Taking this limitation into account, some authors postulate a correlation between maternal mortality and degree of anemia, but there are no prospective studies on this issue and it is unclear what the critical hemoglobin level is in relation to maternal mortality. It appears to be levels below 8–9 g/dL, with the association between moderate anemia and maternal morbidity being unclear. There are currently no studies on the relationship between iron-deficiency anemia present prior to pregnancy and the course of pregnancy, and there are no prospective studies in large cohorts that show the effect of early interventions and treatment of anemia on maternal, fetal, and neonatal outcome (Allen 1997; Algarin et al. 2013; Bencaiova and Breymann 2014; Hercberg et al. 2000; Horowitz et al. 2013).

Nevertheless, the WHO summarized in 2001 "iron deficiency is associated with multiple adverse outcomes for both mother and infant, including an increased risk of hemorrhage, sepsis, maternal mortality, perinatal mortality, and low birthweight."

Diagnostic Principles

The basis of the diagnosis and consequent management of anemia in pregnancy is correct differentiation between the relative or physiological anemia in pregnancy due to the increase in plasma volume on the one hand and "true anemia" with its different

pathophysiological causes on the other hand. When defining the cut off value for anemia in pregnancy, the degree of changes in plasma volume depending on gestational age must be taken into account. Accordingly, hemoglobin levels of <11.0 g/dL in the first and third trimester and hemoglobin levels of <10.5 g/dL in the second trimester indicate possible anemia that should be further investigated. The pathogenesis of anemia in pregnancy may be multifactorial. Thus, it is not enough simply to diagnose anemia based on the hemoglobin level; rather the causes should always be investigated. Various etiological factors which are accompanied by reduced hemoglobin synthesis or increased hemoglobin breakdown or hemoglobin loss need to be considered in the differential diagnosis. In addition, combinations of decreased hemoglobin synthesis and increased cell death occur, e.g., in thalassemia syndromes, as a result of which the diagnosis and treatment may be additionally complicated. The most important dif ferential diagnoses include iron-deficiency anemia and its precursors (to which often too little attention is paid), hemoglobinopathies (thalassemias, sickle cell anaemia), anemia of infection, and renal anemia, e.g., in pregnant women who have had a kidney transplant or have renal failure (Breymann 2002; Breymann et al. 2011).

The first important steps to investigate anemia are a thorough history and clinical examination of the pregnant woman. This often already lays the foundation for correct diagnosis. The next investigations include a full hematological status and determination of specific biochemistry parameters, with the diagnosis of iron deficiency having been complemented in particular by determination of a range of additional promising parameters. The current gold standard for detecting iron deficiency is still the serum ferritin level. In addition, possible infection (chronic or acute) should always be ruled out as a cause. The pathogenesis of anemia is, as described, very varied. Thus, a diagnosis based on hemoglobin levels alone is usually insufficient. The reason for the reduced hemoglobin synthesis should therefore always be investigated, whether through a targeted history, clinical assessment or through investigations on top of the basic work-up (Gibson 1990; Letzky 1990; Milman et al. 1995).

Basic Work-Up

Hemoglobin and Red Cell Indices

The first test for the investigation of anemia mostly includes the hematological profile with the standard parameters:

- hemoglobin concentration
- hematocrit
- MCV, MCH

Although in everyday clinical practice the hemoglobin concentration usually gives the first indication of iron deficiency, it should be borne in mind that both

the hemoglobin level and the red cell indices such as the MCV and MCH have a very low sensitivity and specificity for detecting iron deficiency states and in most cases show significant changes only if iron deficiency has been present for some time. If suspected, more specific and more sensitive tests should be used especially for the early detection of iron-deficiency states and thus for the prevention of iron-deficiency anemia.

Differential Diagnosis and Additional Investigations

Iron-Deficiency Anemia and Specific Parameters of Iron Metabolism

Ferritin

Measurement of the serum ferritin level has the highest sensitivity and specificity for detecting iron deficiency. Ferritin levels of <20 μg/L are proof of iron deficiency, regardless of the hemoglobin level. Ferritin levels between 20 and 50 μ/L are regarded as a gray area, i.e., even if at these levels there are still low iron stores, it is assumed that a fair number of women already have symptoms of iron deficiency at these levels. If the ferritin levels are within the normal range (>50 μg/L), iron-deficiency anemia can be virtually ruled out, unless infection is suspected at the same time (Kirschner et al. 2016). In this situation, the ferritin levels may yield a false normal result, since apoferritin is, like C-reactive protein, an acute phase protein, and increases in infections as well as in inflammatory reactions (e.g., postoperatively). It is assumed that the serum ferritin levels once again correctly represent the iron stores about 6 weeks after surgical operations or childbirth. If the concomitant presence of iron deficiency and anemia is suspected, the presence of infection or inflammation (CRP measurement) must always be excluded in order to be able to draw a clear conclusion about the iron status. In special cases, iron investigations may be supplemented by various parameters (Munoz et al. 2011; Milman et al. 1995).

Serum Iron, Transferrin, Transferrin Saturation

In general, assay of serum iron levels and transferrin levels does not provide any additional benefit for investigating iron deficiency, even in pregnancy, since the serum iron levels in particular are subject to many influences such as diurnal, intraindividual, and interindividual variations. Conclusions as to prelatent iron-deficiency states are possible only in combination with transferrin levels by determining the transferrin saturation. If the ferritin levels are within the normal range, but the transferrin saturation is less than 15%, this is indicative of latent iron deficiency since now iron is being released in higher quantities from circulating transferrin to maintain erythropoiesis. However, it needs to be remembered that the fluctuations in the serum iron levels also affect calculation of transferrin saturation and thus may lead to incorrect interpretations (Milman et al. 1991).

Transferrin Receptors (sTfR)

Various studies have shown that serum transferrin receptors increase in iron-deficiency states or if there is an increased cellular iron requirement and thus are a sensitive and specific indicator of changes in iron kinetics. Transferrin receptors are probably also not affected in the context of infections, and thus they represent a good addition to ferritin assay. The first studies in pregnancy have already been conducted. Low sTfR levels at the start of pregnancy appear to be associated with inhibited erythropoiesis in the first trimester. The increase in sTfR in the course of pregnancy is attributed, on the one hand, to increasing stimulation of erythropoiesis and, on the other hand, to an increasing iron requirement of iron-dependent cell proliferation. It is not known whether inhibited erythropoiesis at the start of pregnancy negatively influences detection of concomitant iron deficiency through measurement of sTfR. There is nothing to suggest that the sTfR concentration is influenced by inflammatory reactions. Thus, this parameter would also be useful for the investigation of unclear situations in pregnancy (normal ferritin in the presence of an elevated CRP) and in the early puerperal phase. In our own studies, we showed that after labor, sTfR are not influenced by the inflammatory reaction at birth, in contrast to ferritin levels (Breymann 2002).

Prevention and Treatment of Iron Deficiency in Nonpregnant Women

Ideally, a woman can compensate for her iron losses through adequate iron intake in the diet. Iron intake in the diet depends on the iron content of the food, the amount ingested and lastly absorption of iron in the intestine and bioavailability of the iron. Foods high in iron such as meat contain up to 2 mg/100 mg, but absorption in the intestine ranges from 1% to 20%, depending on whether the food is of animal or vegetable origin. A daily requirement of 2 mg/iron per day is covered by 300 g of meat/fish but by about 1000 g of soya beans or 5000 g of spinach. This shows that compensating for higher iron losses through diet is unrealistic given current eating habits and quantities (Hercberg et al. 2001; Ahmed 2012; Verdon et al. 2003). On top of this is the fact that the population's knowledge about the iron content of food is usually very low, i.e., people do not know at all which foods are actually high in iron and how much they should consume. We have developed a smartphone application (MyIronfriend™) that aims to help women with this issue and to provide guidance when they do their dailyshopping (www.myironfriend.com). Both oral iron preparations (tablets or drops/ syrup) and intravenous iron preparations can be used for treatment. Oral iron preparations are available as Fe II salts or Fe III complexes, with the absorption of oral preparations being between 1% and 8% depending on the composition. An 80 mg tablet/day corresponds to just under 8 mg iron absorption/day. It can be shown from intervention studies (oral iron versus placebo) that even just daily doses of 20 mg of Fe II salts result in a significant improvement in symptoms of deficiency. As the dosage increases, the gastrointestinal side effects

of oral iron increase because of the toxic oxidative effect of iron in cells (Hidalgoa et al. 2013). This is usually at daily doses >100 mg/day, which results in a reduction in patient compliance. Irrespective of the preparation, almost 20% of women stop oral iron therapy sooner or later. In general, iron (III) complexes show better gastrointestinal tolerability, but are absorbed to a lesser extent (Ortiz et al. 2011). In iron deficiency states that do not respond to oral iron, it is possible to switch to an intravenous iron preparation (iron sucrose, ferric carboxymaltose, iron dextran, iron gluconate). In gynecology, most experience has so far been acquired with the iron sucrose and carboxymaltose preparations. These preparations distinguish themselves above all through their high safety even at high doses (ferric carboxymaltose up to 1000 mg/single administration). The rate of adverse reactions is approximately 5% (dizziness, feeling of heat, limb pain, flu-like symptoms), and severe allergic reactions are very uncommon with iron sucrose and ferric carboxymaltose. Extravasation must be avoided at all costs during parenteral iron administration since following this persistent skin discoloration may occur (Verdon et al. 2003; Krayenbuehl et al. 2011. There are now large randomized trials on the efficacy of iron sucrose and ferric carboxymaltose in females in the puerperal period, in pregnancy (iron sucrose) and in heavy uterine bleeding (Breymann et al. 2008; Favrat et al. 2014; Krayenbuehl et al. 2011; Munoz et al. 2008).

Sustained Iron Therapy

Iron therapy is only useful if the cause of the iron deficiency or iron losses is simultaneously treated. Thus, a woman may once again have empty iron stores a few months after intravenous iron therapy if iron losses are not corrected at the same time. Vegetarians who menstruate and consume little iron in their diet are, for example, not usually able to replenish their iron stores or maintain their replenished stores. Women with periodically high iron losses (menstruation, blood donors) or consumption (competitive sportswomen, pregnant women) are also not able to do this. Thus, in parallel to iron therapy, treatment of the cause of the bleeding disorders is of great importance as well as supportive measures from gynecologists and members of other specialties (e.g., internal medicine specialists, hematologists, dieticians).

Prevention and Treatment of Iron-Deficiency Anemia in Pregnancy

The treatment of anemia is directed at its cause and severity. Maternal and fetal risk factors that may be complicated by anemia also need to be taken into account. The time period that is available for the treatment of anemia (e.g., before childbirth) likewise plays an important role. Later complications can be prevented early on by adopting a prospective and preventive way of thinking, i.e., even milder forms of anemia need to be systematically treated to prevent any exacerbation and to reduce

peripartum complications if there are high blood losses. The administration of allogeneic blood should be avoided at all costs as a last resort in pregnant women and those in the puerperium; as an alternative, newer treatment strategies may be considered for severe iron-deficiency anemia, for example, especially use of well-tolerated parenteral iron preparations or, in special cases, recombinant erythropoietin (Breymann et al. 2011, 2000).

Prevention

There are three ways to improve the body's iron status: to reduce losses, limit consumption, and increase intake. Depending on existing iron stores immediately after pregnancy, sufficient intervals before further pregnancies may be used to replenish the iron stores. In the puerperium, worthwhile strategies to reduce or avoid major blood losses make a contribution at the time of birth. In pregnancy, however, only the option of increasing intake is available: via dietary intake or via targeted pharmacological supplementation.

Pharmacological Supplementation

The benefit of preventive iron administration, that is, general regular administration of iron preparations without actual knowledge of iron stores, continues to be a subject of debate. This approach is recommended and practiced particularly in the industrialized countries. Critical arguments against it include, on the one hand, the lack of evidence that the worldwide prevalence of iron deficiency and consequences of anemia is reduced and, on the other hand, possible harmful effects of nonselective iron administration on the mother. According to the last update to the Cochrane Database, there is no scientific or medical justification for prophylactic iron administration in pregnancy in countries with adequate nutritional resources since epidemiological data do not show any positive effect on the course of pregnancy and/or maternal and fetal outcome (Pena-Rosas et al. 2012). In terms of hematological data (ferritin levels, hemoglobin), randomized placebo-controlled trials do at any rate show a positive effect. Women with low iron stores at the start of pregnancy develop anemia less often if they receive iron substitution. In contrast, it has been shown that iron supplementation in countries with a high prevalence of iron-deficiency states is indeed justified (Murray-Kolb 2012; WHO 2012; Van den Broek 1998). However, it is unclear whether studies on iron substitution in developing countries can be extrapolated to industrialized countries. The correct dosage for pure prophylactic administration is unclear. Current guidelines on purely prophylactic iron supplementation are 60–120 mg elemental iron per day. Lower dosages appear to be less effective. At dosages from 120 mg, adverse reactions increase and patient compliance becomes poorer (Milman et al. 1991, 2014). As women with low iron stores benefit most from prophylactic iron administration, selective iron administration in pregnancy would be the optimum solution. This presupposes investigating the iron

stores since the hemoglobin level that is usually measured in isolation shows a poor correlation with iron stores. The ferritin level must be used for this. According to a study from Denmark, ferritin levels of less than 70 µg/L at the start of pregnancy are indicative of subsequent iron deficiency. However, as the individual iron metabolism during pregnancy can be very different, the best time for measuring iron stores in pregnancy is unclear (Milman et al. 1995, 1991).

Treatment of Iron-Deficiency Anemia in Pregnancy

The preceding sections show that iron-deficiency states and anemia should be treated. The change over time or worsening of the situation can often not be predicted even for mild forms of anemia, and maternal and fetal risks increase with increasing anemia. In deciding on the method of treatment, various factors such as time remaining until birth, severity of the anemia, additional risks (e.g., premature contractions), maternal comorbidity, and patient's wishes (e.g., refusal to have allogeneic blood in severe anemia) should be taken into account. Thus, a Jehovah's Witness with severe anemia 2 weeks before birth requires a different approach compared with a woman who has moderate anemia in the second trimester without additional risk factors. The current most important alternatives for the treatment of anemia are oral iron, parenteral iron, stimulation of hematopoiesis using growth factors (human recombinant erythropoietin), and administration of heterologous blood.

Oral Iron

Oral iron is the gold standard for the treatment of mild-to-moderate iron-deficiency anemia. It is unclear whether weekly or intermittent administration of oral iron is equivalent to daily administration or even better than it. Studies on this issue are currently underway. The ideal dosage for intermittent or weekly administration is also unclear. As the rate of absorption is inversely proportional to the administered dose, dosages between 100 and 200 mg iron daily are a compromise in relation to the hemoglobin increase and tolerability of iron. The recommended dosage is 80–160 mg elemental iron per day. If there is a good response to the oral iron therapy, reticulocytosis occurs within 3–5 days and increases until 8–10 days after treatment. The hemoglobin increase follows after a delay and is, at best, approximately 0.2 g/dL/day or approximately 2.0 g/dL within 3 weeks. Once the hemoglobin levels have returned to normal, oral iron should be continued for at least another 4–6 months until a target ferritin level of approximately 50 µg/L and a transferrin saturation of at least 30% have been reached (Pena-Rosas et al. 2012; Haider et al. 2013).

As already mentioned, gastrointestinal side effects such as constipation, heartburn, and nausea, which occur in up to 30% of female patients and which limit the dose that can be administered, are key disadvantages of oral iron preparations. In this case, the dose must either be reduced or a switch to a different preparation

tried. However, even then the often poor compliance remains a problem. It has been shown that only 36% of pregnant women regularly take oral iron despite being specifically instructed about the problem of iron deficiency. Studies from countries such as Tanzania and Indonesia also show compliance of only 36–42% (Milman 2011).

Parenteral Iron Preparations

Parenteral iron is the most important alternative to oral iron preparations. The indications for parenteral administration of iron include: Parenteral iron administration circumvents the natural mechanism of iron absorption via the intestine and thus protein binding. Nonprotein-bound, free iron is therefore able to circulate. Free iron is toxic since it promotes the formation of hydroxide and oxygen radicals, which in turn result in cell and tissue damage via peroxidation. Thus, parenteral iron should only be administered if the iron status is known, in order to prevent potential iron overload. In principle, a distinction needs to be made between three classes of preparations. They differ on the basis of their pharmacokinetics, complex stability, molecular mass, toxicity, and side effects.

Type I Complexes (Iron Dextrin, Iron Dextran)

These are stable iron complexes with a high molecular weight (>100,000 Da) and high stability (e.g., Imferon®). Iron is therefore released to the transport proteins slowly and competitively in relation to endogenous iron. The free iron is, on the one hand, bound to transferrin and then used for heme synthesis and, on the other hand, transported into the reticuloendothelial system. The plasma half-life of type I complexes is 3–4 days. While the stability and slowly released iron are to be viewed as favorable, it is assumed that the dextran components in particular can result in severe allergic reactions. This reaction appears to be less severe with dextrins. Patients who generally have an allergic reaction to drugs also have a high risk of iron dextran allergy. The reason for the severe allergic reactions has not been determined, but corresponds to an anaphylactic reaction with release of mediators from mast cells. A further hypothesis is that there is the formation of dextran antibody which can lead to severe reactions even at the first contact. Dextran chains form biological polymers of different sizes, which could be responsible for this. Also in favor of this is the fact that dextran 1, for example, a polymer of only 1000 Da, causes virtually no reaction (Chertow et al. 2006; Hoigne et al. 1998; Naim and Hunter 2010; Perewusnyk et al. 2002).

Type II Complexes (Iron Hydroxide-Sucrose Complex)

These are complexes with moderate stability and a molecular weight of 30,000–100,000 Da (Venofer®). After administration of a bolus, peak plasma levels are already reached after 10 min (30 mg/L). Twenty-four hours after administration, the plasma levels have once again reached pretreatment levels. The half-life is 5.5 h, and studies with PET indicate immediate accumulation in the bone marrow, in

parallel to the fall in the plasma levels. In patients, 70–97% of the iron is used for erythropoiesis, depending on the severity of the iron-deficiency anemia. In studies in humans, there were not noted to be either morphological organ changes or lipid peroxidation as a result of free radicals at the usual dosages (1–4 mg/kg body weight). In clinical practice, the substance is to be regarded as very safe; moreover, no biological polymers (see also dextrans) are formed; hence, anaphylactic reactions are extremely rare. The general (adverse) reactions include: metallic taste, feeling of heat, nausea, local irritation, and dizziness (Chertow et al. 2006; Hoigné et al. 1998; Naim and Hunter 2010; Perewusnyk et al. 2002).

Type III Complexes (Iron Hydroxide Gluconate, Iron Hydroxide Citrate, Iron Hydroxide Sorbitol)

Iron gluconates (e.g., Ferrlicit®) are the best-known substances from this group. They are unstable, labile complexes with a molecular weight of less than 50,000 Da. Because of the lower stability compared with iron dextrans and iron sucrose complexes, type III complexes are bound to transport proteins to a lesser extent, while free iron is released short term in higher quantities. Several studies have described maximum transferrin saturation after administration of iron gluconate. It is assumed that the free iron is stored in the organ parenchyma in increased amounts. Free radicals lead to lipid peroxidation and, compared with type I/II complexes, to higher tissue toxicity. With regard to allergic and anaphylactic side effects, iron gluconates, in particular, appear to be comparable to iron sucrose complexes and thus, like iron sucrose, have a better side-effect profile compared with iron dextrans (Chertow et al. 2006; Hoigne et al. 1998; Naim and Hunter 2010; Perewusnyk et al. 2002).

Impaired Magnesium Status and Depression

95

Nicola Veronese and Marco Solmi

Contents

Abstract

Magnesium (Mg) is an element present in everyday dietary plan of regular meals, but it has been shown that a large part of the population presents a low Mg status. Mg has a wide range of physiologic and protective functions within energy regulation and cellular, included neuronal, homeostasis. It obstacles excessive calcium flow into the cells, preventing cells' death, has anti-inflammatory properties, antioxidant action, and interacts with serotonin, a central neurotransmitter

involved in depression pathophysiology. Epidemiologic studies have shown that low Mg status is associated with increased frequency of depression, with both cross-sectional and longitudinal designs. Promising evidence has shown that Mg has antidepressant activity similar to imipramine, and that it can be a valid supplementation to antidepressants in treatment resistant depression. However, at the present state of the art too few and small studies have investigated the role of Mg among other therapeutic means in depression, and any conclusion about its utility in clinical practice cannot be drawn. Future research should shed a light on such an important field needing more evidence.

RCT	Randomized controlled trial
RDA	Recommended daily allowance
SSRI	Selective serotonin reuptake inhibitors

Introduction

Magnesium (Mg) plays a fundamental role in several key metabolic pathways involved in energy expenditure and physiologic cell metabolism (Volpe 2013). Its deficiency is associated with several negative health outcomes in human beings, among which metabolic disorders such as increased sugar blood levels and cardiovascular diseases widely conceived (Veronese et al. 2016). Beyond such severe and frighteningly common conditions, the role of deficiency of Mg in the development of neurological and psychiatric diseases is more complex and ultimately less clear. Mg passes the blood-brain barrier and is physiologically involved in neuron signaling and brain function at a higher order. Thus, any imbalance in Mg status may affect regular neuronal signaling and brain network, in turn possibly playing a role in the onset of neurological and psychiatric diseases, such as dementia, severe mental illnesses (including major depressive disorder, bipolar disorder or schizophrenia, suicidal behavior), and stroke. (Veronese et al. 2015b; Volpe 2013; Carl-Albrecht 2010; Ruljancic et al. 2013).

Within severe mental illness, the role of Mg deficiency in depression is still debated, with some evidences suggesting it has a role in a wide range of pathogenetic steps of mood disorders (Table 1). It was hypothesized that Mg might underpin response to treatment as well, alongside with other factors.

Table 1 Evidences regarding magnesium and psychiatric diseases (others than depression)

Condition	Reference
Premenstrual syndrome	(Pearlstein and Steiner 2000)
Attention-deficit/Hyperactivity disorder	(Kozielec and Starobrat-Hermelin 1997)
Schizophrenia	(Nechifor 2008)

In this chapter, we will discuss the possible mechanisms through which Mg deficiency underpins the development of depression, the epidemiological evidences of such a relationship, and its clinical implications.

Role of Magnesium Deficiency in Depression: Pathological and Molecular Evidences

Animal models have suggested the possible role of Mg in depression according to several pieces of evidence. To mention a couple of studies, mice receiving low Mg diet for several weeks showed enhanced depression-like behavior, as reported by their poor performance in the forced swim test (Singewald et al. 2004), and other tests with depression and anxiety-like attitudes in these animals. Similarly, in rats, Mg deficiency was associated with depression-like and anxiety-related behavior and the administration of Mg supplementations was able to improve these symptoms. (Spasov et al. 2007).

Such evidence is not surprising, and a role of Mg deficiency in depression pathogenesis is to be expected in humans as well. Actually, the role that magnesium is supposed to play in depression can be essentially summarized in three main dimensions as represented in Fig. 1.

The first we will describe is the calcium-mediated excitoxicity, the second is the relationship between Mg and serotonin, and the third is the interplay of Mg and peripheral inflammatory cytokines, alongside with oxidative stress and BDNF.

Mg is a natural calcium antagonist. For this effect, Mg acts blocking the voltage-dependent N-methyl-D-aspartate (NMDA) channel (Fig. 1), which in turn physiologically regulates the entrance of calcium into the neuron (Iseri and French 1984). Physiologic Mg levels are believed to have neuroprotective properties leading to a reduction in the neuron death (Alzheimer 2012; Sobolevskii and Khodorov 2002). Such a beneficial action is supported by the fact that Mg deficiency damages neurons through the excessive opening of NMDA-coupled calcium channels leading to an excessive intraneuronal mitochondrial concentration of calcium, which finally activates some calcium-dependent enzymes regularly silenced in normal conditions. This excitotoxic pathway results in a series of mechanisms (e.g., cytoskeletal breakdown, failure to generate ATP, and production of free radicals) ultimately leading to neuronal death (Durlach et al. 1997). Another effect of Mg deficiency in the development of depression is probably linked to L-glutamate, which in turn can furtherly boost a calcium-mediated neuronal excitoxicity (Mark et al. 2001).

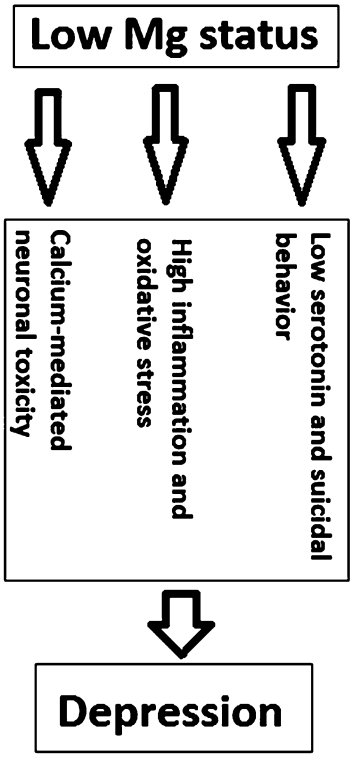

Fig. 1 Role and pathways of magnesium deficiency in depression

From a clinical perspective, as happens for ketamine's antidepressant activity, such a NMDA receptor blockade may result in a mood improvement, and theoretically this is the case also of Mg.

In particular it has been suggested that such low Mg levels' detrimental effects on mood disorders may be localized in particular in hippocampus (Durlach et al. 1997).

Secondly Mg seems to be implicated in the metabolism of different neurotransmitters involved in the pathogenesis of depression (Szewczyk et al. 2008; Durlach et al. 1997), and evidence showing a correlation between platelet magnesium, platelet serotonin, and suicidal behavior in a population of patients with depression furtherly supports a close Mg-serotonin interplay with clinical implications (Ruljancic et al. 2013). Such an interaction plays at a central level as well, as shown in animal models where the forced swim test performance is linked to serotonin receptors and is improved by concomitant administration of Mg and antidepressants (Cardoso et al. 2009). Moreover, Mg has shown to protect neurons in the cerebellum from hypoxic damage through an increase in BDNF (Golan et al. 2004).

Third, a subclinical Mg deficiency status has been demonstrated to be associated with chronic inflammatory state (Nielsen 2014), and Mg seems to able to decrease inflammatory cytokines. More in detail, in vivo Mg has shown to induce a decrease in TNF-alpha and IL-6, in vitro to reduce inflammatory cytokines' genes and

proteins (Sugimoto et al. 2012), and low Mg status has been associated with oxidative stress in subjects with type 2 diabetes mellitus (Araujo Sampaio et al. 2014). In other words, Mg deficiency seems to be associated with an increased inflammatory state and oxidative stress level (as shown by the increased levels of oxidative stress markers, e.g., lipid, protein, and DNA oxidative modification products). Finally, other research has suggested a potential relationship between Mg deficiency and reduction in antioxidant barriers (Zheltova et al. 2016). Since both inflammation (Kohler et al. 2017) and oxidative stress (Black et al. 2015) play a role in the development of depression, it is possible that deficiency in Mg contributes to depressive mood through affecting these pathways.

Epidemiological Evidences of Magnesium Deficiency and Depression

Mg deficiency is largely present in the general population (Veronese et al. 2014) and some individuals (such as diabetic subjects) are particularly prone to this condition (Veronese et al. 2016). Some research suggests that optimal Mg levels are associated with healthy life (Veronese et al. 2015a). However, despite such an important role of Mg and physical and mental well-being, more than half of the American individuals do not reach the suggested RDA for Mg (Whang 1987). Since several conditions associated with Mg deficiency (poor nutrition, gastrointestinal and renal diseases, insulin resistance and/or type 2 diabetes, alcoholism, stress, and certain medications) are also associated with depression (Serefko et al. 2016), the interest on Mg status in populations is increasing, and given the above-mentioned mechanisms, Mg deficiency as a putative risk factor for depression has been object of growing interest.

Table 2 summarizes the findings of epidemiological studies regarding Mg deficiency and depression in human beings. In a systematic review, Derom et al. found that a higher dietary intake of Mg is probably associated with lower prevalence and incidence of depression (Derom et al. 2013), suggesting a protective role of Mg. However, the same authors failed to find any significant association between other estimates of Mg status (e.g., blood and cerebrospinal levels) and the presence of

Table 2 Epidemiological evidence of Mg deficiency in depression

	Association	References
Dietary	Mg deficiency is associated with higher prevalence and incidence of depression	(Derom et al. 2013)
Serum/ plasma	Less evident association between Mg deficiency (hypomagnesemia) and depression	(Derom et al. 2013; Cheungpasitporn et al. 2015)
Other measurements	Not consistent results regarding cerebrospinal fluid Mg status, analyzed through phosphorous nuclear magnetic resonance spectroscopy, seems to be lower in depressed people	(Derom et al. 2013; Eby and Eby 2010)

depression. These latter findings are surprising and are in contrast with other investigations which reported that cerebrospinal Mg is probably low in both treatment-resistant suicidal depression and in patients that have attempted suicide (Eby and Eby 2010). Consistently with an association between depression and Mg deficiency, other investigations reported that serum Mg levels are lower in depressed people compared to healthy controls (Levine et al. 1999; Joffe et al. 1996). As evidence accumulated enough across years, other researchers recently and definitively confirmed a possible role of low Mg levels in predicting depression showing that hypomagnesemia increased the presence of depression of about 34% in a meta-analysis including almost 20,000 participants, with a low heterogeneity of results (Cheungpasitporn et al. 2015). Such an increased risk, even if with a statistically marginal significance, survived after sensitivity analysis according to cross-sectional study or longitudinal design (Cheungpasitporn et al. 2015).

While a magnesium deficiency may be considered among the causes that contribute to depression, it cannot be said on the other hand, at the present state of evidence, that a low Mg status should be expected in all subjects with depression. More probably, a subgroup of depression cases may have Mg deficiency as a contributing factor to onset or maintenance of the disease.

Moreover, beyond serum Mg levels, brain magnesium has been found low in depressed subjects as well, using neuroimaging techniques, such as phosphorous nuclear magnetic resonance spectroscopy (Eby and Eby 2010). However, the most consistent evidence regards in fact the association between low dietary Mg intakes and depression, or blood levels of Mg and depression, while other estimates of Mg (such as blood) are less used for epidemiological purposes, thus limiting any conclusion on the relationship between brain Mg and depression.

Clinical Implications of Mg Deficiency in Depression

Figure 2 summarizes the clinical implications of Mg deficiency as risk factor for depression. Animal and in vitro models suggest a relevant role of Mg deficiency for the development of depression, with response to antidepressants and anxiolytics drugs in response to experimentally induced Mg deficiency states (Szewczyk et al. 2008). Also, in these laboratory studies such a response to psychopharmacologic agents is augmented by Mg administration, suggesting an interaction between Mg, antidepressants, and anxiolytics (Szewczyk et al. 2008).

Data involving human subjects show similar results about the potential implications of Mg use as a therapeutic mean for depression. Mg supplementation should be considered as a safe intervention, with used doses in clinical trials ranging from 300 mg to 4 gr die (Du et al. 2016). Its use has been tested in a limited, but meaningful number of studies.

One randomized controlled trial (RCT) compared Mg efficacy with imipramine 50 mg, in 23 adults with depression, and hypomagnesemia and type 2 diabetes mellitus, showing equivalent efficacy between the two interventional arms (Barragan-Rodriguez et al. 2008). Another recent cross-over placebo-controlled

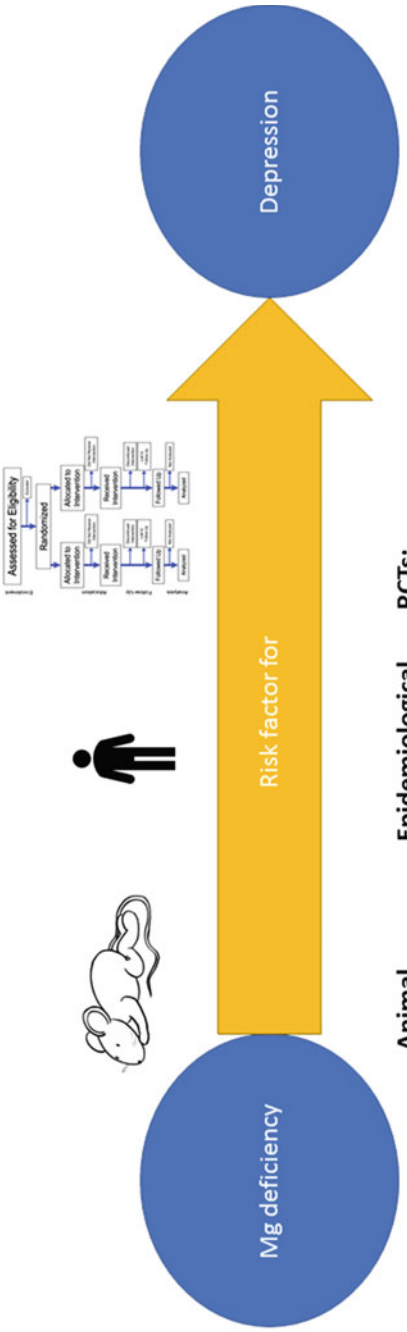

Fig. 2 Clinical implications of magnesium deficiency in depression

Table 3 Questions still open regarding magnesium and depression.

1. Should serum magnesium levels be assessed in all depressed individuals?
2. What is the precise role of magnesium in depression?
3. Can magnesium supplementation improve depressive symptoms?
4. Should magnesium supplementation be used as add-on therapy in depression?

study assessing Mg impact on depressive symptoms in treatment resistant depression, showed a correlation of 4 mg of Mg infusion and Patient Health Questionnaire-9 scoring, but not of Hamilton Rating Scale for Depression, after 7 days of treatment (Mehdi et al. 2016). A further investigation on a small group of patients described a notable response rate in patients with treatment resistant depression concomitantly treated with probiotics and Mg in addition to SSRI (selective serotonin reuptake inhibitors) (Bambling et al. 2017). Overall, however, a small total sample size and a limited number of studies have assessed effects of Mg on depression to draw any definitive conclusion.

It cannot be excluded that a subgroup of patients with low serum Mg may benefit the most from Mg supplementation, but whether routine Mg serum levels' first line screening are warranted or not in patients with depression is still a question to be addressed. Mg serum levels assessment, however, should be considered among concomitant factors maintaining depressed mood in cases showing partial or no response at all to standard antidepressant treatment instead. Vice versa patients with low Mg state should be monitored for an increased risk of depression, and Mg integration in those cases should be warranted as a preventive mean against mood disorders (Table 3).

Magnesium and Antidepressants

A different perspective should be used to evaluate concomitant administration of Mg and antidepressants. In this context, the association between Mg and medications is complex and may differentially affect drugs' efficacy according to the used compound, even beyond antidepressants class and depression (Eby and Eby 2006). For example, it was demonstrated that Mg supply decreased the intensity of morphine-induced physical drug dependence (Nechifor 2008), and that lithium, neuroleptics, and benzodiazepines treatment may require lower doses when supplemented with Mg in bipolar affective disorders (Heiden et al. 1999). Mg is supposed to play its antidepressant activity and to interact with antidepressants as NMDA antagonist, through GSK-3 inhibition, and boosting serotoninergic action rather than noradrenergic action of antidepressants (Szewczyk et al. 2008), as shown in Fig. 3. Such an interaction, has also shown to correlate with the risk of suicidal behavior, with low platelet serotonin and magnesium levels are present with higher frequency when self-harming occurs. Other specific data regarding antidepressants are, however, needed.

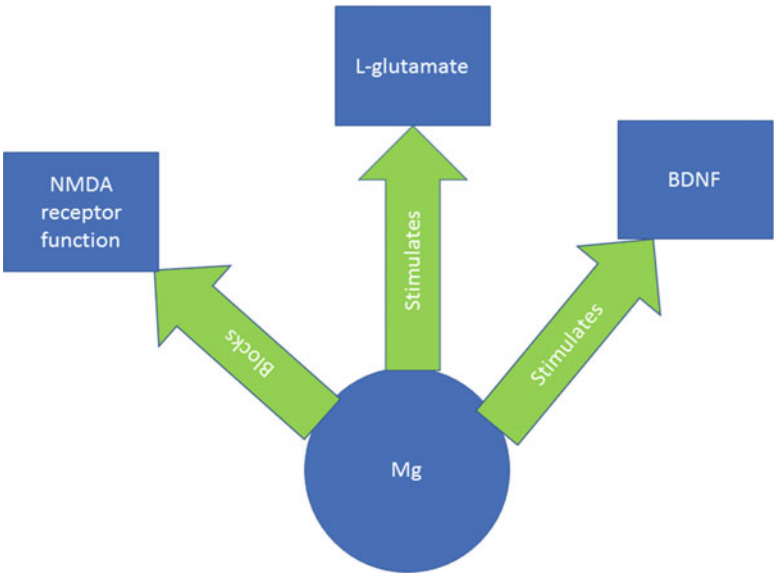

Fig. 3 Mechanisms of Mg action as antidepressant

Conclusion

Mg deficiency is a common condition in general population. The impact of this condition in the development of depression is probably important, but still too few studies use dietary Mg as proxy for Mg status. In the future more observational studies are needed to better characterize the relationship between Mg and depression, which ideally assess Mg status with more precise, valid and reliable methods than Mg dietary intake. The same is for the role of Mg supplementation of antidepressant treatment in patients suffering from depression. While promising evidence is available already, more studies should address several questions, with larger samples. In particular, it is still unclear whether Mg improves depressive symptoms in specific population such as patients with hypomagnesemia or treatment resistant depression only, or conversely if it may be a valid treatment coadjuvant for the whole population affected by depression.

Policies and Protocols

In this chapter, we have summarized the role of magnesium in depression. We have started describing the relevance of magnesium in cellular and neuronal homeostasis, and in a wide range of severe conditions. Secondly, we have focused on depression and described the possible mechanisms that may underpin a role of poor magnesium

status in increasing the risk of depression, identifying three main pathophysiologic domains. Then, we have moved to epidemiologic data supporting an association between depression and low magnesium status. Finally, we have summarized what is the state of the art of the efficacy evidence of magnesium in several depression figures, such as depression in presence of hypomagnesemia, and treatment resistant depression. We have ultimately concluded that evidence is not enough at the present time to confirm or exclude any relevant role of magnesium among treatment means for depression.

We suggest that more studies in the future focus on magnesium supplementation of depression treatment, and in particular that trials with specific features are needed. First of all trials should include larger sample sizes, and have a randomized double-blinded design, to minimize any possible risk of bias. Moreover, studies should focus on specific populations, in order to answer the question whether magnesium is helpful in treating depressive symptoms in case of hypomagnesemia only, or if its properties are useful in amplifying antidepressants' action in any figure of depression, regardless the magnesium state.

Summary Points

- Magnesium is an important physiologic regulator of cellular homeostasis, including neurons.
- Low magnesium status is frequent.
- Low magnesium status is involved in several severe medical conditions, such as diabetes and cardiovascular disease.
- Low magnesium status can contribute to depression pathogenesis or maintenance through calcium-mediated cellular toxicity, disruption of inflammatory cytokines homeostasis, and impaired serotonin balance.
- Low magnesium status increases the risk of depression, and can be frequent in a population affected by depression.
- Several animal studies suggest that hypomagnesemia leads to depression.
- Several animal studies suggest that magnesium supplementation has antidepressant activity.
- Several animal studies suggest that magnesium supplementation amplifies the action of antidepressants according to behavioral tests.
- Preliminary evidence suggests a role of magnesium supplementation in improving depression in patients with hypomagnesemia.
- Studies in humans are too few and with small sample sizes to draw any definite conclusion about the role of magnesium in depression, regardless the magnesium status.
- Further studies are needed to better characterize the role of magnesium in treating depression, with larger sample sizes, randomized double blind design, and subjects with either low or normal magnesium state.

relaxation, neurotransmitter release, protein biosynthesis, cellular energy production, mitochondrial functions, stabilization of cell membranes, transmembrane ion flux, genome stability, bone development, and glucose homeostasis. The intestine, kidneys, and bone are the major sites regulating whole-body Mg balance. Food, drinking water, and Mg-containing supplements are the main sources of Mg exposure. Recommended intakes for Mg have been established by scientific bodies, but values differ substantially. In North America, Mg intakes fall short of dietary recommendations for a large segment of the population. Overt Mg deficiency and marked hypomagnesemia can cause a wide range of symptoms and have serious health consequences; however, this degree of deficiency is rare in the general population. At present, the prevalence of Mg deficiency in the general population is unclear because of the uncertainty regarding Mg intakes needed for optimal health and the lack of an ideal biomarker of Mg status. Many observational studies have shown an inverse association between Mg intake and risk of diseases and health conditions, but there is a need for large, placebo-controlled, randomized trials to address the issue of causality. There is also a need for a comprehensive review of the existing evidence to determine if a reference interval for total serum (plasma) Mg concentration based on a health outcome can be established.

Introduction

Magnesium (Mg) is an alkaline earth metal with atomic number 12. It is an essential mineral nutrient and the fourth most abundant cation in the human body and the second most abundant intracellular cation after potassium. The adult human body contains ~22–26 g of Mg, most of which is present in bone (~55%), muscle (~25%), and soft tissues (~20%) (Swaminathan 2003; Wester 1987). Only a small fraction of total body Mg is present in the extracellular fluid (<1%) and serum (~0.3%).

Within cells Mg functions as a structural component of organic molecules and a catalytic cofactor in hundreds of enzymatic reactions (Pasternak et al. 2010). Table 1 lists some of the many diverse biochemical processes that require Mg. A number of biological functions are related to Mg's role as a regulator of calcium and potassium ion transport including muscle contraction and relaxation, neurotransmitter release, action potential conductance, and regulation of vascular tone. Bound to ATP or GTP, Mg maintains a favorable conformation of the nucleotides which facilitates the release of phosphate for energy requiring reactions. Mg is also important for protein biosynthesis, cellular energy production, mitochondrial functions, stabilization of cell membranes, transmembrane ion flux, genome stability, bone development, and glucose homeostasis (Pasternak et al. 2010; Swaminathan 2003; Volpe 2013; Elin 1994; Wolf and Cittadini 1999).

Whole-Body Magnesium Metabolism

The intestine, kidneys, and bone are the major sites that regulate whole-body Mg balance (Fig. 1). Dietary Mg is absorbed from the small and large intestines by two processes: a passive transport system that involves solvent drag and a saturable active transport system. The efficiency of Mg absorption is ~40–60% but can vary considerably depending on the quantity of Mg ingested (Schwartz et al. 1984; Andon et al. 1996). Fractional absorption is inversely proportional to the amount of Mg ingested. Mg is mostly absorbed by the passive system when intakes are high, whereas the active system predominates when intakes are low.

The kidneys function to maintain Mg balance by regulating the reabsorption of filtered Mg. Mg excretion in the urine increases to eliminate excess body Mg, whereas urinary Mg excretion is reduced to conserve Mg under conditions of deficiency. Bone is a store for Mg that supplements the extracellular fluid and tissues when Mg levels decline. Diet, health conditions (e.g., digestive disorders, kidney diseases), or medications (e.g., hypermagnesuric diuretics) that alter gastrointestinal, renal, or bone Mg metabolism can lead to Mg deficiency or toxicity.

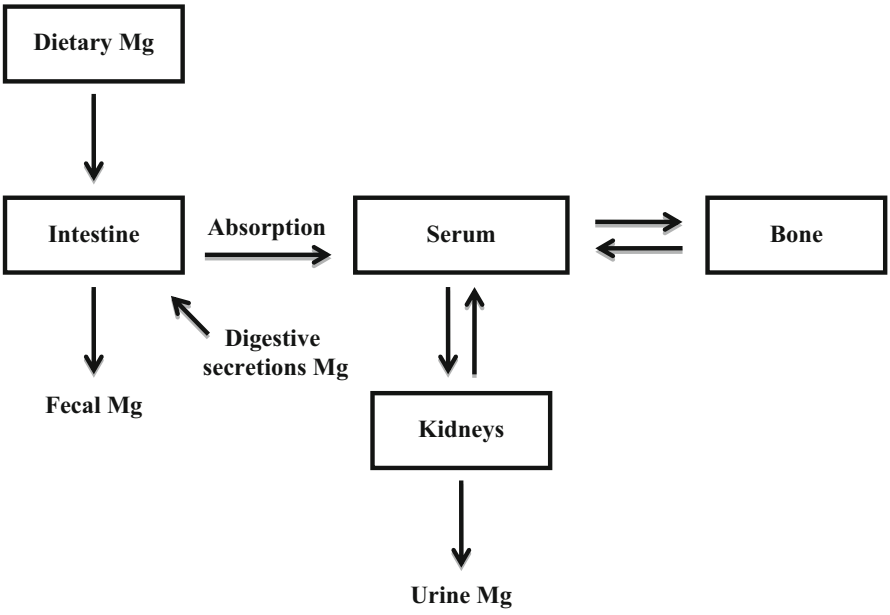

Fig. 1 Major sites regulating whole-body magnesium homeostasis. The intestine, kidneys, and bone are the main sites controlling whole-body magnesium balance. Magnesium is absorbed in the small and large intestines. Bone stores magnesium and supplements the serum under conditions of deficiency. The kidneys play a critical role in regulating body magnesium through the reabsorption of filtered magnesium. When magnesium is in excess, urinary magnesium excretion is increased. Under conditions of magnesium deficiency urinary excretion is reduced. Magnesium status is primarily affected by dietary magnesium intake and factors that alter intestinal magnesium absorption or urinary magnesium excretion Key: *Mg* magnesium

Dietary Reference Values (DRVs) for Magnesium

Mg is a mineral nutrient required in relatively large amounts. At present, Mg intakes needed for optimal health are not well defined. Recommended intakes and tolerable upper intake levels (UL) for Mg by life-stage group established for North America (Canada and United States) and the European Union (EU) are shown in Table 2. As part of the North American dietary reference intakes, the Institute of Medicine (IOM) established an estimated average requirement (EAR) for Mg for children, adolescents, and adults (Institute of Medicine 1997). The EARs were based on Mg balance studies and range from 65 to 350 mg day^{-1}. For children 1–3 y, 4–8 y, and 9–13 y EARs and Recommended Dietary Allowances (RDAs) were set the same for males and females. Values for males were set higher for adolescents and adults. For pregnancy the EARs were established at an additional 35 mg day^{-1} based on accretion of lean body mass and an adjustment factor for a bioavailability of 40%. For lactation recommended intakes were set the same as for nonlactating women because of the lack of evidence indicating that Mg requirements are increased during lactation. It was presumed that reduction in urinary Mg excretion and increased Mg resorption from bone provides the additional Mg needed for milk production. For infants 0–6 mo an Adequate Intake (AI) was established based on average intake of human milk (780 mL day^{-1}) and the average concentration of Mg in human milk (34 mg L^{-1}). The AI for 7–12 mo old infants was derived by adding Mg consumed from human milk and solid food.

The European Food Safety Authority (EFSA) Panel on Dietetic Products, Nutrition and Allergies (NDA) established DRVs for Mg for the EU (EFSA Panel on Dietetic Products, Nutrition and Allergies (NDA) 2015). The panel noted the limitations of using balance studies to set DRVs and it was concluded that Average Requirements (ARs) and Population Reference Intakes (PRIs) could not be derived for any life-stage group and therefore AIs were established based on observed intakes in nine EU countries. AIs ranged from 80–350 mg day^{-1}. For infants aged 7–11 mo the AI was derived by extrapolating upward from the estimated Mg intake in exclusively breast-fed infants 0–6 mo and taking into consideration observed average Mg intakes from a limited amount of surveys. AIs for children, adolescents, and adults were based on observed intakes in healthy populations in the EU. Similar AIs were established for both sexes for children 1– $<$ 3 y and 3– $<$ 10 y. AIs for children/adolescents 10– $<$ 18 y and adults $\geq$18 y were set higher for males compared to females. It was concluded that there was a lack of evidence to support higher requirements during pregnancy or lactation and AIs for women aged $\geq$18 y were set the same as for non-pregnant or non-lactating women.

The IOM selected diarrhea as the critical endpoint for setting the UL for Mg. The UL for Mg is unique in that it applies only to Mg consumed from nonfood sources. A UL of 350 mg day^{-1} for supplementary Mg was established for persons aged $>$8 y. It was assumed that children were as vulnerable to the effects of supplementary Mg as adults and the ULs for children were derived from the adult UL by extrapolating downward based on body weight. It was concluded that there was no evidence to suggest that pregnant and lactating women are more vulnerable

[a]Values were obtained from (Institute of Medicine 1997)

[b]Values for AIs were obtained from (EFSA Panel on Dietetic Products, Nutrition and Allergies (NDA) 2015) and the value for the UL was obtained from (Scientific Committee on Food 2001)

[c]UL only applies to supplementary magnesium

[d]UL only applies to readily dissociable magnesium salts and compounds like magnesium oxide in nutritional supplements, water, or added to food and beverages

[e]Values for females are in parentheses

to the adverse effects of supplementary Mg. ULs for pregnancy and lactation were set the same as for non-pregnant or non-lactating women. A UL was not established for infants because of the absence of data on the effects of Mg supplements in infants.

The Scientific Committee on Food (SCF) established a UL for Mg for the EU based on a similar endpoint, a transient laxative effect (Scientific Committee on Food 2001). The UL does not apply to Mg normally present in foods and beverages and was established for readily dissociable Mg salts (e.g., chloride, sulfate, aspartate, etc.) and chemical compounds like Mg oxide in nutritional supplements, or added to food and beverages. The same UL of 250 mg day^{-1} was established for persons aged $\geq$4 y including pregnant and lactating women. A UL for children aged $\leq$3 y was not established given the lack of data on adverse effects for this age group and that it was deemed inappropriate to extrapolate from the UL for older children and adults based on body weight.

Sources of Magnesium Exposure

Food, Mg-containing dietary supplements, and drinking water are the main sources of Mg exposure. Mg can also be absorbed through the skin or by inhalation; however, for most persons this amount is negligible in comparison to total daily intakes. The Mg content of some Mg-rich foods available in Canada is shown in Table 3 (Health Canada 2015). The Mg contents were obtained from the Canadian Nutrient File (CNF) and are shown per serving size and 100 g of the food. Nuts, seeds, legumes, seafood, cereals, and dark green vegetables are rich sources of Mg.

Supplement use can make a substantial contribution to total Mg intakes. The most commonly used multivitamin-multimineral supplements sold in Canada and the United States usually contain 50–100 mg of Mg (Nielsen Market Track 2012; Ford and Mokdad 2003). A 100 mg supplement corresponds to 24–32% of the RDA for adults.

Drinking water can also be an important source of Mg intake. A survey of bottled water products and municipal water sources in Ottawa, Ontario, Canada, showed that Mg content varies widely among sources of drinking water (Bertinato and Taylor 2013). Values ranged from 0 mg L^{-1} in purified water up to 103 mg L^{-1} in mineral water. Consumption of 2.2 L day^{-1} for women and 3.0 L day^{-1} for men [approximately the amount of water consumed from all beverages for adults at the 50th percentile (Institute of Medicine 2005)] of drinking water containing the highest amounts of Mg can provide more than 20% of the RDA.

Some studies in rats and humans have suggested that the bioavailability of Mg from certain organic compounds may be greater compared to some inorganic compounds (Coudray et al. 2005; Walker et al. 2003). However, a study that fed rats similar amounts of Mg from three inorganic (Mg oxide, Mg sulfate and Mg chloride) and five organic (Mg citrate, Mg gluconate, Mg orotate, Mg malate and EDTA disodium Mg) Mg compounds (in the context of a high phytic acid diet) reported similar Mg bioavailability from all compounds (Bertinato et al. 2014b).

Table 3 Magnesium content of foods

Food	Serving size	Magnesium per serving (mg)	Magnesium per 100 g (mg)
Nuts and seeds			
Brazil nuts (without shell)	60 mL	133	375

Table 3 (continued)

Food	Serving size	Magnesium per serving (mg)	Magnesium per 100 g (mg)
Banana (raw)	1 (medium)	32	27
Papaya (raw)	1/2 fruit	32	21

Average values for magnesium content of magnesium-rich foods available in Canada. Magnesium content is shown per serving size of the food source or per 100 g of the food. Data obtained from Health Canada. Canadian Nutrient File (2015). Available at http://www.hc-sc.gc.ca/fn-an/nutrition/fiche-nutri-data/index-eng.php

Rats were fed Mg at an amount inadequate to maintain optimal Mg status and the ability of each compound to preserve Mg status of the rats was examined. The results showed that Mg status of the rats (assessed by bone, serum and urine Mg concentrations) fed the different Mg compounds was similar after a 5 week feeding period indicating that any differences in the bioavailability of Mg among compounds were small and physiologically irrelevant.

Magnesium Intakes

In Canada and the United States, Mg intakes are lower than dietary recommendations for a large segment of the population (Ford and Mokdad 2003; Health Canada 2012). Mg intakes in the US population were estimated by 24 h dietary recalls from the National Health and Nutrition Examination Survey 1999–2000 (Ford and Mokdad 2003). Median intakes for adults aged ≥20 y were 326 mg day^{-1} (mean: 352 mg day^{-1}) for white men and 237 mg day^{-1} (mean: 256 mg day^{-1}) for white women. Median intakes were 237 mg day^{-1} (mean: 278 mg day^{-1}) for African American men and 297 mg day^{-1} (mean: 330 mg day^{-1}) for Mexican American men. Median intakes were 177 mg day^{-1} (mean: 202 mg day^{-1}) for African American women and 221 mg day^{-1} (mean: 242 mg day^{-1}) for Mexican American women. Racial differences were observed. Mean intakes were lower for African Americans compared to white Americans for both sexes. For the three racial groups examined, women had lower intakes compared to men.

More recent national estimates of usual Mg intakes were determined for the US population in the National Health and Nutrition Examination Survey 2005–2006 (U.S. Department of Agriculture 2009). Usual Mg intakes were based on 24 h dietary recalls from participants 1 y of age and over. More than half of Americans 19 y and over had Mg intakes from food and water below the EAR. A comparable shortfall in Mg intake exists in Canada. Results from the Canadian Community Health Survey, Cycle 2.2 (CCHS 2.2) conducted in 2004 showed that among Canadians 19 y and older greater than 34% had intakes from food and water below the EAR (Health Canada 2012). For several sex-age groups, estimates exceeded 40% below the EAR.

Mg intakes from food (fortified or not fortified) in nine EU countries (i.e., Finland, Germany, Italy, United Kingdom, France, Netherlands, Ireland, Sweden, and Latvia)

were analyzed by the EFSA Panel on Dietetic Products, Nutrition and Allergies for the purpose of setting AIs for Mg (EFSA Panel on Dietetic Products, Nutrition and Allergies (NDA) 2015). The range of average Mg intakes (without consideration of Mg intake from dietary supplements) was 317–439 mg day^{-1} for men and 254–357 mg day^{-1} for women 18– < 65 y of age. For men and women aged 65– < 75 y, the range was 312–407 mg day^{-1} and 241–343 mg day^{-1}, respectively. The range of Mg intakes for older adults aged >75 y were 264–388 mg day^{-1} for men and 232–347 mg day^{-1} for women.

Assessment of Magnesium Status

Accurate assessment of physiological Mg status presents a challenge since an ideal nutritional biomarker is lacking. The most studied and commonly used biomarkers are listed in Table 4. The Mg loading test (also called the Mg retention test) is a sensitive method for evaluation of Mg deficiency (Rob et al. 1999). The method involves parenteral administration (usually intravenously) of a known quantity of Mg and determination of the amount of Mg excreted in the urine over a 24 h period. This allows calculation of the percentage of the Mg dose retained by the body. With increased severity of Mg deficiency, the percentage of the Mg load retained by the body increases. A strong negative correlation exists between percentage Mg retained and Mg concentration in bone. A shorter version of the Mg loading test that infused the Mg load over 1 h (instead of the standard 8 h) also proved useful for assessment of Mg deficiency (Rob et al. 1999). Although considered the "gold standard" for evaluating Mg status, the Mg loading test is complex and time consuming. Thus, this test is not ideal for use in large studies or for routine screening. In addition, it is unsuitable for persons with impaired renal function.

Total serum or plasma Mg concentration is the most frequently used method for assessing Mg status in humans. A population-based reference interval for total serum Mg concentration of 0.75–0.955 mmol L^{-1} was established based on results from the first National Health and Nutrition Examination Survey (NHANES I) conducted in the United States between 1971 and 1974 (Lowenstein and Stanton 1986). Thus, a serum Mg concentration lower than 0.75 mmol L^{-1} is usually considered as hypomagnesemia.

Table 4 Nutritional biomarkers of magnesium status

Magnesium loading (retention) test
Serum or plasma total magnesium concentration
24 h urine magnesium excretion
Red blood cell magnesium concentration
Bone magnesium concentration

Many biomarkers in various biological samples have been studied for their potential to measure magnesium status. Listed are the best characterized and most commonly used biomarkers.

Despite its widespread use, serum Mg concentration has certain limitations. Serum Mg concentration can be affected by changes in concentrations of serum proteins such as albumin. At low and high albumin concentrations, a linear relationship with serum Mg has been reported (Kroll and Elin 1985); however, the effect appears minimal when albumin concentrations are within the normal reference interval. Serum Mg concentration may not always accurately reflect intracellular Mg deficiency. Serum Mg concentration is tightly controlled primarily by renal Mg excretion. Bone also maintains serum Mg concentrations by supplementing the serum under conditions of deficiency. This strong homeostatic control may explain, at least in part, the poor association observed between dietary Mg intakes and serum Mg concentrations, in particular when Mg intakes exceed nutritional requirements.

Despite certain limitations, low-serum Mg concentrations usually indicate Mg deficiency. In animal models of dietary Mg restriction, serum Mg has been shown to be reduced in a dose-dependent manner demonstrating that serum Mg responds to dietary Mg deficiency and reduced Mg status (Bertinato et al. 2014a; Bertinato et al. 2014b). In humans, serum Mg responds to long-term changes in Mg intakes (Klevay and Milne 2002) and increases with Mg supplementation (Witkowski et al. 2011; Zhang et al. 2016a). A recent meta-analysis of randomized controlled trials of oral Mg supplementation showed that serum (plasma) Mg concentration increases in a time- and dose-dependent manner (Zhang et al. 2016a). Notably, increases were greater for persons with lower baseline serum Mg concentrations. It has been suggested that a serum Mg concentration below 0.75 mmol L^{-1} is a useful indicator of Mg deficiency, but a value greater than 0.75 mmol L^{-1} does not exclude deficiency (Arnaud 2008; Elin 2010).

Twenty-four hour urine excretion of Mg responds to Mg intake and may provide meaningful information on Mg homeostasis and status. Analyzes of results from Mg depletion and supplementation studies showed an overall response of 24 h urinary Mg excretion to dietary Mg intake (Witkowski et al. 2011). Analyzes of data from randomized controlled trials of Mg supplementation showed that 24 h urine Mg excretion was increased compared to the placebo groups and responded to the supplementation in a dose- and time-dependent manner (Zhang et al. 2016a). The response of 24 h urinary Mg to supplementation was greater for persons with higher baseline serum Mg concentrations or 24 h urine Mg excretion.

Mg depletion and supplementation studies show that red blood cell (RBC) Mg concentration (expressed as RBC volume) responds to Mg intake (Witkowski et al. 2011). Analyzes of nine randomized controlled trials of oral Mg supplementation showed that RBC Mg was increased compared to the placebo groups (Zhang et al. 2016a). A similar dose (i.e., 300 mg day^{-1}) was used in all these studies which prevented evaluation of a dose-response relationship.

Bone Mg concentration is a sensitive measure of total body Mg status and decreases in a dose-dependent manner in animal models of dietary Mg restriction (Bertinato et al. 2014a; Bertinato et al. 2014b). Bone Mg concentration is a valuable tool for evaluating Mg status in experimental animals, but the invasiveness of this method limits its use in humans.

A number of other potential biomarkers in various biological samples have been tested for suitability in assessing Mg status (Witkowski et al. 2011; Zhang et al. 2016a). However, for these biomarkers the number of studies is limited and thus conclusions regarding their value cannot be accurately assessed. Results from two trials did show that fecal Mg concentrations were higher in Mg supplemented versus placebo groups (Zhang et al. 2016a).

Physiological Effects of Magnesium Deficiency

Persons with Mg deficiency can be asymptomatic or present a number of clinical symptoms (Table 5). The metabolism of potassium and calcium is dependent on Mg. Low serum potassium concentration (hypokalemia) is a common manifestation of Mg deficiency and is most likely caused by increased potassium excretion by the kidneys. Low-serum calcium concentration (hypocalcemia) is often observed with Mg deficiency. Mg deficiency can impair secretion of parathyroid (PTH) hormone. Lower-circulating PTH reduces intestinal calcium absorption and calcium reabsorption from bone which can lead to hypocalcemia. There is also evidence to

Table 5 Clinical symptoms of magnesium deficiency

Altered mineral metabolism
Hypocalcemia (responsive to magnesium therapy)
Hypokalemia (responsive to magnesium therapy)
Cardiac abnormalities
Cardiac arrhythmias
Electrocardiogram changes
Neuromuscular symptoms
Tremor
Myoclonic twitches or jerks
Convulsions
Chvostek's sign
Trousseau's sign
Carpopedal spasm
Ataxia
Nystagmus
Dysphagia
Tetany
Muscle fasciculation
Muscle cramps
Psychiatric disturbances
Depression
Psychosis

Listed are clinical symptoms that may be observed in patients with overt magnesium deficiency and marked hypomagnesemia.

suggest end-organ resistance to the action of PTH when Mg deficient (Rude et al. 1976). Correction of the hypokalemia or hypocalcemia is dependent on Mg therapy.

Mg deficiency can have profound effects on the cardiovascular system. Cardiac arrhythmias and electrocardiogram changes can occur. In one study, postmenopausal women were fed a diet providing Mg at ~33% of the RDA. Five of the 14 women in the study developed heart rhythm changes which required Mg repletion before completion of the 78-day Mg depletion period of the study (Nielsen et al. 2007). Neuromuscular hyperexcitability is an early sign of clinical Mg deficiency. Neuromuscular symptoms can include tremors, myoclonic jerks, convulsions, Chvostek's sign, Trousseau's sign, carpopedal spasm, ataxia, nystagmus, dysphagia, tetany, muscle fasciculation, and muscle cramps (Flink 1981). Mg deficiency can also cause psychiatric disturbances such as depression and psychosis. It is important to mention that clinical symptoms of Mg deficiency can be secondary to metabolic changes in other minerals such as calcium or potassium.

Clinical symptoms of Mg deficiency are usually observed in patients with moderate to severe Mg deficiency and marked hypomagnesemia (<0.6 mmol L^{-1}). This degree of deficiency is rare in the general population. The effect of milder degrees of hypomagnesemia (Mg deficiency) on health is less understood. There is evidence, mostly from cross-sectional or prospective cohort studies, showing that low Mg intakes (compared to current dietary requirements) common in the general population are associated with increased risk of chronic diseases and health conditions.

Prospective cohort studies have shown a significant inverse relationship between Mg intake and incidence of type 2 diabetes. Meta-analyses have reported relative risks of 0.85 (95% CI: 0.79–0.92) (Larsson and Wolk 2007) and 0.86 (95% CI: 0.82–0.89) (Dong et al. 2011) for every 100 mg day^{-1} increment in Mg intake. In the Nurses' Health Study and the Health Professionals Follow-up Study, women were followed for 18 y and men for 12 y (Lopez-Ridaura et al. 2004). Comparing the highest with the lowest quintile of total Mg intake, the relative risk of type 2 diabetes was 0.66 (95% CI: 0.60–0.73) in women and 0.67 (95% CI: 0.56–0.80) in men.

Meta-analyses of eight cross-sectional and two prospective cohort studies showed a pooled relative risk of metabolic syndrome of 0.88 (95% CI: 0.84–0.93) for every 150 mg day^{-1} increase in Mg intake for adults (Ju et al. 2014). Meta-analysis of six cross-sectional studies reported that for every 100 mg day^{-1} increment in Mg intake the overall risk of having metabolic syndrome was decreased by 17% (Dibaba et al. 2014).

A qualitative summary of 29 observational studies relating dietary Mg intake to blood pressure suggests an inverse association (Mizushima et al. 1998). A meta-analysis of 34 randomized, double-blind, placebo-controlled trials indicate a causal effect of Mg supplementation on reducing blood pressure in adults (Zhang et al. 2016b). A significant reduction of systolic (2.00 mm Hg) and diastolic (1.78 mm Hg) blood pressure was observed with Mg supplementation at a median dose of 368 mg day^{-1} for a median duration of 3 months. An increase in serum Mg concentration by 0.05 mmol L^{-1} was also observed in comparison to the placebo groups and secondary analyses showed that serum Mg concentration was inversely associated with diastolic, but not systolic blood pressure.

A meta-analysis of prospective cohort studies showed a significant nonlinear inverse relationship between Mg intake and total cardiovascular disease events comprising stroke, coronary heart disease, and cardiovascular disease death (Qu et al. 2013a). The largest reduction in risk was observed when comparing intakes of 150–400 mg day^{-1}. In a separate meta-analysis of prospective cohort studies dietary Mg was not significantly associated with cardiovascular disease, but was associated with a 22% lower risk of ischemic heart disease (Del Gobbo et al. 2013). Dietary Mg and fatal ischemic heart disease showed a nonlinear inverse relationship, with the association detected up to ~250 mg day^{-1}. Another meta-analysis of prospective cohort studies failed to observe an association between Mg intake and total cardiovascular disease mortality, but an inverse relationship was found in females suggesting that sex may be an important modifier (Xu et al. 2013). Associations between sudden cardiac death and dietary Mg intake or plasma Mg concentration were examined prospectively in the Nurses' Health Study (Chiuve et al. 2011). Results showed a lower relative risk of sudden cardiac death in women in the highest versus the lowest quartile of dietary Mg intake or plasma Mg concentration.

A meta-analysis of eight prospective cohort studies revealed an inverse association between Mg intake and total or ischemic stroke (Nie et al. 2013). In a large Dutch cohort of adults aged 21–70 y, Mg intake was also associated with reduced risk of stroke (Sluijs et al. 2014). Associations between stroke and intakes of Mg, potassium, and calcium were examined in the Nurses' Health Study I and II (Adebamowo et al. 2015). For women in the highest compared to the lowest quintiles for total Mg intake, the pooled multivariate relative risk of total stroke was 0.87 (95% CI: 0.78–0.97). In that study high intake of potassium, but not calcium, was also associated with a lower risk of stroke.

A meta-analysis of eight prospective cohort studies showed a relative risk for colorectal cancer of 0.89 (95% CI: 0.79–1.00) when comparing the highest to the lowest category of Mg intake (Chen et al. 2012). A meta-analysis of seven prospective cohort studies showed a relative risk for colorectal cancer of 0.81 (95% CI: 0.70–0.92) when comparing the highest to the lowest Mg intakes (Qu et al. 2013b). The inverse association was nonlinear with the greatest reduction in risk occurring for Mg intakes between 200 and 270 mg day^{-1}.

Low Mg intake may decrease bone mineral density (Orchard et al. 2014) and impair physical performance (Veronese et al. 2014). Studies in rats suggest that adequate Mg intake is important for growth of lean body mass (Bertinato et al. 2016; Venu et al. 2005; Venu et al. 2008).

Prevalence of Magnesium Deficiency

Marked hypomagnesemia is common in hospitalized patients with reported incidence rates of 11% (Wong et al. 1983). Higher incidence rates of 65% have been reported among critically ill patients (Ryzen 1989). The primary causes are reduced Mg absorption and increased urinary excretion that can result from disease, malnourishment, or medications. Mg deficiency is common among alcoholics and

both type 1 and type 2 diabetics. Low Mg intake, reduced absorption, and increased urinary excretion contribute to the poor Mg status observed in alcoholics. It has been estimated that as high as 13.5–47.7% of type 2 diabetics are hypomagnesemic (Pham et al. 2007). The cause is multifactorial and includes increased loss of Mg in the urine from osmotic diuresis and possibly insulin resistance. A cross-sectional study in Ottawa, Canada, showed that serum Mg concentration was lower in South Asian Canadians compared to white Canadians (Bertinato et al. 2015). After controlling for use of diabetes medication, racial differences in serum Mg were no longer significant suggesting that the higher incidence of diabetes in South Asians makes them more vulnerable to Mg deficiency.

In North America, the increase in food processing most likely has contributed to the shortfall in Mg intakes compared to dietary recommendations. However, the prevalence of Mg deficiency in the general population is not known because of the uncertainty regarding Mg intakes needed for optimal health. At present, there are large discrepancies in DRVs for Mg established by authoritative scientific bodies (Institute of Medicine 1997; EFSA Panel on Dietetic Products, Nutrition and Allergies (NDA) 2015; Joint FAO/WHO Expert Consultation 2004).

The challenge in determining the prevalence of Mg deficiency in the general population is further compounded by the lack of a biomarker with a defined reference interval for health that can be used for routine evaluation of Mg status and in large studies. Total serum Mg concentration is the most widely used measure; however, the normal reference interval was based on serum Mg concentrations in the US population and not a health outcome. Thus, accurate assessment of the prevalence of Mg deficiency using this reference interval is not possible and can lead to large underestimates or overestimates.

Policies and Protocols

Research on the Health Effects of Low Magnesium Intakes and Nutritional Biomarkers of Magnesium Status

Overt Mg deficiency and marked hypomagnesemia can induce a number of clinical symptoms and have serious health consequences, but this degree of deficiency is uncommon in the general population. At present, there is a poor understanding of Mg intakes needed for optimal health and an ideal biomarker for assessment of Mg status is lacking, making it difficult to determine the incidence of Mg deficiency in the general population. Many studies have reported an inverse association between Mg intake and risk of chronic diseases and health conditions. However, much of the evidence comes from observational studies making it impossible to establish a causal relationship. There is a need for large, well-controlled, randomized clinical trials on the effects of Mg intakes on risk of chronic diseases and health conditions that will allow for evaluation of a dose-response relationship and address the issue of causality. Recent studies suggest that total serum (plasma) Mg concentrations can provide meaningful information on Mg status (Witkowski et al. 2011; Zhang et al.

2016a). Given that serum Mg can be easily measured at low cost, there is a need for a comprehensive review of the evidence to determine if a reference interval (or at minimum a lower cut-off value) for serum Mg based on a health outcome can be established. This will allow for accurate assessment of the prevalence of Mg deficiency and related health risk in populations which can be used to inform nutrition policies and regulations aimed at improving Mg status if deemed necessary.

Dictionary of Terms

- **Adequate Intake (AI)** – Recommended average daily intake based on estimates of nutrient intake of apparently healthy people that are presumed adequate.
- **Canadian Nutrient File (CNF)** – A food composition database that contains average values for nutrients in foods available in Canada.
- **Dietary Reference Values (DRVs)** – A set of recommended intakes for a nutrient that is often specific for life-stage groups.
- **Estimated Average Requirement (EAR)** – The average daily nutrient intake sufficient to meet the nutritional needs of 50% of the healthy persons in a particular life-stage group.
- **Hypocalcemia** – Low serum or plasma calcium concentration.
- **Hypokalemia** – Low serum or plasma potassium concentration.
- **Hypomagnesemia** – Low serum or plasma magnesium concentration.
- **Nutritional biomarker** – A quantifiable substance or characteristic in an organism that provides information on the physiological status of a nutrient.
- **Recommend Dietary Allowance (RDA)** – The average daily nutrient intake sufficient to meet the nutritional needs of 97.5% of the healthy persons in a particular life-stage group.
- **Tolerable Upper Intake Level (UL)** – The highest average daily nutrient intake that is likely to cause no adverse health effects to nearly all persons in a particular life-stage group.

Summary Points

- Magnesium is a mineral nutrient that functions as a structural component of organic molecules and a cofactor in hundreds of enzymatic reactions.
- Magnesium is required for calcium and potassium ion transport, muscle contraction and relaxation, neurotransmitter release, protein biosynthesis, cellular energy production, mitochondrial functions, stabilization of cell membranes, transmembrane ion flux, genome stability, bone development, and glucose homeostasis.
- The intestine, kidneys, and bone are the major sites regulating whole-body magnesium balance.
- Recommended intakes for magnesium established by scientific bodies differ considerably.

- Food, drinking water and magnesium-containing supplements are the major sources of magnesium exposure.
- Magnesium intakes fall short of dietary recommendations for a large proportion of the North American population.
- Total serum (plasma) magnesium concentration is the most commonly used biomarker for assessing magnesium status.
- Clinical manifestations of overt magnesium deficiency and marked hypomagnesemia can include hypocalcemia, hypokalemia, cardiac abnormalities, neuromuscular symptoms, and psychiatric disturbances.
- Magnesium deficiency and hypomagnesemia is common in hospitalized patients and persons with diabetes or alcoholism.
- The prevalence of magnesium deficiency in the general population is unknown because of the uncertainty regarding magnesium intakes required for optimal health and the lack of an ideal biomarker of magnesium status.
- Many observational studies have shown an inverse association between magnesium intake and risk of chronic diseases and health conditions.
- There is a need for large, placebo-controlled, randomized trials to examine the effects of a range of magnesium intakes on risk of diseases and health conditions to establish causal inference.
- There is a need for a comprehensive review of the existing evidence to determine whether a reference interval for total serum magnesium concentration can be established based on a health outcome.

Selenium and Cognition: Mechanism and Evidence

97

Dawd Gashu and Barbara J. Stoecker

Contents

Abstract

Selenium (Se) is important for cognition by way of its contribution to the reduction of oxidative stress. Reactive species (RS) are generated during the normal course of metabolism in the body. Evidence shows that RS are known to regulate cellular functions. They also participate in the immune system and biosynthesis of macromolecules. On the other hand, accumulated RS are highly toxic to the body and they are major concern in the pathogenesis of chronic diseases including cancers, cardiovascular disease, and neurodegenerative

diseases. Every aerobic cell is vulnerable to attack by RS consequently, resulting in oxidative stress. However, the brain is particularly susceptible to oxidative stress due to its composition and physiology. Oxidative stress to the brain is associated with cognitive deficits, mood disorders, and behavioral problems. Evidence from animal and human studies suggest the importance of selenium for cognitive performance, mood, and behavior through protection against oxidative damage to substrates including low-density lipoproteins (LDL), hydroperoxide, hydrogen peroxide, peroxynitrite, and tert-butyl hydroxyperoxide (t-BHP). The dose response relationship between Se and cognitive performance is non-linear suggesting both deficiency and excess intake results in adverse neurobehavioral outcomes. In addition, through its role in thyroid metabolism, limited evidence suggests the importance of selenium in improving cognitive performance of persons with hypothyroidism.

Keywords

Alzheimer's disease · Antioxidant · Brain · Cognition · Depression · Oxidative stress · Mood · Reactive oxygen species · Selenoproteins · Selenium

List of Abbreviations

AD	Alzheimer's disease
ATP	Adenosine triphosphate
CSF	Cerebrospinal fluid
CuZn-SOD	Copper, zinc-superoxide dismutase
DNA	Deoxyribonucleic acid
GHS	Glutathione
GPx	Glutathione peroxidase
IL-6	Interleukin-6
LDL	Low density lipoprotein
MCI	Mild cognitive impairment
NBNA	Behavioral neurological assessment
PKU	Phenylketonuria
RNA	Ribonucleic acid
ROS	Reactive oxygen species
RS	Reactive species
rT3	Reverse triiodothyronine
SeMet	Selenomethionine
SePP	Selenoprotein P
SOD	Superoxide dismutase
T_4	Thyroxin
T_3	Tri-iodothyronine
T_2	Di-iodothyronine
TBARS	Thiobarbituric acid reactive substances
t-BHP	Tert-butyl hydroxyperoxide
TrxR	Thioredoxin reductase

Introduction

Selenium (Se) is important for cognition by way of its contribution to the reduction of oxidative stress. Prooxidants and reactive species (RS) (oxygen and nonoxygen RS) are indispensable products of the normal body metabolism. Reactive species participate in the normal vascular physiology, cellular oxygen sensing, and genomic stability and transcription regulation (Alfadda and Sallam 2012). In addition, the immune system requires certain oxidative states to destroy pathogens and control inflammation. Reactive species are also implicated in the biosynthesis of thyroid hormones (Brieger et al. 2012). On the other hand, RS at higher concentrations are highly toxic to biological macromolecules such as lipid, protein, and DNA, and thus are major concerns in the pathogenesis of chronic diseases including cancers, cardiovascular disease, and neurodegenerative diseases (Datta et al. 2000).

Oxygen is essential for cellular respiration, but about 5% of oxygen in the body is converted into reactive oxygen species (ROS) thus all aerobic cells are prone to oxidative damage. Attributable to its physiology and composition, the brain, however, is at higher risk of oxidative stress (Halliwell 2006). The underlying factors for brain's susceptibility to oxidative stress are summarized in the paragraph below.

The brain requires significant ATP generation thus high oxygen (O_2) utilization which is estimated to be 20% of the basal O_2 consumption. This high O_2 consumption yields high RS relative to other organs. High dopamine concentration in the neurons can undergo oxidation to generate metabolites such as 6-hydroxydopamine that are toxic to the brain. Normally, glutamate is found in smaller amounts in the extracellular fluid of the brain. However, release of glutamate upon neuronal cell death and slow or inefficient clearance of this glutamate by glial cells results in over accumulation. In addition, inactivation of the enzyme glutamine synthase that converts glutamate to glutamine is another notable risk factor for the accumulation of glutamate. This over accumulation induces oxidative damage to the neurons in the brain. Furthermore, free metal ions such as iron in different parts of the brain stimulate the initiation of free radicals through Fenton-type reactions. The brain is also an organ vulnerable to oxidative stress because neuronal membranes are rich in polyunsaturated fatty acids that are extremely susceptible to lipid peroxidation. Finally, even though the brain is potentially highly susceptible to RS, it is equipped only with modest antioxidant systems (low concentrations of catalase, glutathione peroxidase, and vitamin E) (Halliwell 2006; Cui et al. 2004; Kim et al. 2000).

Unbalanced redox states in the body, where the intake and endogenous synthesis of RS exceeds the handling capacity of the antioxidant systems, result in the development of oxidative stress (Halliwell 2006). Oxidative stress in the brain has been suggested to negatively influence cognitive performance and cause mood disorder and behavioral deficits (Berr et al. 2000). Evidence from animal and human studies supports the benefit of antioxidant compounds in counteracting RS (Fukui et al. 2002; Keller et al. 2005). Selenium is a potent antioxidant nutrient. It exists in the active sites of several enzymes that catalyze reactions essential to the protection of tissues against oxidative damage and consequently has been associated with prevention of cognitive and behavioral deficits (Steinbrenner and Sies 2009).

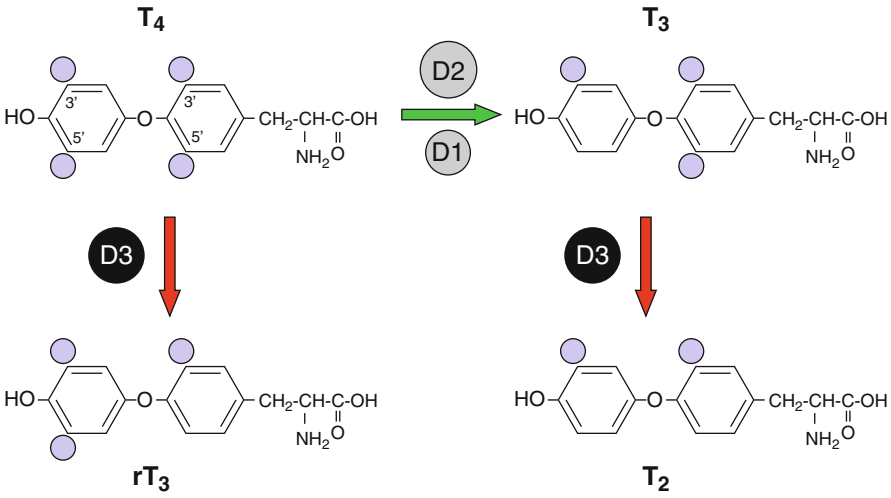

Fig. 1 Schematic presentation for the role of iodothyronine deiodinase enzymes in thyroid hormone metabolism (Adapted with permission from Pol et al. 2010)

Thyroid hormones regulate genes involved in myelination, synaptogenesis, and neuronal cell differentiation during early brain development (Bernal 2007). This process is thought to explain why deficiencies in iodine, the basis of thyroid hormones, contribute to delayed or reduced cognitive functioning. Selenium is an important cofactor for iodothyronine deiodinase enzymes involved in the conversion of the inactive thyroid hormone thyroxin (T_4) into the biologically active form triiodothyronine (T_3), or into the inactive metabolite reverse triiodothyronine (rT_3) and di-iodothyronine (T_2) (Fig. 1). In addition, the selenoenzyme thioredoxin reductase (TrxR) protects the autoxidation of the thyroid gland by hydrogen peroxide (H_2O_2) produced during the synthesis of thyroid hormones (Beckett and Arthur 2005). Thus, through its role in normal thyroid hormone synthesis and protection of the thyroid gland against oxidative damage, Se may influence cognitive performance. This review summarizes available evidence and underlying mechanisms on the relationship between Se nutrition and cognitive performance, mood and behavior.

Selenium and Selenoproteins

Selenium is a trace element needed by the body in small amounts. It is classified as a metalloid, exhibiting intermediate properties between metals and nonmetals. The element exists in organic forms associated with amino acids such as selenocysteine and selenomethione; and in inorganic forms as selenite (SeO_3^{-2}), selenide (Se^{2-}), selenate (SeO_4^{-2}), and elemental selenium (Se). Selenium enters the food chain through plants, which take it up from the soil. Soil Se distribution in the world is

Table 1 Range of selenium concentration in foods from different parts of the world (Navarro-Alarcon and Cabrera-Vique 2008)

Food item	Concentration range (ng/g)[a]
Meat[b]	27.0–770.0
Organ meats (pork kidney, pork liver)	256.0–1543.0
Fish (salmon, tuna, sardines)	270.0–810.0
Milk and milk products[c]	0.7–100.0
Fruits[d]	1.4–76.0
Vegetable[e]	3.0–180.0
Legumes (lentils and peanuts)	18.0–75.0
Refined cereals (bread, pasta)	5.8–131.8
Eggs	0.7–172.8

[a]Se concentration varies widely based on type of food and country of origin
[b]Beaf, lamb, rabbit, ham, oyster
[c]Cow's milk, cheese, yoghurt, butter, condensed milk, ice cream, buffolo milk
[d]Apple, kiwi, grapes, Sharon fruits, mango, orange
[e]Garlic, celery, lettuce, onion, green peas, pepper

highly variable (0.1–4.5 mg/kg) to the extent that deficiency and toxicity can occur among populations residing in nearby areas. Selenium status of populations is largely dependent on the concentration of phytoavailable Se (i.e., available for plant uptake) in the soil where staple crops are growing. Absorption of Se in humans is efficient and thus, deficiency mainly occurs in areas where dietary intakes are inadequate due to soil factors. Summary of range of Se concentration in foods from different parts of the world is indicated in Table 1. Phytoavailability of Se is influenced by soil physicochemical characteristics such as pH, soil mineral composition, organic matter content, soil textural class (clay, sand, silt fractions), and presence of Se-competing ions in the soil. In addition, even though Se has no role in crop nutrition, some species of plants are physiologically adapted to higher Se absorption and accumulation. Selenium through selenoproteins has diverse biological functions including thyroid hormone synthesis, DNA synthesis, immune function, fertility, and in the antioxidant defense system (Mehdi et al. 2013).

Selenium in the form of selenocysteine is a key component of the active site of diverse selenoproteins of essential biological functions. Selenoproteins predominantly play antioxidant roles in the body. So far, 25 selenoproteins have been discovered in human beings. Of the selenoproteins, selenoprotein P (SELENOP) and glutathione peroxidase (GPx) are the most studied in the context of their role in the prevention and control of oxidative damage. List and biological function of selenoproteins are summarized in Table 2. SELENOP is an extracellular glycoprotein containing 10 selenocysteine residues. About half of the circulating Se in blood plasma is found in the form of SELENOP which transports Se from the liver to different parts of the body and maintains a steady state of the element in the brain (Traulsen et al. 2004). For example, deletion of the SELENOP gene in animal models caused reduction in whole body Se by increasing urinary Se excretion (Burk et al. 2006). SELENOP also plays a critical role in protection of the body

Table 2 Common selenoproteins and their biological role (Brown and Arthur 2001)

Selenoproteins	Biological role
Glutathione peroxidase (GPx) Cytosolic GPx (GPx-1), gastrointestinal GPx (GPx-2), plasma GPx (GPx-3), phospholipid hydroperoxide GPx (GPx-4), epididymal GPx (GPx-5), olfactory epithelium GPx (GPx-6)	Reduce lipid hydroperoxides and H_2O_2 into alcohol and water
Iodothyronine deiodinases (deiodinase type 1, deiodinase type 2, deiodinase type 3)	Activation or deactivation thyroid hormones
Selenoprotein P (Se-P1, Se-P2, Se-P6, Se-P10)	Selenium supply from the liver to certain organs such as the brain, testis, and kidney Defense against oxidative injury
Selenoprotein W	Muscle metabolism in animals
Thioredoxin reductase (TrxR)	Catalyzes the reduction of thioredoxin substrate
Seleno-phosphate synthetase	Incorporation of selenocysteine into functional selenoproteins
Sperm capsule selenoprotein GPx4	Sperm mitochondrial capsule synthesis which aids sperm motility and protection against oxidative damage

against oxidative damage. In an in vitro system, Traulsen et al. (2004) reported the protection of SELENOP against oxidation of low-density lipoproteins (LDL). SELENOP, in human brain cell culture, was implicated in protecting astrocytes (ROS detoxifying cells in the brain) against oxidative stress induced by tert-butyl hydroxyperoxide (t-BHP) (Steinbrenner et al. 2006a). Similarly, SELENOP prevented *t*-BHP induced oxidative cell death by preventing disintegration of endothelial cell membrane (Steinbrenner et al. 2006b).

The other selenoprotein GPx is a family of enzymes known to reduce lipid hydroperoxides and H_2O_2 into alcohol and water, respectively. Eight isoforms of GPx have been identified. All isoenzymes have a catalytic center composed of glutamine and tryptophan residues. However, they show tissue and substrate specificity (Imai and Nakagawa 2003; Steinbrenner and Sies 2009). Of the eight isoforms, cytosolic glutathione peroxidase GPx (GPx-1), gastrointestinal GPx (GPx-2), plasma GPx (GPx-3), phospholipid hydroperoxide GPx (GPx-4), epididymal GPx (GPx-5), olfactory epithelium GPx (GPx-6) are selenoproteins with a selenocysteine active site (Brigelius-Flohé and Maiorino 2013).

Antioxidation Role of Se Compounds

The antioxidant potential of Se has been investigated by several researchers and nucleophilicity of the element is considered to be the basis for reactivity of selenocompounds and selenoproteins (Arteel and Sies 2001). Kunwar et al. (2007) investigated the in vitro antioxidant activity of a selenocysteine compound, 3,3-diselenobispropionic acid, and reported that the compound prevented the

depletion of erythrocyte glutathione (GSH) from free radical-induced hemolysis. A comparative study on superoxide radical scavenging capacity of Se (selenocarbamates) and sulfur (thiocarbamate) compounds by Takahashi et al. (2005a) indicated that the scavenging activity of selenocompounds ranged from 8.6–68.7% while activity ranged only between 2.9% and 29.5% for the tested thiocarbamates. In addition, tertiary selenoamide compounds (Takahashi et al. 2004), selenourea compounds (Takahashi et al. 2005b), and 1,3-selenazolidin-4-one compounds (Nishina et al. 2011) were reported to show superoxide anion scavenging capacity.

Free metal ions such as iron are important in initiating the generation of free radicals that attack macromolecules in the body. However, Se compounds are also known to effectively inhibit metal-mediated oxidative damage (Battin et al. 2011). In addition, some selenoenzymes exhibit metal coordination systems at their active site to inhibit metal-mediated oxidative damage. For example, molybdo-selenoprotein and Se-tungsten complexes at the active site of formate dehydrogenase enzymes are able to inhibit metal-mediated DNA damage (Battin et al. 2011).

Role of Selenoproteins in the Brain

The brain can retain Se at the expense of other tissues even during a state of Se depletion. It is also a priority organ for Se repletion indicating its key role for brain function. Selenium transport and homeostasis in the brain is carried out by SELENOP (Nakayama et al. 2007). Thus, a change in Se nutrition affects the activity of SELENOP. Conversely, an alteration to SELENOP affects Se levels in the body. An earlier study on the rate of clearance of Se from plasma after administration of ^{75}Se labeled SELENOP or ^{75}Se labeled GPx to Se deficient rats reported a fast clearance of ^{75}Se labeled SELENOP from plasma compared to ^{75}Se given as GPx, suggesting the transporting role of SELENOP. That study also reported that the brain was the priority organ for Se repletion (Burk et al. 1991). Similarly, target deletion of the SELENOP gene in mice resulted in Se deficiency in the brain and consequently neurological pathology (Hill et al. 2004). For example, disrupted spatial learning and synaptic dysfunction were reported among SELENOP deficient mice (Peters et al. 2006). Even interfering with the function of SELENOP by replacing it with the shorter version, SELENOP1$^{\Delta 240–361}$, or deletion of its receptor were associated with severe brain injury (Valentine et al. 2008).

Selenium and Cognitive Function

Selenium is important throughout the lifecycle, from fetal development through to the elderly. The formation, growth, and development of fetal brain cells are very rapid (Clouchoux et al. 2012). Certain nutrients including Se are thought to be especially important for optimal growth and development of the brain and consequently for cognitive function (Georgieff 2007). A recent

prospective mother and child cohort study investigated the impact of serum Se in different periods of pregnancy on child psychomotor functions at ages 1 and 2 years and indicated that maternal Se status during the first trimester of pregnancy was positively associated with motor development at 1 year, and Se levels in cord blood showed significant positive association with language development at 2 years. However, serum Se level at the second or third trimester had no significant association with any of the tested cognitive domains (Polanska et al. 2016).

Strong association between maternal erythrocyte Se at 27–28 weeks gestation and psychomotor development and language comprehension in young children at 1.5 years of age was also observed. Interestingly, the association was mainly apparent in girls (Skröder et al. 2015). Although, there is no clear evidence for an effect of gender on cognitive performance being mediated by Se, in female rats estrogen could influence transport and concentration of Se in the brain (Zhou et al. 2012). In another study in rats, long-term Se deficiency in mothers caused growth retardation to the offspring in utero and after delivery. Se deficiency was also associated with spatial learning and memory deficit in the offspring (Hong et al. 2006). A mother–new born dyad epidemiological study in China found an inverted 'U' relationship between cord blood Se and scores for the Neonatal Behavioral Neurological Assessment (NBNA). The authors reported 100 μg/L cord blood Se to be the maximum point on the U-shaped curve (Yang et al. 2013). Thus, the dose response relation between Se and cognitive outcome is not always linear, and both deficiency and excessive intake may result in adverse neurobehavioral outcomes. Therefore, interventions involving Se nutrition should be done with care and after thorough analysis of usual dietary intakes especially because Se has a narrow tolerable range between deficiency and toxicity (WHO 1996).

Controlling for potential confounders in the analysis such as micronutrient status (Fe, I, Zn), parental education, and anthropometric measurements, young children in Ethiopia with low serum Se had significantly lower scores on two reasoning subtests of the Wechsler Preschool and Primary Scale of Intelligence and the school readiness test than children with adequate Se (Gashu et al. 2016) (Fig. 2). Selenium deficiency can be due to inadvertent lack of Se in the diet or due to deliberate reduction of dietary components that also contain Se. For example, phenylketonuric (PKU) patients may be at greater risk of Se deficiency because they must consume low protein diets that consequently may be low in Se (van Bakel et al. 2000). A study on PKU patients that measured antioxidant cofactors (i.e., Se, retinol, tocopherol, coenzyme Q_{10}, a free radical damage marker in plasma (malondialdehyde)) and antioxidant enzymes in red blood cells (GPx, catalase, superoxide dismutase) reported significantly lower values of Se, coenzyme Q_{10}, and catalase in these blood components. In cognitive test analyses, more omission errors, fluctuating attention and inconsistency of response times, and slowing reaction time were recorded among the groups with lower plasma Se (Gassió et al. 2008).

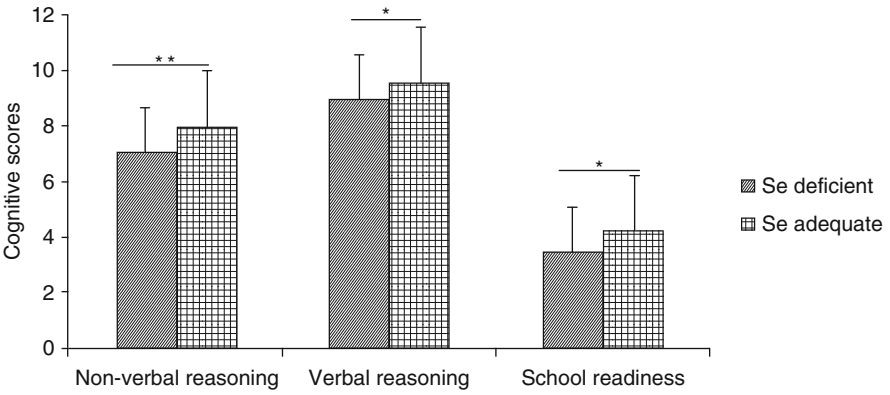

Fig. 2 Comparison of cognitive performance among selenium deficient young children and children of adequate selenium nutrition (*the difference is significant at $p < 0.05$, or **$p < 0.01$) (Adapted with permission from Gashu et al. 2016)

Selenium and Cognitive Decline in the Elderly

Cognitive decline is an important cause of disability and suffering particularly to the elderly and it contributes costs to healthcare systems. Despite progress in understanding the pathophysiology of the disease, it remains a significant challenge to modern science and medicine. Oxidative stress however is known to be a major player in the incidence of cognitive impairment and Alzheimer's type of dementia (Mecocci and Polidori 2012).

In a 9-year longitudinal follow-up study (n = 1389) of French elderly people (age 60–71 years) to evaluate the relationships between cognitive decline and oxidative stress, a decrease in plasma Se over time was associated with cognitive decline. Over the 9 years follow-up, participants with plasma Se level at the top tertile had a lower risk of developing cognitive decline. Subjects with the lowest plasma Se had greater odds (OR 1.58, 95% CI 1.08–2.31) of cognitive decline compared to participants with the highest plasma Se (Akbaraly et al. 2007; Berr et al. 2012). To investigate whether oxidative stress could explain cognitive decline in the elderly (60–70 years) in a cohort study of older subjects (n = 1166), plasma Se and carotenoids as antioxidant micronutrients, and thiobarbituric acid reactive substances (TBARS) as an indicator of lipoperoxidation were measured. Subjects in the highest percentile for TBARS had increased risk of cognitive decline emphasizing the importance of oxidative stress in cognitive decline and the protective role of Se (Berr et al. 2000). In a cross sectional survey of 2000 stable rural Chinese elderly (≥65 years), Se status was significantly associated with cognitive function. Also to best explain the dose-response relationship, the authors compared cognitive performance by nail Se quintiles and found a significant increase in performance on six out of seven cognitive tests as a function of Se quintile

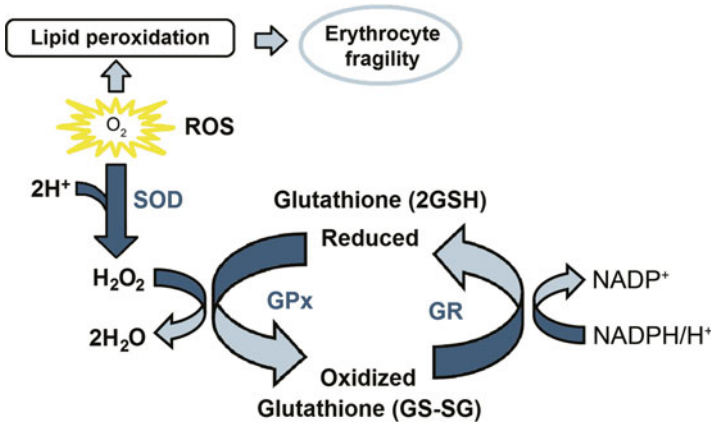

Fig. 3 Stepwise deactivation of reactive species with superoxide dismutase and glutathione peroxidase enzymes (Adapted with permission from Mineo et al. 2014). Superoxide dismutase catalyzes the dismutation of superoxide radical into H_2O_2 then glutathione peroxidase further converts H_2O_2 into H_2O

(Gao et al. 2007). In addition, among a sample of 484 (40–97 years) residents of communities in Texas and New Mexico, exposure to high ground water Se was associated with better memory function and reduced risk of cognitive decline (Hall et al. 2012).

The body has multiple protective antioxidative systems. Several of these are interdependent. Copper, zinc-superoxide dismutase (CuZn-SOD) catalyzes the dismutation of the superoxide radical (O_2^-) into hydrogen peroxide (H_2O_2) (Weydert and Cullen 2010). The Se-dependent GPx further converts H_2O_2 into H_2O (Fig. 3). The ratio of CuZn-SOD activity to GPx thus determines protection against oxidative damage from superoxide radical (O_2^-) and H_2O_2. To investigate the protective effect of antioxidant enzymes on the cognitive function of the elderly, Berr et al. (2004) measured red blood cell activity of CuZn-SOD and GPx. Subjects with cognitive decline exhibited significantly lower red blood cell GPx but higher SOD indicating high conversion rate of superoxide radical (O_2^-) into H_2O_2 but slow rate of H_2O_2 reduction.

Selenium and Alzheimer's Disease

Alzheimer's disease (AD) is a progressive brain disorder that leads to cognitive decline. Although the etiology of AD is unclear and believed to involve several factors, it has been commonly associated with the presence of oxidative stress in response to increased accumulation of oxidative products of nucleic acids (nuclear DNA, mitochondrial DNA, and RNA) (Moreira et al. 2008) and protein carbonyls (Aksenov et al. 2001) to areas of the brain important for cognition such as the neocortex, hippocampus, and other subcortical regions. In addition, amyloid β-peptide plays a role in the pathogenesis of AD (Butterfield et al. 2001) by

disrupting the blood-brain barrier consequently exposing the brain for T-lymphocytes invasion (Farkas et al. 2003; Ryu and McLarnon 2009).

Researchers have investigated various aspects of the postmortem damage seen in human AD patients using cell and tissue culture and animal models. An over-expression of SELENOP in postmortem human tissues with lesions of AD was documented (Bellinger et al. 2008). Another study of SELENOP and AD showed that compared to the control cells, SELENOP deficient cells had higher susceptibility for apoptotic cell death by amyloid β-peptide induced oxidative damage suggesting the protective role of SELENOP in AD (Takemoto et al. 2010). In addition, Se in the form of seleno-L-methionine (SeMet) improved survival of rat hippocampal neurons by preventing oxidative stress due to amyloid β-peptide accumulation (Xiong et al. 2007).

A significant positive correlation between serum trace element concentrations (Se, Fe, Cr, and Co) and cognitive scores was reported among a group of people with cognitive impairment nondementia (a subclinical phase of dementia) and a group of people with manifestation of AD. Patients with AD of the dementia type exhibited the lowest serum Se concentration compared to patients with cognitive impairment nondementia and control groups (Smorgon et al. 2004). A study comparing Se status in AD patients, subjects with mild cognitive impairment (MCI) and a control group, showed that the AD group had the lowest plasma Se (Cardoso et al. 2014). In addition, elderly subjects with AD had significantly lower Se concentration in plasma, erythrocyte, and nail samples compared to control groups of similar age, again suggesting the important relationship between Se deficiency and AD (Cardoso et al. 2010).

Selenium and Depression

Biomarkers and behavioral alterations that may be associated with depression have been investigated in animal models and human beings. Selenium deficiency may have a role in the pathophysiology of depression by diminishing dopamine concentrations in the cerebrospinal fluid (CSF) and brain regions, and by inducing inflammation to the brain through inflammatory cytokines (Miller et al. 2009; Castaño et al. 1997). In a nested case-control study of Se deficient and Se adequate women, higher odds of depression symptoms were reported among Se deficient women (Pasco et al. 2012). In aged mice, consumption of diets high in antioxidants showed promising effects on improving psychomotor performance by reducing interleukin-6 concentration in the brain (Richwine et al. 2005). However, Se supplementation to healthy individuals with adequate baseline Se with no symptom of mood disorder had no mood improving benefit (Hawkes and Hornbostel 1996). In a randomized control trial of the effect of Se on mood of 501 healthy UK elderly, supplementation with 100, 200, or 300 μg Se/day as high-Se yeast for 6 months significantly increased blood Se level but not mean total mood score. In addition, there was no difference among supplementation dose groups suggesting Se supplementation to healthy individuals with normal baseline Se status may not benefit mood and supplementation

should not be encouraged particularly given that the element has a narrow range between adequate and toxic dose (Rayman et al. 2006).

Role of Se for Cognition via Thyroid Metabolism

Thyroid hormone is an important factor in regulating the process of synaptogenesis, myelination, and neuronal cell differentiation throughout brain development (Ahmed et al. 2008). Selenium is an essential component of iodothyronine deiodinase enzymes important for normal thyroid metabolism, and it is a cofactor of the TrxR enzyme that protects the thyroid gland against oxidative stress by H_2O_2 produced during thyroid hormone synthesis (Beckett and Arthur 2005). The relationship between thyroid hormones and cognitive function is well established. Lower concentration of thyroid hormone, a condition called hypothyroidism, is an important risk factor for cognitive decline (del Ser et al. 2000; Klein et al. 2001). Based on its importance to normal thyroid metabolism, adequate Se nutrition is considered as a factor that might be important for cognitive performance. For example, a study designed to evaluate the possible benefit of Se supplementation on reversing cognitive dysfunction exposed to the antithyroid drug methimazole and exhibiting lower thyroid hormone production over the experimental period as evaluated using elevated plus maze, open field, and Morris water maze tests shows that hypothyroid rats in general exhibited high latency in locomotory performance and deficiency in memory and learning abilities compared to the control groups. Interestingly, Se supplementation reversed the hypothyroidism associated learning and memory deficits (Dias et al. 2012). However, there is a dearth of literature concerning possible roles for Se in cognition via its effects on thyroid hormone metabolism by the selenodependant enzyme, iodothyronine deiodinase.

Policies

- Selenium is an important component of the body's protection from oxidative damage and consequently is important in prevention and reversal of oxidative stress induced cognitive decline, mood, and behavioral deficits. However, Se supplementation to healthy individuals with marginal or adequate Se status is not beneficial and should be discouraged especially given that Se has a narrow margin between adequate and toxic concentration.
- Concentration of plant-available Se in soils largely determines staple crop Se concentrations and therefore the Se nutritional status of populations. However, Se distribution and availability in the soils is highly variable globally. Thus, soil mapping and integration with food system datasets can identify Se deficiency risks and inform the design of public health nutrition interventions. In addition, interventions must be carefully monitored because there is a narrow range between Se deficiency and toxicity.

- Selenium is implicated to play diverse roles in the human body including synthesis of macromolecules, fighting against viral infections, fertility, and prevention of chronic disease. It is also shown to be important for neurobehavioral development in the fetal period to cognitive performance through to old age. Selenium nutrition should get the desired attention in international micronutrient guidelines and recommendations.

Dictionary of Terms

- **Alzheimer's disease** – First identified by Dr. Alois Alzheimer during 1906. It is the commonest form of irreversible dementia characterized by severe difficulties in memory and thinking.
- **Amyloid plaque** – Abnormal deposition of toxic proteins called amyloid β peptides in neuron cells.
- **Antioxidants** – Exogenous or endogenous substances that inhibit oxidation of other molecules.
- **Cognition** – The mental processes of thinking, memory, problem-solving, reasoning, and other high-level functions of the brain.
- **Fenton reactions** – Reduction of hydrogen peroxide to produce reactive oxygen species under the catalytic action of trace elements, mainly iron.
- **Lipid peroxidation** – A metabolic degradation of unsaturated fatty acids by reactive oxygen species
- **Oxidative stress** – Damage to body tissues due to excessive reactive species beyond the capacity of the antioxidant defense system.
- **Prooxidants** – Xenobiotic or endogenous substances that themselves are reactive species or support generation of reactive species to induce oxidative stress to the body.
- **Selenocysteine** – Considered as the "21st amino acid" which is analogous to the amino acid cystein but containing selenium in place of sulfur.
- **Selenoproteins** – Proteins in the body containing one or more selenocystein amino acid residues.
- **Thyroid hormones** – Hormones (thyroxin and triiodothyronin) produced by thyroid gland.

Summary Points

- This chapter reviews the role of selenium nutrition on cognitive performance.
- Accumulation of reactive species generated during the normal course of metabolism is highly toxic to biological macromolecules and is a major concern in the pathogenesis of chronic diseases and a significant factor for cognitive decline.
- Even though every aerobic cell is at risk of oxidative damage, the brain is especially vulnerable and this condition is a significant factor for cognitive decline.

- Selenium compounds and selenoproteins exhibited a strong antioxidant role against oxidative substrates such as low-density lipoproteins, hydroperoxide, hydrogen peroxide perxynitrite, tert-butyl hydroxyperoxide, and several others. Selenium deficiency or altering the structure or deletion of selenoproteins is associated with severe brain injury.
- Maternal Se status is associated with cognitive ability of the new born. However, the relationship between maternal Se and cognitive ability is not linear (inverted "U") suggesting both deficiency and excessive Se intake may result in adverse neurobehavioral outcomes.
- Selenium nutrition in the elderly prevents the progression of Alzheimer's disease, cognitive decline, mood disorder, and depression. However, Se supplementation to healthy individuals with adequate baseline Se with no symptom of mood disorder has not been shown to improve mood.
- Hypothyroidism is associated with reduced cognitive performance. However, Se nutrition prevents and reverses hypothyroidism-induced cognitive deficits.
- Limited or no literatures are available on the role of Se in cognition through its effect on thyroid hormone metabolism thus new studies are recommended.

Abstract

Selenium is a trace element, which is required for normal growth and development of animals and humans. It works by incorporating into proteins to make selenoproteins. These selenoproteins help to prevent free radicals from causing cellular damage, which may in turn lead to the development of various chronic diseases. Selenium deficiency, although is rare, can happen when the body does not have enough selenium. This chapter will review systematically the effects of selenium deficiency on fibrosis in various chronic diseases, such as cardiac fibrosis, liver fibrosis, kidney fibrosis, cystic fibrosis, thyroid fibrosis, oral submucous fibrosis, and pancreatic fibrosis in both animal and human studies. Moreover, their prevention and treatment with selenium supplement will be evaluated as well.

Keywords

Cardiac fibrosis · Cystic fibrosis · Fibrosis · Kidney fibrosis · Liver fibrosis · Oral submucous fibrosis · Selenium deficiency · Selenium supplement · Thyroid fibrosis · Pancreatic fibrosis

List of Abbreviations

CCL_4	Carbon tetrachloride

TIMP	Metalloproteinase inhibitor
WHO	World Health Organization

Introduction

Selenium is an important element, which is necessary in small amounts for the growth and development of animals and humans (Moghadaszadeh and Beggs 2006; Papp et al. 2007; Roman et al. 2014). Selenium is incorporated into proteins to form vital selenoproteins such as glutathione peroxidase (GPx) as a part of the active site (Lu and Holmgren 2009). In the ecosystem, bacteria, fungi, and plants serve as the primary producers, as they can easily integrate and convert inorganic selenium into organic selenium species. By consumption of the primary producers,

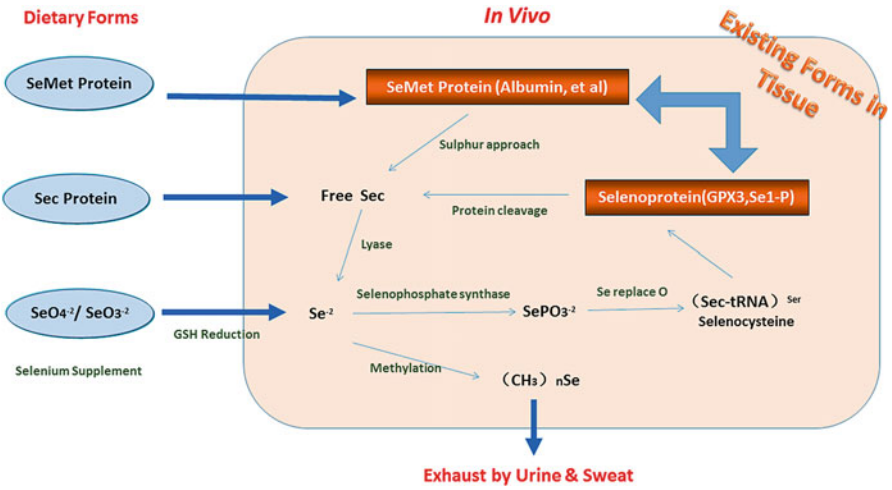

Fig. 1 Representative photo of selenium metabolism. Selenium can be in the dietary forms of SeMet, Sec proteins, and other selenium salts; when in vivo, selenium is incorporated into proteins to form vital selenoproteins, and the metabolite can be exhausted by urine or sweat

both forms of selenium enter the food chain and move to higher trophic levels (Chapman et al. 2010). In vivo, selenium is absorbed through the gastrointestinal tract in the form of selenite. Following its reduction to selenide by enterocytes, selenium is bound to albumin and transferred to the liver, where it is used for the synthesis of cellular glutathione peroxidase (cGPx), other selenoproteins, and metabolites (i.e., selenosugars). The selenium is then re-excreted into the bloodstream and transferred to the kidney, where it is degraded and utilized to synthesize extracellular glutathione peroxidase (eGPx) and selenosugars (Patterson et al. 1989; Suzuki and Ogra 2002; Swanson et al. 1991). Representative of the selenium metabolism is shown in Fig. 1.

Selenium deficiency is an issue faced worldwide, particularly in developing countries (Johnson et al. 2010; Spallholz et al. 2004). According to the World Health Organization (WHO), 40 countries encountered low-selenium or selenium-deficient problem, and China is one of them (Li et al. 2007). Although there are some areas with high-selenium intake in China, the selenium-deficient areas account for 72% of the total area, which translate to 70 million people facing the potential adverse health impacts as a result of selenium deficiency (Gao et al. 2011). A long-term selenium-deficient diet could lead to damages in multiple organs of the body (Han et al. 2016, 2017; Tan et al. 2002) and induce diseases, such as Keshan disease (KD, endemic cardiomyopathy) and Kashin-Beck disease (KBD, endemic osteoarthropathy) in China (Fig. 2). However, the relationship between selenium deficiency and tissue fibrosis in chronic diseases has not been fully explored. In this chapter, the studies on the relationships between various tissue fibrosis and selenium deficiency from animal and/or human will be reviewed systematically (Table 1). Furthermore, it will provide a comprehensive knowledge of the effects of selenium deficiency on fibrosis in

Fig. 2 Characteristics of KBD patients. (**a**) Deformed joints in two knees and (**b**) flexion of the terminal finger joints or deformed fingers of grade III KBD adult (male, 58 years age). chronic diseases. Lastly, the applications of selenium supplements for the prevention and treatment of fibrosis will be evaluated (Table 2).

Selenium Deficiency and Cardiac Fibrosis

Cardiac fibrosis, a pathological process common to most cardiac diseases, is often present at the end-stage heart failure caused by various factors, such as ischemia, pressure overload, and many others (Dai et al. 2013; Duerrschmid et al. 2013; Lopez-Andrès et al. 2012). Cardiac fibrosis is a tissue response to injury, characterized by an increased number of fibroblasts in the injured area and excess deposition of extracellular matrix (ECM) proteins, which results in scarring. This scarring leads to the distortion of the structure and function of the organs (Elnakish et al. 2013; Zambrano et al. 2013). It has been reported that selenium deficiency led to

Table 1 Selenium deficiency-related fibrosis in chronic diseases. The findings of fibrosis from animal and human studies related to selenium deficiency

Fibrosis	Animal studies	Human studies
Cardiac fibrosis	Myocardial fibrosis via effects on DNA methylation balance in mice (Metes-Kosik et al. 2012) Severe degenerative changes in aortic vessel wall's ultrastructure in spontaneously hypertensive rats (Ruseva et al. 2012)	Erythrocyte glutathione peroxidase activity was significantly lower than normal value; scattered and irregular areas of myocardial loss and fibrous replacement (Inoko et al. 1998) Subepicardial fibrosis in an "occidental" dilated cardiomyopathy patient (Johnson et al. 1981)
Liver fibrosis	Hepatic periportal fibrosis obvious thickening of blood vessel wall, increase in bile duct, and hyperplasia of collagen fiber; upregulated MMP1/3 and downregulated TIMP1/3 were observed in the liver from the low-selenium group (Han et al. 2016)	Selenium in serum was lower in cirrhosis than in controls and was more reduced in ascitic than in compensated patients (Casaril et al. 1989)
Kidney fibrosis	Significantly decreased body weight and selenium concentration in the kidney and damaged the ultrastructure of the glomerulus and tubules; increased MMP1/3 and decreased TIMP1/3 at the mRNA and protein levels in kidneys (Han et al. 2016)	
Cystic fibrosis		Mean plasma and erythrocyte selenium levels were reduced in cystic fibrosis children (Neve et al. 1983) Glutathione peroxidase activity (GSH-Px) was reduced in cystic fibrosis and in children with dietetically treated phenylketonuria (Ward et al. 1984) The marginally reduced intestinal absorption of ^{75}Se in two children with cystic fibrosis (Heinrich et al. 1977) Whole blood, plasma, and red blood cell selenium levels were significantly lower in patients with cystic fibrosis (Rea et al. 1979; Stead et al. 1985)
Thyroid fibrosis	The thyroids in selenium-deficient condition express more macrophage with obvious TGF-β immunostainings; the proliferation index of the epithelial cells decreased (Contempre et al. 1995)	The thyroid gland of a myxedematous cretin from the Himalayan region in 1908, which consisted of large and uniform fibrous strands with little remaining functional thyroid tissue (McCarrison 1909) Thyroid was atrophied, with loss of epithelial tissue, extensive fibrosis, and lymphocytic infiltration; selenium deficiency is a cofactor to the iodine deficiency (DeQuervain and Wegelin 1936) Selenium deficiency combine with

(*continued*)

Table 1 (continued)

Fibrosis	Animal studies	Human studies
		iodine deficiency increased necrosis, induced fibrosis, and impeded compensatory epithelial cell proliferation (Contempre et al. 1995)
Oral submucous fibrosis	Selenium can influence immune response by making immune cells more resistant to oxidative stress (Matés et al. 2012)	A significantly decreased selenium level in serum of oral squamous cell carcinoma patients as compared to the controls (Khanna et al. 2013)
Pancreatic fibrosis	Vacuolation and hyaline body formation in acinar cells and loss of zonation (Gries and Scott 1972)	

Table 2 Selenium supplements for prevention of fibrosis in chronic diseases. The findings of selenium supplements for prevention of fibrosis in animal and human studies

Fibrosis	Animal studies	Human studies
Cardiac fibrosis	Significantly reduced methylation potential, DNA methyltransferase activity, and DNA methylation (Metes-Kosik et al. 2012)	Selenium did not normalize the left ventricular dysfunction (Inoko et al. 1998)
Liver fibrosis	Selenium supplement showed positive effects on CCl_4 liver injury and fibrosis (Ding et al. 2010; He et al. 1999; Liu et al. 2014; Shen et al. 2005)	A negative correlation was found between serum selenium and aminoterminal peptide of type III procollagen, suggesting a protective role of selenium against fibrosis (Lu et al. 1986)
Cystic fibrosis		The improvement of lipid peroxidation markers was not related to the selenium supplementation (Portal et al. 1995)
Thyroid fibrosis		Preventing a reduction in thyroid echogenicity after 6 months of treatment and in reducing thyroperoxidase and thyroglobulin autoantibodies after 12 months (Nacamulli et al. 2010) Lower thyroid peroxidase autoantibody titers and a significantly higher improvement in well-being and/or mood (Toulis et al. 2010)
Pancreatic fibrosis	Acinar nuclei enlarged and became vesiculated, the cytoplasm filled the empty lumens as well; the fibrous tissue gradually disappeared (Gries and Scott 1972) Prevention of pancreatic degeneration and increasing the relative weight (Cantor et al. 1975)	

reactive myocardial fibrosis and systolic dysfunction accompanied by an increased myocardial oxidant stress, which might lead to myocardial fibrosis via effects on DNA methylation balance (Tao et al. 2013).

It has been reported that low-selenium intake caused extensive degenerative changes in the ultrastructure of the aortic vessel walls of spontaneously hypertensive rats. In addition, the histological examination found that multiple atherosclerotic spots spread along the thoracic aorta and even to the abdominal aorta (Ruseva et al. 2012). Plaques with fibrosis and hyalinosis predominated in the abdominal aorta, which were located near the branches of the arteries, and caused deformation and stenosis of the aorta lumen (Ruseva et al. 2012). Fibrosclerotic plaques with multiple necrosis and lipid drops in the media were found to be involved in the whole wall of the aortic vessel as well (Ruseva et al. 2012). The smooth muscle cells were functionally transformed to fibrocytes due to the degeneration and vacuolization. Consequently, the vessel wall thickened.

A case report study on a 38-year-old man with Crohn's disease showed that when he was at the age of 28, he developed rapidly progressing heart failure and ventricular premature beats associated with selenium deficiency following 16 years of total parenteral nutrition (Inoko et al. 1998). The concentration of his serum and erythrocyte selenium and his erythrocyte GPx activity were significantly lower than normal value. Although he had received selenium supplements and did not have heart failure symptoms for 11 years, he was diagnosed with congestive heart failure at 38 years old. After his death, microscopic examination of the myocardium revealed scattered and irregular areas of myocardial loss and fibrosis, which were located specifically in the midmural area of the left ventricular free wall (Inoko et al. 1998). Another case report by Johnson et al. (1981) mentioned an "occidental" patient whom selenium deficiency was associated with dilated cardiomyopathy. The autopsy also revealed midmural-localized subepicardial fibrosis, indicating that the midmural change was the characteristic of selenium deficiency-related cardiomyopathy. The damage to the left ventricle and the resulting dysfunction, if fully developed, may be irreversible despite the use of selenium supplements (Inoko et al. 1998).

Selenium Deficiency and Liver Fibrosis

Liver fibrosis is the scarring process that represents liver's response to injury. All chronic liver diseases can lead to liver fibrosis. An animal study (Han et al. 2017) of rats with long-term selenium-deficient diet showed that the ultrastructure of hepatocytes was changed, with clumped and condensed chromatin, random-shaped and enlarged nucleolus, evidently swollen mitochondria with a large decrease in electron density, and an unclear double-membrane structure of mitochondria. In a pathological analysis, the low-selenium rats showed hepatic periportal fibrosis, obvious thickening of blood vessel walls, increase in the size of the bile ducts, and hyperplasia of collagen fiber (Fig. 3). Alterations of MMP1/3 and TIMP1/3 expressions were also observed. More importantly, the difference in the

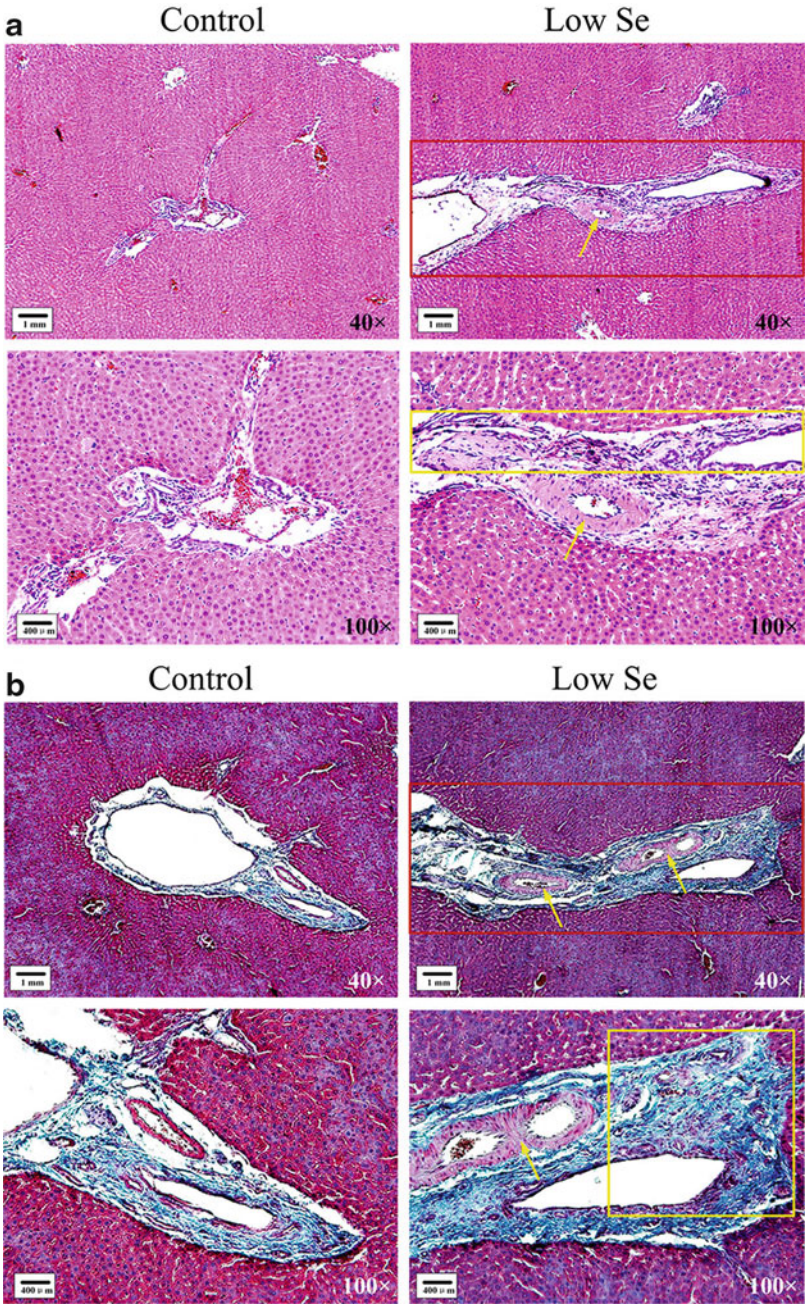

Fig. 3 Representative HE staining (**a**) and Masson's staining (**b**) of rat's liver from low-selenium and control groups. The pathological changes included fibrosis in hepatic periportal, thickening of blood vessel wall, increase in bile duct, hyperplasia of collagen fiber as well as bile duct in the hepatic portal of selenium-depleted group both from the HE and Masson's staining (With permission of Han et al., Biol Trace Elem Res, 2017, 175(2): 396–404)

expression of TIMP1/3 in the hepatic central vein and sinusoid comparing with the hepatic periportal area has been well-investigated in this study. In the hepatic central vein and sinusoid, upregulated MMP1/3 and downregulated TIMP1/3 were observed in the liver from the low-selenium group, which caused ultrastructure alterations of the hepatocyte. However, in the hepatic periportal area, both upregulated MMP1/3 and TIMP1/3 were detected and might be related to the fibrosis formed in the portal tracts. Thus, collagen fibers were formed in hepatic periportal except in the hepatic central vein and sinusoid. However, different cell sources, including endothelial cells, hepatic stellate cells (HSCs), or macrophages, may contribute to the differences of MMPs/TIMPs, which will be investigated in further studies.

A study on the comparison between 55 patients with alcoholic cirrhosis and 47 healthy individuals has been carried out to assess the concentration of selenium in the serum (Casaril et al. 1989). The selenium in serum was lower in patients with cirrhosis than in controls and was even lower in the ascitic patients than in compensated patients. A negative correlation that was found between serum selenium and aminoterminal peptide of type III procollagen suggested a protective role of selenium against fibrosis: selenium, as an important free radical scavenger, may protect the liver in alcoholic subjects from the oxidative damage that caused hepatic fibrosis (Lu et al. 1986).

Selenium Deficiency and Kidney Fibrosis

Kidney (renal) fibrosis is a direct consequence of the kidney with limited capacity to regenerate after injury. Renal scarring causes a progressive loss of the renal function, which eventually leads to the end-stage of the renal function failure. There was mounting evidences that suggested the importance of selenium in the development of chronic kidney disease (Zachara et al. 2006). The kidney, acts as a kind of selenium reservoir, is the organ with the largest concentration of selenium in the body (Loeschner et al. 2014). A previous study reported that the body weight and selenium concentration in the kidney of the rats with a selenium-deficient diet for 109 days significantly decreased (Han et al. 2016). The diet also caused damage to the ultrastructure of the glomeruli and tubules, which showed an obvious proliferation of the mesangial cells, the fusion of podocyte foot processes, and the thickening of the glomerular basement membrane. The glomeruli also had a slightly vacuolar degeneration of the tubule epithelial cells, an increase at the gaps between adjacent cells with edema fluid or protein solution, and edema of microvilli along with the increased gap and decrease of links between adjacent cells. Pathological changes with fibrosis around the renal hilum aorta and in the renal collecting duct were also observed in rats with selenium-depleted diet (Fig. 4). In addition, having a selenium-deficient diet caused an increased MMP1/3 and a decreased TIMP1/3 at the mRNA and protein levels in the kidneys (Han et al. 2016). The damage of the ultrastructure and ECM by the low amount of selenium in the kidney might affect the functions of the kidney.

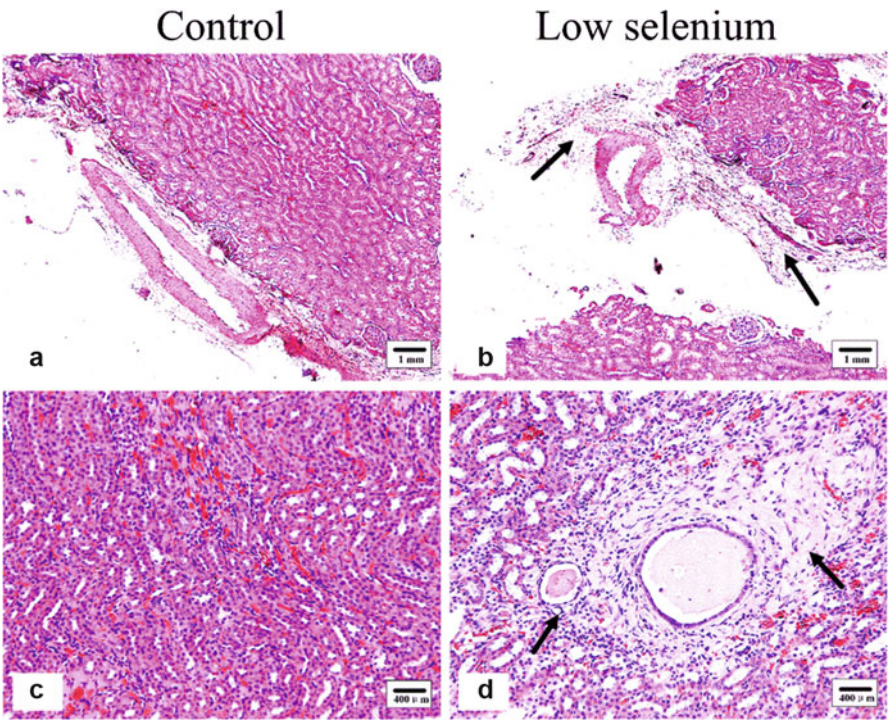

Fig. 4 Representative HE staining of rat's kidney from low-selenium and control groups. Control groups: (**a**) (40×), (**c**) (100×); low-selenium groups: (**b**) (40×), (**d**) (100×). In the low-selenium groups, increased fibers were observed around the renal hilum aorta (**b**) and increased fibrous tissues were detected in the renal collecting duct (**d**)

Selenium Deficiency and Cystic Fibrosis

Cystic fibrosis is a dangerous genetic disease that can cause extensive damage to the lung and digestive system, among other organs. A possible deficiency of the trace element selenium in cystic fibrosis has been well-investigated (Dworkin et al. 1987). Even though there were controversial results, it was evident that selenium deficiency was the primary factor that caused cystic fibrosis (Lloyd-Still and Ganther 1980; Castillo et al. 1981). The plasma and erythrocyte selenium of 20 children (aged 7–19 years) (Neve et al. 1983) with cystic fibrosis were measured and showed that the average of plasma and erythrocyte selenium levels (63 ng/ml ± 15 and 329 ng/g Hb ± 86) were markedly lower than the age-matched controls (82 ng/ml ± 13 and 404 ng/g Hb ± 116). Another study on a long-term selenium status in children from North East Scotland (Ward et al. 1984) also showed that the blood selenium content was significantly lower in the children with cystic fibrosis and coeliac disease than the age-matched control groups. Although younger patients (age 3–6 years) with cystic fibrosis did not present

clinical features of selenium deficiency, they expressed a reduced GPx activity. The lessened blood selenium in patients with cystic fibrosis, even when treated, could be due to malabsorption of selenium, which was shown in one study (Heinrich et al. 1977), where marginally reduced intestinal absorption of ^{75}Se in two children with cystic fibrosis was observed. The children with cystic fibrosis only absorbed 60% and 75% of the radiolabeled ^{75}Se from pork compared with 76% and 100% in healthy adults. It has been suggested that selenium deficiency might be one of the causes of cystic fibrosis (Wallach 1979). It must be noted that the lower blood selenium and GPx observed in younger patients (age 3–6 years old) may be a phenomenon attributed to the small sample sizes of those studies.

The study on the total selenium and selenium species in sera (Michalke 2004) showed that the sera from cystic fibrosis patients contained significantly lower values of total selenium, selenocysteine, and cationic/neutral selenium compounds in comparison to the sera of the healthy volunteers. The total selenium in the sera of cystic fibrosis patients was 58 ± 10 μ/L, which was notably lower than the sera in healthy persons (102 ± 12 μg/L). Selenocysteine in the cystic fibrosis was also much lower with a −75% difference from the healthy group. From these results, it could be concluded that the lowered selenocysteine values together with the lowered cationic/neutral selenium compounds in the cystic fibrosis patients indicated a selenium-depleted regulated pathway combined with a reduced capability of protective functions such as protection from peroxides.

The study by Dworkin et al. showed that the whole blood, plasma, and red blood cell selenium levels were significantly lower in patients with cystic fibrosis as compared to the age-matched controls. Plasma selenium levels were generally significant in short-term dietary selenium intake (Rea et al. 1979), while red blood cell selenium levels, which usually reflected the long-term dietary selenium intake, were more closely related to the activity of the selenoenzyme GPx. A similar drop in both plasma and red blood cell selenium levels suggested a chronic deficiency of selenium in these cystic fibrosis patients.

Lloyd-Still and Ganther (1980) found that the total blood selenium levels in patients with cystic fibrosis were only 55% of the normal blood selenium levels, which meant that the erythrocyte GPx levels were similar between the two groups. On the other hand, a study by Castillo et al. (1981) showed that the levels of serum selenium and GPx in patients with cystic fibrosis were similar as in the healthy cohorts. However, their patients underwent extensive nutritional counseling. Despite this, in their subgroup of cystic fibrosis patients with vitamin E deficiency, serum selenium was significantly lower than the control. Recently, Stead et al. (1985) reported that there was a significant diminished serum selenium level in young adults with cystic fibrosis. In the study, 20 young patients (age 19–34 years old) with cystic fibrosis, including two with cancer, had low serum selenium concentrations accompanied with low serum vitamin E concentrations. It was suggested that the low level of selenium in the blood was associated with an increased risk of carcinoma, especially when the reduced vitamin E level existed at the same time. Moreover, the older patients with cystic fibrosis might have even higher risk for the development of carcinoma (Stead et al. 1985).

Selenium Deficiency and Thyroid Fibrosis

McCarrison (1909) described the thyroid gland of a myxedematous cretin from the Himalayan region in 1908, as consisting of large and uniform fibrous strands with little remaining functional thyroid tissue. In 1936, DeQuervain and Wegelin (1936) described a very similar picture in Switzerland. The thyroid was atrophied, with loss of epithelial tissue, extensive fibrosis, and lymphocytic infiltration. It was suggested that both iodine and selenium deficiency were cofactors in the pathogenesis of myxedematous cretinism. Therefore, it was proposed that a remarkably increased level of the hydrogen peroxide in the iodine-deficient thyroid glands would be controlled by the hydrogen peroxide and its derived free radicals. A study (Contempre et al. 1995) was carried out to investigate the effect of the possibly impaired cellular defense mechanisms associated with selenium deficiency on thyroid necrosis and tissue repair. Pharmacological doses of iodide were administrated to induce necrosis in iodine-deficient thyroids, and it was also noted that the necrotic thyroid glands were accompanied with selenium deficiency, and the necrosis eventually led to fibrosis. Thus, the selenium deficiency paired with iodine deficiency increased necrosis, induced fibrosis, and impeded compensatory epithelial cell proliferation. These results were compatible with histological and functional descriptions of thyroid tissue from myxedematous cretins.

According to the above study, selenium deficiency-induced free radical damage and fibrosis of the thyroid are thought to be involved in the pathogenesis of myxedematous cretinism. A rat model has been replicated to explore the role of selenium deficiency in defective tissue repair and explain the relationship between selenium deficiency and tissue fibrosis (Contempre et al. 1995). It showed that the proliferation indexes of epithelial cells and fibroblasts were comparable between selenium-deficient and control groups. However, the thyroids in selenium-deficient condition expressed more macrophages. Consequently, these thyroids developed fibrosis. In the selenium-deficient rat model, the macrophages showed obvious transforming growth factor (TGF-β) immunostaining, and the use of anti-TGF-β antibodies restored the proliferation indexes of the epithelial cells and fibroblasts and completely prevented the thyroids from developing fibrosis. The results indicated that the inflammatory reaction and an increased TGF-β played a potential role in the active fibrotic process that occurred in the selenium-deficient thyroids (Contempre et al. 1995).

Selenium Deficiency and Oral Submucous Fibrosis

Oral submucous fibrosis is a chronic debilitating oral cavity disease, which is characterized by the inflammation and progressive fibrosis of submucosal tissues. Oral cancer is a major cause of cancer morbidity and mortality worldwide and is prevalent in most areas with high tobacco consumption. Selenium, among other trace minerals, plays an essential role in many biochemical reactions, and it has been demonstrated that the concentrations of various important trace minerals were

changed over the course of the malignant disease. Khanna and her colleagues investigated the selenium levels in the sera of patients with oral submucous fibrosis and oral squamous cell carcinoma in comparison with controls (Khanna et al. 2013) to identify predictors among these parameters for disease occurrence and progression. The study revealed significant lower levels of selenium in the sera of the cancer patients as opposed to the controls. Having known that selenium forms an integral part of the enzyme GPx, type I iodothyronine, deiodinase, metalloprotein, fatty acid binding protein, and selenoprotein P, selenium is considered as an antioxidant nutrient. The role of selenium is complex, which can be attributed to its immune modulating and antiproliferative properties to influence immune response by making immune cells more resistant to oxidative stress (Matés et al. 2012).

Selenium Deficiency and Pancreatic Fibrosis

Pancreatic fibrosis is a defining feature of chronic pancreatitis, which refers to the abnormal activation of stromal cells and deposition of ECM, which eventually impair the exocrine and endocrine functions of pancreas. One study on the day-old chicks fed with a selenium-deficient amino acid diet discovered that the chicks developed exocrine pancreatic degeneration and fibrosis (Gries and Scott 1972). In the study, the chicks were raised on a diet containing vitamin E and bile salts to maintain high plasma tocopherol levels. At 6 days old, the chicks started showing deficiency lesions, which exhibited vacuolation and hyaline body formation in acinar cells, as well as loss of zonation. Subsequently, the acinar cytoplasm started to shrink toward the nuclear end of the cell. In addition, an enlarging central lumen in the acinus and the appearance of fibroblasts were noticed in the interacinar tissue. Eventually, the pancreatic acinus consisted of a ring of cells composed mainly of small, dense-staining nuclei surrounding a lumen and embedded in cellular connective tissue. Some acinar necrosis was also noted.

Selenium Supplements for the Prevention of Fibrosis

Up to this point, it has been explained that a selenium-deficient diet may cause human chronic disease in the myocardium, liver, kidney, pancreas, and thyroid. Selenium is an essential trace element, which can be found in various forms and concentrations in the soil and in small amounts in certain foods and water. The human body requires very little amount of selenium; the minimum daily recommended dietary allowance is only 55 μg for adults. Although overadministration of selenium will highly increase the risk of disease, it is difficult to "overdose" selenium through food intake. Nevertheless, considering there is a possible risk of overadministration of selenium, proper intake of selenium supplement is important. Studies on the effects of selenium supplement on the prevention of pancreatic, myocardial, liver, thyroid, and cystic fibrosis in animals and humans will be discussed extensively.

In Animal Studies

Selenium supplements have been used effectively for the prevention of pancreatic fibrosis as demonstrated in several animal studies. One study on the prevention of pancreatic fibrosis in chicks (Gries and Scott 1972) showed that 4 days after supplying 0.1 ppm selenium to the deficient diets, acinar nuclei enlarged and became vesiculated, while cytoplasm filled the empty lumens. The fibrous tissue gradually disappeared due to the enlarged acini. After 2 weeks of having selenium supplement, the pancreas returned to the normal appearance. Another study (Cantor et al. 1975) investigated the efficacy of selenium dietary supplements in the form of sodium selenite, selenomethionine, selenocysteine, wheat, and tuna meal on the prevention of pancreatic fibrosis in chicks. Histological examination of the pancreases revealed that wheat and selenomethionine were the most effective sources of selenium. Among the three selenium compounds, selenomethionine was four times more effective than the others in preventing pancreatic degeneration and increasing the relative weight and selenium concentration of the pancreas.

Selenium supplements also had a positive effect on the prevention of liver damage as shown in animal studies. He and colleagues (1999) reported that selenium could be used as an antioxidant to preserve the liver tissue structure and function of the CCl_4-injured liver in rats and inhibit collagen synthesis in the human hepatocytes. In the study, there was increased blood selenium and GPx activity, as well as improvement of ultrastructure of the damaged liver, and a decrease of lipid peroxides content in the selenium supplementation group as compared to the control group. Another study on selenium supplementation (Ding et al. 2010) using CCl_4-induced mice damaged liver and fibrosis demonstrated that selenium decreased liver inflammation rather than causing necrosis by CCl_4. Selenium increased hepatocyte apoptosis, pro-apoptotic BAX and Bcl Xs/l proteins, and matrix metalloproteinase-9. Selenium also decreased stellate cell number and fibrosis after CCl_4 treatment. It was further indicated that selenium supplements could decrease hepatic fibrosis by lowering the number of collagen-producing stellate cells and accelerating collagen degradation. Liu and his group (2014) investigated the effects of selenium-enriched probiotics (SP) on the CCl_4-induced liver fibrosis in rats. Their results showed that SP significantly decreased serum alanine aminotransferase, aspartate aminotransferase, hepatic hydroxyproline, and malondialdehyde levels but increased GPx, superoxide dismutase, and glutathione levels in rats when treated with CCl_4. The SP could suppress both hepatic inflammation and necrosis induced by CCl_4. In addition, SP could reduce significantly the expression of α-smooth muscle actin, collagen, TGF-β 1, TIMP1, and inflammation-related gene, as well as the apoptosis of the activated HSCs in the rats. Their results also suggested that SP could protect the liver from fibrosis by attenuating hepatic oxidative stress, suppressing hepatic inflammation, and inducing apoptosis of HSCs. A study on the effects of dietary supplement with vitamin E and selenium on rat hepatic stellate cell apoptosis (Shen et al. 2005) showed that the combination of vitamin E and selenium supplements at a given level could inhibit CCl_4-induced activation and proliferation of HSCs and promote the apoptosis of the activated HSCs in acute damage phase. Vitamin E and selenium

could also effectively decrease the degree of hepatic fibrosis and promote the recovery process.

However, one animal study (Metes-Kosik et al. 2012) with adult C57/BL6 mice showed that the selenium supplementation reduced significantly methylation potential, DNA methyltransferase activity, and DNA methylation. In the study on mice fed with the selenium-supplemented diet, reactive myocardial fibrosis and diastolic dysfunction caused by altered myocardial matrix gene expression were observed in spite of lower oxidant stress and absence of myocardial hypertrophy. Their results indicated that both selenium deficiency and modest selenium supplementation led to a similar phenotype of abnormal myocardial matrix remodeling and dysfunction in a normal mice heart. This study suggested that more investigation would be required to focus on the important role of selenium in the maintenance of the balance between redox and methylation pathways while optimizing selenium status for the prevention and treatment of heart failure.

In Human Studies

Selenium supplementation has been shown to be very effective in the prevention of thyroiditis. In one study on autoimmune thyroiditis with 76 consecutive patients (Nacamulli et al. 2010), 30 cases were given no treatment, while 46 cases were treated with a single oral dose (80 μg/day) of sodium selenite for 12 months, showing that dietary supplementation with physiological doses of selenium seemed to be effective in preventing a reduction of thyroid echogenicity after 6 months of treatment and in reducing thyroperoxidase and thyroglobulin autoantibodies after 12 months. In a systematic review (Toulis et al. 2010), it was shown that 3-month administration of selenium supplement to the patients with Hashimoto's thyroiditis (HT) resulted in significant lower thyroid peroxidase autoantibodies titers and a notable higher improvement in well-being and/or mood when compared with the controls, suggesting that selenium supplementation could be useful as an adjunctive therapy to levothyroxine in the treatment of HT.

However, controversial results from the treatment of cystic fibrosis with selenium supplementation have been demonstrated. In the study by Portal and his group (1995), lipid peroxidation was assessed in 27 children with cystic fibrosis after a double-blind selenium supplementation. The results showed that the improvement of lipid peroxidation markers was not related to the selenium supplementation when compared with the control groups. They also reported that a decrease in the plasma level of fragile equilibrium and selenium concentrations was found in the patients administered with the placebo. On the other hand in another study, the plasma level of fragile equilibrium and selenium concentrations was increased when patients were administered with selenium supplements. In the study, the selenium status of cystic fibrosis patients was close to normal before any treatment in the Grenoble area, which could be explained by the progress in the nutritional nursing care of the children and by the addition of selenium to the diet. It has also been shown (Inoko et al. 1998) that after selenium supplementation to the patient with Crohn's disease,

he was free from symptoms of heart failure for 11 years. However, it did not normalize the left ventricular dysfunction, and he eventually suffered from heart failure at the age of 38 years (Inoko et al. 1998).

Policies and Protocols

Selenium is considered as a "double-edged sword" element because of its toxicity at concentrations slightly higher than what is required for normal physiological functions. There is a U-shaped association between selenium intake and health, and this may explain the contradictory results from clinical trials of the impact of selenium on disease. People with selenium-deficient diets may benefit from selenium supplementation in terms of disease/health outcomes, whereas populations with preexisting adequate or high-selenium status may suffer from detrimental health outcomes instead (Rayman 2012). Nevertheless, selenium is required in trace amounts for the development and well-being of humans and is vital in the maintenance of structures and functions of human organs. Therefore, moderate selenium supplements in diets, especially in selenium-deficient countries, are highly recommended. Selenium supplements are especially critical for normal development in children who are under the risk of selenium deficiency. The concentration of selenium supplement should be critically assessed. Selenium supplements could exhibit either antioxidant or oxidant function or even both. Thus, the toxicological behavior of selenium supplements should be tested before recommending appropriate selenium intake concentration in vivo. Organic selenium supplements with lower toxicity and higher bioactivities in vitro and in vivo may provide a better choice.

Dictionary of Terms

- **Fibrosis** – The formation of excess fibrous connective tissue as a reparative response to injury or damage. This can be a reactive, benign, or pathological state. Fibrosis may refer to the connective tissue deposition that occurs as part of normal healing or to the excess tissue deposition that occurs as a pathological process.
- **Chronic disease** – Persists for a long time, lasting 3 months or more, by the definition of the US National Center for Health Statistics. Chronic diseases which tend to become more common with age generally cannot be prevented by vaccines or cured by medication nor do they just disappear.
- **Selenium deficiency** – Lack of the essential mineral selenium, which can cause diseases such as Kashin-Beck disease and Keshan disease in China. Some chronic diseases are related to selenium deficiency. Treatment involves ensuring intake of the recommended dietary allowance of selenium.
- **Selenium supplement** – An increase of selenium-rich foods may be able to help prevent selenium deficiency diseases. It's believed that selenium can benefit these

by its ability to fight inflammation, reduce free radical oxidative stress, and help with antioxidant activity.

- **Trace element** – A chemical element whose concentration (or other measure of amount) is very low (a "trace amount"). The exact definition depends on the field of science: in analytical chemistry, a trace element is one whose average concentration of less than 100 parts per million (ppm) measured in atomic count or less than 100 μg/g. In biochemistry, a trace element is a dietary element that is needed in very minute quantities for the proper growth, development, and physiology of the organism. In geochemistry, a trace element is one whose concentration is less than 1000 ppm or 0.1% of a rock's composition.
- **Autopsy** – Postmortem examination in order to find the cause of death or the extent of disease.

Summary Points

- This chapter reviews the relationship between selenium deficiency and fibrosis in chronic diseases.
- This chapter also reviews the use of selenium supplements for the prevention and treatment of fibrosis in chronic diseases.
- Selenium deficiency causes cardiac fibrosis in both animal and human studies.
- Selenium deficiency is involved in liver fibrosis in both animal and human studies.
- Selenium deficiency causes kidney fibrosis in the animal study.
- Selenium deficiency causes cystic fibrosis in human studies.
- Selenium deficiency causes thyroid fibrosis in both animal and human studies.
- Selenium deficiency causes oral submucosa fibrosis in the human study.
- Selenium deficiency causes pancreatic fibrosis in laboratory animals.
- Effect of selenium supplement on pancreatic fibrosis in animal studies.
- Effect of selenium supplement on liver fibrosis in animal studies.
- Effect of selenium supplement on thyroid fibrosis in human studies.
- Effect of selenium supplement on cystic fibrosis in human studies.
- Effect of selenium supplement on cardiac fibrosis in animal and human studies.

Abstract

This review is focused on the adult lung in health and disease and the effect of zinc on both states. Pulmonary fibrosis (PF), chronic obstructive pulmonary disease (COPD), and asthma are some of the major health problems in the world. Zn is present in protein-bound and ionic forms, and plays important roles in mediating the function and structure of proteins, and in maintaining physiological homeostasis. It was found that zinc is involved in the regulation of sex hormones and that it also has effects on lung lipid metabolism and the immune system. It is known that sex affects lung development and physiology. Androgens enhance airway branching but delay alveolar maturation contributing to increased respiratory morbidity in prematurely born male infants. It was shown that there are sex-specific trends in the incidence, prevalence, and mortality of diseases, such as COPD and PF. In men, there is a gradual decline in testosterone secretion that begins after 30 years old, with the signs and symptoms of testosterone deficiency typically presenting after the age of 65. The absence of androgens induces oxidative stress and lipid peroxidation in lung, synchronically with changes in the expression of cytoprotective markers, what could be part of the mechanisms involved in the development of the previously mentioned diseases. Therefore, not only the levels of zinc, but also of testosterone are important in order to maintain the lungs healthy and functional.

Keywords

Lung · Androgens · Men · Lung diseases · Zinc · Sex hormones · Testosterone · Oxidative stress · Zinc deficiency · Androgen disorder · Decline testosterone · Pulmonary fibrosis · Chronic obstructive pulmonary disease

List of Abbreviations

AE2	Alveolar epithelial type II
AECs	Alveolar epithelial cells
AR	Androgen receptors
ARKO	AR knocks out
ASM	Airway smooth muscle
BHR	Bronchial hyperresponsiveness
CAT	Catalase
COPD	Chronic obstructive pulmonary disease
COX-2	Ciclooxigenase 2
DHT	Dihydrotestosterone
ECM	Extracellular matrix
EMT	Epithelial–mesenchymal transition
ER	Endoplasmic reticulum
GD17	Gestational day 17
GPx	Glutathione peroxidase
Hoxb5	Hox protein b5
Hsp27	Heat shock protein 27

Hsp70	Heat shock protein 70
IL-8	Interleukin-8
IPF	Idiopathic pulmonary fibrosis
LTB4	Leukotriene B4
MUC5B	Common genetic variant in mucin 5B
NF-κB	Nuclear factor κB
NOX	NADPH oxidase
PF	Pulmonary fibrosis
RCC	Renal cell carcinoma
RT	Radiotherapy
SMAD2P	Smad protein 2P
SMAD7	Smad protein 7
SPA	Surfactant protein A
SPC	Surfactant protein C
TBARS	Thiobarbituric acid reactive substances
TERC	Telomerase RNA component
TERT	Telomerase reverse transcriptase
TNF-a	Tumor necrosis factor-a
UPR	Unfolded protein response
Zn	Zinc

Introduction

A wide variety of pulmonary disorders can result in pathologies that affect the airway and/or lung stroma. Over the past years, numerous advances have been made in the understanding of lung diseases. Pulmonary fibrosis (PF), chronic obstructive pulmonary disease (COPD), and asthma are some of the major health problems and considered to be some of the most prevalent features of age- and sex-related diseases affecting millions of people in all countries. Besides that, other emerging conditions are also relevant, including smog (developing countries), sand storms, nanoparticles, and man-made fibers; while epigenetic modifications in general are acquired in response to environmental stimuli.

Disorders of the airways, lung, chest wall, and diaphragm will affect ventilation while pathologies of the lung and cardiovascular system, as well as peripheral tissues will affect respiration and consequently the exchange of gases (Goodman and Fuller 2015). Nasal, bronchial, and alveolar epithelia play critical barrier and homeostatic functions. Lung epithelium is the initial affected site of environmental and inflammatory stimuli since it constitutes the interface between the internal milieu and the external environment as well as being a primary target for inhaled respiratory drugs. It also responds to changes in the external environment by secreting a large number of molecules and mediators that signal to cells of the immune system and underlying mesenchyme (Knight and Holgate 2003).

Aging is associated with a physiologic reduction of appetite and food intake. Body weight decreases after 60 years, which is mainly due to muscle loss. The

combination of muscle loss and reduced food intake predisposes older people to undernutrition. In undernourished older people, combined treatment with testosterone and nutritional supplementation reduced the number of people hospitalized and duration of hospital admissions (Piantadosi et al. 2011). In addition, zinc is essential for immune response regulation and it is known that T cell function declines with age. In elders, inadequate stores of zinc might be a risk factor of pneumonia. Therefore zinc supplementation has the potential to reduce not only the number and duration of pneumonia episodes, but also all-cause mortality in older people. Based on a thorough review of the literature and given the upper safe limit of zinc, it is concluded that a dose of 30 mg elemental zinc per day for 3 months might be adequate to improve the immune function, and to reduce the risk of infections (Barnett et al. 2016).

Besides that, Zn is an important component of the testosterone-signaling pathway, since AR has two zinc finger motives. On this regard, it is known that sex steroids can affect different lung components, and they may play a role in important diseases such as asthma, COPD, pulmonary fibrosis, cancer, and even pulmonary hypertension. Sex-specific trends in the incidence, prevalence, and mortality of diseases such as COPD and PF have been reported. Multiple studies have suggested that the incidence and prevalence of PF is higher in males than females and females have better survival rates (Table 1). PF is a progressive interstitial lung disease leading to scarring. This pathology has a higher prevalence in males compared to females (Meltzer and Noble 2008) with faster progression, and less survival in males than females (Han et al. 2008; Olson et al. 2007). In contrast, the prevalence of chronic obstructive pulmonary disease (COPD) is increasing in females and the number of women dying from this disease now surpasses men in the United States (Han et al. 2008).

While numerous genetic, environmental, social, and behavioral factors are proposed to contribute to these trends, it is also likely that cellular and molecular mechanisms driving the diseases development and/or progression are not fully conserved between sexes (McGee et al. 2014). In contrast, asthma incidence and severity is greater in women than in men, and also women are more likely to develop corticosteroid-resistant or "difficult-to-treat" asthma. Puberty, menstruation, pregnancy, menopause, and oral contraceptives are known to contribute to the outcome of diseases in women, suggesting a role for estrogen and other hormones that affect allergic inflammation (Keselman and Heller 2015).

Table 1 Sex specific trends in lung stromal diseases. The effects of gender in lung stromal chronic diseases (pulmonary fibrosis and COPD: chronic obstructive pulmonary disease) varies. The incidence of pulmonary fibrosis is higher in males, although the survival rates are higher in women. The opposite occurs in COPD

	Lung stromal diseases	
	Pulmonary fibrosis	COPD
Incidence/ prevalence	Less than males (Meltzer and Noble 2008)	Increasing in females
Survival rates	Less than females (Han et al. 2008; Olson et al. 2007)	Less than males

Respiratory Diseases

Fibrogenesis is a dynamic process and was proposed to occur in all organs within four common phases: (i) initiation, due to injury of the organ/tissue; (ii) inflammation and activation of effector cells; (iii) enhanced synthesis of extracellular matrix (ECM); and (iv) deposition of ECM with progression to end-organ failure (Rockey et al. 2015).

Fibrotic lung disorders can be divided into diseases with known and unknown etiology (Fig. 1). Among those with unknown etiology, idiopathic pulmonary fibrosis (IPF) is a common diagnosis. It is a fatal disease with poor prognosis and limited therapeutic options. Alveolar epithelial type II (AE2) cells play a key role in lung fibrosis and they have a crucial role in epithelial regeneration and interaction with fibroblasts. An alternative explanation for the lack of confirmation that genetic mutations lead directly to fibrosis is that exposure to additional environmental injurious agents, in genetically predisposed individuals, is required for the development of lung fibrosis (Wolters et al. 2014).

The other disease is chronic obstructive pulmonary disease (COPD). It is a progressive pathology that includes emphysema and chronic bronchitis. Emphysema is characterized by damaged alveoli while chronic bronchitis is characterized by inflamed airways with excess mucus formation. Kamil et al. (2013) suggest sex-specific and race-related differences in the manifestation of COPD, although the mechanistic basis for such differences is not completely understood. This disease is characterized by chronic inflammation throughout the airways, parenchyma, and

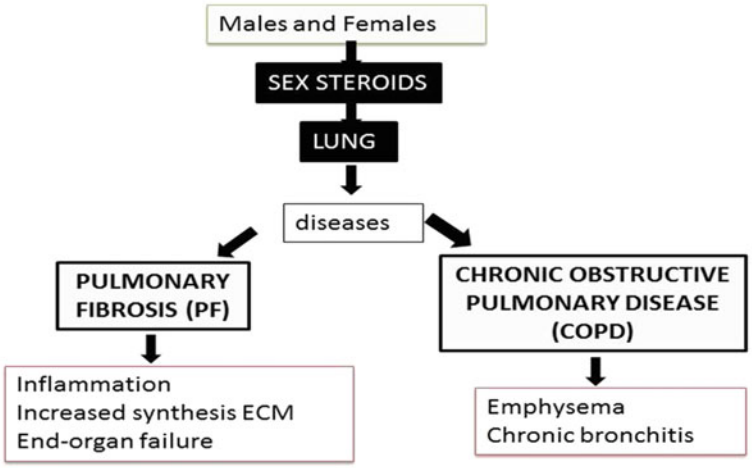

Fig. 1 Lung pathology and sex steroids. Fibrotic lung disorders are divided into diseases with known and unknown etiology. Wolters et al. (2014) thought that exposure to environmental injurious agents, in genetically predisposed individuals, is required for the development of lung fibrosis. Chronic obstructive pulmonary disease (COPD) is a pathology that includes emphysema and chronic bronchitis. Kamil et al. (2013) suggest sex-specific and race-related differences in the manifestation of COPD, although the differences are not completely understood

pulmonary vasculature. Activated inflammatory cells release a variety of mediators – including leukotriene B4 (LTB4), interleukin-8 (IL-8), tumor necrosis factor-a (TNF-a), and other compounds – capable of damaging lung structures or sustaining neutrophilic inflammation (Pauwels et al. 2001). Cigarette smoke exposure is associated with an increased risk of COPD.

Asthma involves both intrinsic and environmental factors suggesting that it is multifactorial in origin. Asthma is characterized by three major features: airway structural remodeling (involves both airway and epithelial cells); functional changes (airway hyperresponsiveness, edema, mucus production); and inflammatory changes (activation of inflammatory cells) (West et al. 2013; Wright et al. 2013). There is not a simple relationship between sex hormone levels and asthma symptomatology. Considerable evidence suggests that asthma is more common in prepubescent males compared to females, but following puberty, it is more common in females than in males (Melgert et al. 2007).

Zinc

Zinc (Zn) is well known as an essential trace element for a variety of biological activities. This ion is the second most abundant trace element in the body, and as a consequence, zinc deficiency is considered a public health problem. Zinc deficiency implies growth retardation and increased infectious disease morbidity such as diarrhea and pneumonia, especially in the first 2 years of life.

The body of an adult human (70 kg) contains about 2–3 g of zinc, which is absorbed from our dietary sources in the proximal small intestine, either the distal duodenum or proximal jejunum (Krebs et al. 1998), and released from there into the blood. However, the supply of zinc by our diet is dependent on its amount and bioavailability. It has been estimated that in a Western mixed diet, this bioavailability is about 20–30% of total contained zinc (Gallaher et al. 1988). The main sources of zinc are oysters, red meat, and poultry. Other good food sources include beans, nuts, certain types of seafood such as crab and lobster, whole grains, and dairy products (USDA 2011).

Zinc Biological Roles

In biological systems, Zn is present as protein-bound and ionic forms, and plays important roles in mediating the function and structure of proteins, and in maintaining physiological homeostasis. Plasma concentration of trace elements as zinc and copper are affected by physiological conditions such as age, gender, and nutritional status, as well as by pathophysiological conditions, like inflammation and the presence of cardiovascular risk factors (Ghayour-Mobarhan et al. 2005). Aging has been associated with a general decrease of plasma Zn, especially in elderly subjects with a suboptimal nutritional status (Prasad 2008).

Zinc plays an important role in lung functions and also functions as an antioxidant and anti-inflammatory agent with pro-survival effects. Zinc deficiency leads to oxidative damage in the airways by inducing the infiltration of inflammatory cells and increasing superoxide and nitric oxide production. These unique properties of zinc may have significant therapeutic benefits in human pulmonary diseases (Prasad 2008). In line with our findings, it has been shown that the peroxidation of lipid molecules induced by ROS, oxidative stress, and inflammation was significantly attenuated with zinc in a model of zinc-deficient rats. The localization of the abundant labile Zn in the apical cytoplasm of the airway epithelium is controlled by zinc transporters (Murgia et al. 2006). Zinc is also in the active site of ADAM33 metalloproteinase, which is expressed in pulmonary fibroblasts and bronchial smooth muscle cells (Orth et al. 2004), and it is important for extracellular matrix changes and airway remodeling after repeated damage and repair (Zou et al. 2004). It has been shown that Zn deficiency produces the nuclear translocation of Nuclear Factor-kβ (NF-kβ) in rat lungs and human airway epithelial cells (Gomez et al. 2006). NF-kβ is a cytoplasmic transcription factor that once translocated to the nucleus mediates the expression of pro-inflammatory cytokines (Oteiza and Mackenzie 2005).

The immune system requires essential micronutrients and trace elements such as iron, zinc, copper, and selenium for optimal function. In addition, Cu and Zn play a central or putative role in the development of important age-related diseases, including cardiovascular disease, cancer (Zuo et al. 2006), and type 2 diabetes (Mocchegiani et al. 2008), among others. Also, the Cu/Zn ratio seems to be of clinical importance as an inflammatory-nutritional biomarker and a sensitive predictor of mortality in elderly subjects aged 70 years and above. Cu/Zn ratio variability in elderly populations suggests that the decline of Zn circulating levels with age depend on physiopathological changes. Zn plasma concentrations have positive correlations with albumin, RANTES (Regulated on Activation, Normal T-cell Expressed, and presumably Secreted) after adjustment for multiple confounders. Cu/Zn ratio was positively associated with markers of systemic inflammation and age and negatively associated with albumin serum levels (Giacconi et al. 2016).

Regarding the immune system, zinc is indispensable for a suitable and sufficient immune response against pathogens. Zinc is crucial for normal development and function of cells mediating innate immunity, neutrophils, and natural-killer cells. Phagocytosis, macrophages, intracellular killing, and cytokine production are also affected by zinc deficiency. Human lung fibroblast cells cultured under zinc-deficient conditions undergo oxidative stress and DNA damage as well as cell's ability to repair this damage is also compromised (Ho et al. 2003). Patients with zinc deficiency show inadequate granulocyte migration (Hasan et al. 2016) and an inefficient T cell-mediated function (Barnett et al. 2010). This leads to increased susceptibility to a variety of pathogens; in particular, these patients are prone to develop pneumonia. Thus, zinc adequacy is necessary for maintaining DNA integrity and may be important in the prevention of DNA damage and cancer (Prasad 2008).

Implications of Zinc in Several Diseases

Elders' inadequate stores of zinc might be a risk factor of pneumonia. Zinc supplementation might be beneficial to Ancient with low serum zinc levels Such a measure has the potential to reduce the number and duration of pneumonia and the amount and duration of antibiotic use due to pneumonia. A dose of 30 mg of elemental zinc per day might be adequate to improve immune function, and reduce the risk of infections. However, it needs to be emphasized that in order to provide conclusive evidence, controlled studies are needed to determine the efficacy of zinc supplementation as a potential low-cost intervention to reduce morbidity and mortality due to pneumonia in this vulnerable population (Barnett et al. 2010). Elders that live in nursing homes were supplemented with 30 mg/day Zn for 3 months; however not all zinc-deficient elders reached adequate concentrations, but the increase in serum zinc was associated with the enhancement of T cell numbers (Barnett et al. 2016).

An involvement of zinc in the regulation of sex hormones can be concluded indirectly, as several alterations that can occur during pregnancy upon zinc deficiency. Zinc deficiency also alters testosterone levels and modifies sex steroid hormone receptor levels (Om and Chung 1996) (Table 2). The nuclear receptor for sex steroid contains zinc fingers motif in their protein structure that might explain zinc dependency of these hormonal systems (Sauer et al. 2016). Zn fingers are common among gene regulatory proteins (Richer et al. 1998). Specificity of HRE binding is determined by the more highly conserved hydrophilic first Zn finger (C1) (Green and Chambon 1987), while the second Zn finger (C2) is involved in dimerization and stabilizing DNA binding by ionic interactions with the phosphate backbone of the DNA (O'Malley 1990).

That is why Zn is rising as a very important trace element in lung, not only due to its role in the regulation of sex hormones but also due to its effects on lung lipid metabolism and the immune system. It is known that the major phospholipid component (at the air–liquid interface) is phosphatidylcholine (70–80%). Our own laboratory showed that a moderate Zn deficiency (in vivo) can induce a

Table 2 Levels of zinc and testosterone in child and man. This table shows the level of zinc and testosterone in men, at different ages according to the works of Rubio et al. (2007) and Rey et al. (2006)

	Child	Man
Zinc serum level (mg/day) (Rubio et al. 2007)	3 mg (1–3 years)	8 mg (9–13 years)
	5 mg (4–8 years)	11 mg (14–>70 years)
Testosterone serum level (ng/ml) (Rey et al. 2006)	1.00–3.00 (0–6 months)	2.68–5.60 (12–17 months)
	0.10–0.32 (6–9 months)	2.80–8.00 (adult)

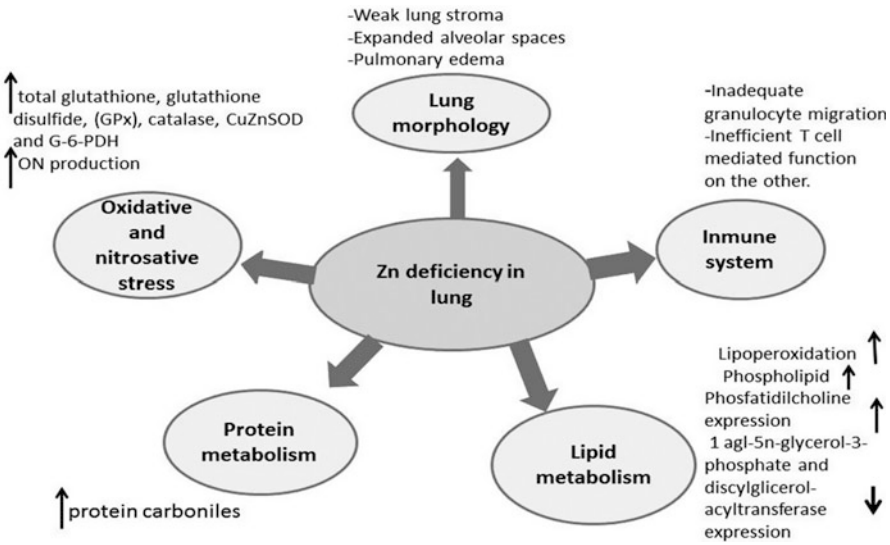

Fig. 2 Effect of Zn deficiency in lung. Zinc is necessary for maintaining the immune system, lipid metabolism, lung morphology, protein metabolism and, more important, it is the main actor in regulating the oxidative and nitrosative stress in the respiratory system

physiological stimulus that enhances phospholipid synthesis and changes especially the pattern of phospholipids, in adult rat lung. We found that the amount of 1-acyl-sn-glycerol-3-phosphate and the diacylglycerol acyltransferase expression decreases significantly in Zn-deficient lung, while phosphatidylcholine increases (Gomez et al. 2002, 2003). It is also known that Zn deficiency is accompanied by oxidative and nitrosative stress associated with significant morphological changes in lung parenchyma (Gomez et al. 2006; Fig. 2). What is more, Frey and collaborators (2000) demonstrated that fragmented phospholipids increase in the lung of patients with adult respiratory distress syndrome. All these results suggest that the lipid concentration in the lung (especially phospholipids) is modified directly or indirectly by a zinc-deficient diet.

Zinc also plays a role in systemic glycemic control through its effects on insulin biosynthesis within pancreatic β-cells and probably by modulating the insulinemic effects on target tissues. Kolahian et al. (2015) demonstrated that the supplementation of diabetic rats with leucine, zinc, and chromium, alone and in combination, was associated with significant improvements in the function and structure of respiratory system. The nutritional supplements enhance the enzymatic antioxidant activity of catalase, glutathione peroxidase, myeloperoxidase, and superoxide dismutase. Further, reinforcement of subjects with type 2 diabetes with these supplements may be an efficient method for preventing and/or treating diabetes-induced respiratory system dysfunction.

Androgens and Lung

Due to the above mentioned relationship between zinc and sex steroid hormones, our review will now focus on the adult lung in health and disease and the putative effect of sex steroids. However, it is also relevant to acknowledge the contribution of sex steroids in the developing lung and the influences in modulating postnatal lung growth and function.

Testosterone Biological Actions

Testosterone is the principal circulating androgen in males and this hormone is also secreted by ovaries and in small amounts by the adrenal gland (Mooradian et al. 1987). Testosterone can regulate the structure and function of nonreproductive organs including bone, lung, skeletal muscle, brain, liver, kidney, and adipocytes. Sex hormones exert their biological effects primarily through genomic mechanisms; however, they also elicit nongenomic effects. Testosterone and its active metabolite, 5α-dihydrotestosterone (DHT), exert their biological actions via androgen receptor (AR), also known as nuclear receptor subfamily NR3C4 (Chang et al. 2014). Data on sex steroid receptor expression in lung parenchymal cells is limited. The lung parenchyma comprises ~75% of cells, mainly in the alveoli. All the major sex steroid receptors have been found in the alveolar epithelium (Mikkonen et al. 2010). Additionally, the enzymes aromatase and 17β-hydroxysteroid dehydrogenase are localized in the same epithelium (Plante et al. 2009).

The biological activity of sex steroids depends on many factors including the availability of the unbound ligand, receptor expression and distribution, nuclear translocation, and signaling pathway. If the availability of free testosterone or the activity of androgen receptors (AR) and associated signaling pathways are altered during aging, then increasing the concentrations of testosterone may not be sufficient to fully reverse the effects of elders on different pathogenesis (vom Steeg et al. 2016).

Effects of Testosterone Decline in Human Health

In men there is a gradual decline in testosterone secretion that begins after 30 years old, with the signs and symptoms of testosterone deficiency typically presenting after the age of 65 (vom Steeg et al. 2016). Age-related reductions in testosterone production are associated with symptoms including decreased libido, erectile dysfunction, fatigue, depression, reduced strength, bone loss, and increased abdominal fat (vom Steeg et al. 2016).

In this regard, Lauretti et al. (2016) demonstrated that most patients with chronic obstructive pulmonary disease (COPD) share many risk factors and similar etiological agents with erectile dysfunction. Both conditions cause serious interference with the quality of life and sexual relationships (Lauretti et al. 2016). Additionally, fat-

free mass loss and physical inactivity are key features of COPD and are related to impaired muscular oxidative metabolism. The preservation of muscle mass and function through the protection of the mitochondrial oxidative metabolism is an important challenge in the management of COPD patients, where androgen therapy improves muscle mass and force but is insufficient, by itself, to improve lung function and clinical outcome (Samaras et al. 2014). Nevertheless, in combination with physical training and nutritional supplementations, androgen therapy is associated with increased fat-free mass and muscle force, together with increased peak workload and endurance time, and improved survival at least 1 year after the end of therapy. A short-term androgen therapy (3 months) could optimize the effects of rehabilitation in selected patients, but longer studies are warranted in order to identify whether mid- or long-term pulmonary rehabilitation could further improve the clinical outcome (Samaras et al. 2014). Smith and collaborators (2008) showed that testosterone is an efficacious vasodilator in pulmonary vasculature and this is not modulated by the patient's sex. This action suggests that testosterone therapy may be beneficial to male patients with pulmonary arterial hypertension. Unfortunately, androgen therapy could not be offered to female patients, due to the secondary male sexual characteristics that may develop as a result of the treatment.

Testosterone and Cancer Progression

Androgen/AR signaling has an important role in the initiation and progression of many hormone-related cancers. Chang et al. (2014) used various AR knock out (ARKO) mouse models in individual cells to study AR roles in various tumors. They led to very interesting yet distinct conclusions: while AR functions with positive roles to promote tumorigenesis in prostate, liver, bladder, kidney, breast, and lung cancers, AR functions differentially in either suppressing or promoting metastases in these tumors. AR functions as stimulator in bladder, kidney, and lung metastases since knockout of the AR in BCa urothelial cells, renal cell carcinoma (RCC) epithelial cells, and lung cancer cells led to decrease in metastasis as compared with their controls (Chang et al. 2014).

Although radiotherapy (RT) is an important cancer treatment modality, the cell killing induced by radiation is not tumor- or cell-type specific. The response to radiation is dynamic and involves several mediators of inflammation and fibrosis that are produced by macrophages, epithelial cells, and fibroblasts. Wu et al. (2009) found that androgen deprivation by castration augmented the radiation RT-induced inflammatory response. The increased NF-κB activity and subsequent elevated COX-2 by castration might be the underlying mechanism responsible for the increase in RT-induced inflammatory response. Data also indicate that RT-induced fibrosis is related to TGF-β1-induced epithelial-mesenchymal transition (EMT) and is probably mediated via the PI3K/Akt signaling pathway. These results suggest that sex differences play an important role in the inflammatory response, so that when androgen deprivation is concurrently used with irradiation

treatment, the modulating effects on the RT-induced inflammation and fibrosis should be taken into consideration for radiotherapy-associated complications (Wu et al. 2009).

Androgen Impact in Male Lung

Our experimental studies showed that androgen deprivation in male rats, over a period of 30 days, induced oxidative stress and lipid peroxidation in lung, synchronically with changes in the expression of cytoprotective markers (Alvarez et al. 2015). Some oxidative stress parameters [e.g., TBARS, catalase (CAT), and glutathione peroxidase (GPx) activities] were significantly increased in castrated rats, returning to the control values after the administration of testosterone. The same happened with NADPH oxidase (NOX) and GPx expression increased in castrated rats and they showed a decrease to control values in rats supplemented with testosterone. Immunohistochemistry showed a decreased expression of Hsp27 and increased expression of Hsp70i in castrated animals. During the androgen replacement period, Hsp70i was higher than the control group while Hsp27 showed a trend towards an increase in the same group. Taken together, all the results of this work suggest that the absence of androgens induces oxidative stress and lipid peroxidation in lung, synchronically with changes in the expression of cytoprotective markers. It is important to notice that some of the parameters recovered with the addition of testosterone (Alvarez et al. 2015).

Accumulating evidence suggests that sex affects lung development and physiology. Indeed, a higher incidence of respiratory distress syndrome is observed in male compared to female preterm neonates at comparable developmental stage. Experimental studies demonstrated an androgen-related delay in male lung maturation. Bresson et al. (2010) showed that there is a real delay in lung maturation between male and female in this period, the latter pursuing already lung maturation while the proper is not yet fully engaged in the differentiation processes at gestational day 17 (GD17). In addition, they provide a list of genes that are under the control of androgens within the lung at the moment of surge of surfactant production in murine fetal lung.

Androgens enhance airway branching but delay alveolar maturation contributing to increased respiratory morbidity in prematurely born male infants. Androgen effects on lung branching morphogenesis are partially mediated by Hoxb5 protein regulation. This level of regulation occurs partially through changes in cellular localization of SMAD2P and SMAD7 proteins and it involves interactions with TGF-β signaling (Volpe et al. 2013). This ability of androgen signaling to maintain the expression of Hoxb5 protein likely contributes to the known delayed airway epithelial maturation in male infants but positively contributes to the increased airway arborization and ultimate increased lung capacity in males compared to females.

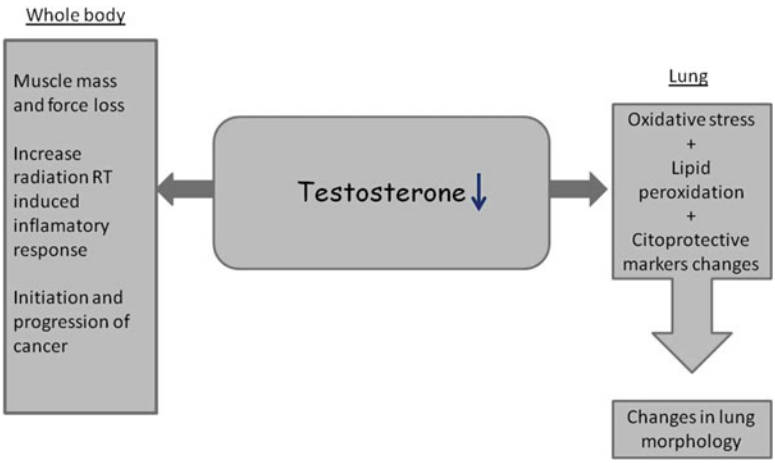

Fig. 3 Pathophysiological effects of testosterone decrease. On the right, the effects of testosterone decrease on the whole body can be seen. On the left, the *box* shows effects of a decrease in testosterone in lung

Conclusion

Considerable advances have been made in the understanding of the pathophysiology of lung diseases. The development of new treatment modalities is therefore critically important.

Besides that, we can conclude that not only the levels of testosterone, but also zinc levels are important in order to maintain the lungs healthy and functional (Fig. 3).

Policies and Protocols

For many years, little attention was paid to respiratory disorders and its relation with zinc. The knowledge presented in this chapter sheds light on the importance of zinc in the respiratory system.

Pulmonary fibrosis (PF), chronic obstructive pulmonary disease (COPD), and asthma are some of the major health problems in the world. It is known that sex affects lung development and physiology and also Zinc is involved in the regulation of sex hormones, specially testosterone, and the immune system (Fig. 4). Androgens enhance airway branching but delay alveolar maturation contributing to increased respiratory morbidity in prematurely born male infants. In men, there is a gradual decline in testosterone secretion that begins after 30 years old, however the signs and symptoms of testosterone deficiency typically

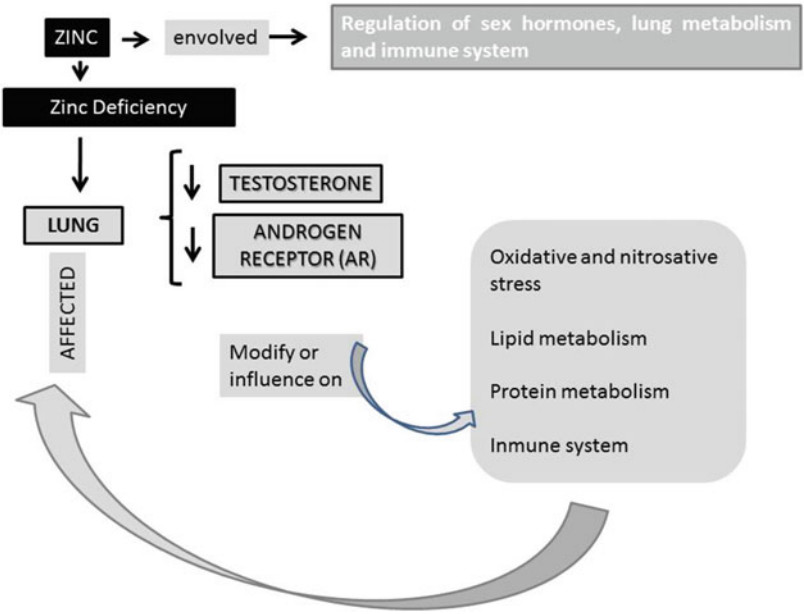

Fig. 4 Integrative image of the relation between lung, zinc, and testosterone. Zinc participates in the regulation of the synthesis of testosterone, in the regulation of the immune system, as it also directly affects the lung (it produces oxidative and nitrosative stress, modifies lipid and protein metabolism, and affects the immune system). In addition androgens also regulate lung function, so that the sum of the effect of zinc deficiency and androgen deficiency leads to a complex pathophysiological situation

presenting after the age of 65. The absence of androgens induces oxidative stress and lipid peroxidation in lung, synchronically with changes in the expression of cytoprotective markers.

Taken together this information points out the importance of Zn levels in the population. Zinc is supplied by our diet. It has been estimated that in a Western mixed diet, this bioavailability is about 20–30% of total contained zinc (Gallaher et al. 1988). The main sources of zinc are oysters, red meat, and poultry; beans, nuts, certain types of seafood such as crab and lobster, whole grains, and dairy products (USDA 2011). Therefore, it is crucial to have a well-designed diet in order to ensure the required level of zinc. Unfortunately, there are many countries with malnutrition and famine. Therefore, specific governmental policies aimed at counteracting these problems are required.

For the other way, in low- and middle-income countries "moderate zinc deficiency" increase and do not have symptoms. The reason of this situation is the use of the unbalanced diet (especially vegetarian and vegan diet). So these populations should have educational programs showing the importance of a balanced diet; pregnant mothers, infants, and aging people should be targeted as a priority group for education on nutritional aspects. Supplementation programs with

micronutrients would help to reduce the incidence of respiratory diseases in vulnerable population.

High-income countries also have health educational programs to raise awareness on the negative effects of unbalanced diets. Specific guidelines should be designed to promote a better design of the family menu.

Furthermore, high-income countries also need health education programs to raise awareness of the negative effects of unbalanced diets. Specific guidelines will be designed to promote a better family menu design. In addition, environmental health policies should be applied worldwide in order to reduce famine as well as its deleterious and mortal consequences on humanity.

Dictionary of Terms

- **COPD** – is a term used to describe progressive lung disease and the same is characterized by increasing breathlessness. Many people mistake their increased breathlessness and coughing as a normal part of aging.
- **Asthma** – is a chronic (long-term) lung disease that inflames and narrows the airways. Asthma causes recurring periods of wheezing (a whistling sound when you breathe), chest tightness, shortness of breath, and coughing. Affects people of all ages, but it most often starts during childhood.
- **Pulmonary fibrosis** – is one of a family of related diseases called interstitial lung diseases that can result in lung scarring. As the lung tissue becomes scarred, it interferes with a person's ability to breathe. In addition, in some cases, the cause of pulmonary fibrosis can be found. But most cases of pulmonary fibrosis have no known cause. These cases are called idiopathic pulmonary fibrosis (IPF).
- **Zinc deficiency** – It is a lowering from micronutrient "Zinc" in the body. The amount that the man requires depends on age, sex, and physiological state. Zinc deficiency could be mild, moderate, acute, or chronic. Any of them can lead to a health problem.
- **Androgens** – are a group of hormones that primarily influence the growth and development of the male reproductive system. The most active androgen is testosterone, which is produced by the testes. The other androgens are produced mainly by the adrenal cortex – the outer portion of the adrenal glands – and only in relatively small quantities.

Summary Points

- This review is focused on the adult lung in health and disease.
- Pulmonary fibrosis (PF), chronic obstructive pulmonary disease (COPD), and asthma are some of the major health problems in the world.
- Zn is present in protein-bound and ionic forms, and plays important roles in mediating the function and structure of proteins, and in maintaining physiological balance.

- Zinc is involved in the regulation of sex hormones.
- Sex affects lung development and physiology.
- Zinc also has effects on lung lipid metabolism and the immune system.
- Androgens enhance airway branching but delay alveolar maturation contributing to increased respiratory morbidity in prematurely born male infants.
- There are sex-specific trends in the incidence, prevalence, and mortality of diseases such as COPD and PF.
- In men, there is a gradual decline in testosterone secretion that begins after 30 years old, with the signs and symptoms of testosterone deficiency typically presenting after the age of 65.
- The absence of androgens induces oxidative stress and lipid peroxidation in lung, synchronically with changes in the expression of cytoprotective markers.
- Not only the levels of testosterone, but also of zinc are important in order to maintain the lungs healthy and functional.

Abstract

Over the past 20 years, many researchers have demonstrated the critical role of zinc (Zn), a group IIb metal, in diverse physiological processes, such as growth and development, maintenance and priming of the immune system, and tissue repair. Zinc nutritional importance has been known for a long time, but in the last decades, its importance in immune modulation has arisen. This chapter aims at describing the mechanisms involved in the regulation of zinc homeostasis and their effects on the immune response focusing on those that are implicated in the inflammation. Zinc functions as a modulator of the immune response through its availability, which is tightly regulated by several transporters and regulators. When this mechanism is disturbed, zinc availability is reduced, altering survival, proliferation, and differentiation of the cells of different organs and, in particular, cells of the immune system. Zinc deficiency causes a decrease in innate and adaptive immunity. In addition, during zinc deficiency, the production of pro-inflammatory cytokines increases, influencing the outcome of a large number of inflammatory diseases or worsening other pathologies.

Keywords

Zinc · Metallothioneins · Immunity · Inflammation · Cytokines · Immune diseases · Antioxidant · Oxidative stress

List of Abbreviations

FDA	Food and Drug Administration

ZIP (Zrt-Irt-Protein)	SLC 39a
ZnT	SLC 30a

Introduction

Zinc, an essential trace element and a member of one of the major subgroups of the micronutrients, has attained prominence in nutrition and health, especially for the growth and development of infants and children (Hambidge et al. 2010; Kaur et al. 2014). It is ubiquitously present in all biological systems and has unique and extensive functions within these systems (Bhowmik et al. 2010; Hambidge et al. 2010). The adult human (~70 kg weight) contains about 2–3 g of zinc in the body, with higher average in men than in women, 0.1% of which is replenished daily through dietary intake (Bhowmik et al. 2010). It is found in all organs, secretions, fluids, and tissues of the body, with 85% of the whole body zinc in muscle and bone, 11% in the skin and liver, and the remaining in all other tissues. In multicellular organisms, virtually all zinc is intracellular, 30–40% is located in the nucleus; 50% in the cytoplasm, organelles, and specialized vesicles (for digestive enzymes or hormone storage); and the remainder in the cell membrane (Bhowmik et al. 2010). It serves as a catalytic, structural, and protein interface component for diverse biological functions (Bhowmik et al. 2010). These include carbohydrates, lipids, and nucleic acid synthesis, sequence recognition, transcriptional regulation, cytoskeletal and membrane integrity, apoptosis, synaptic signaling, gene expression, cellular energy metabolism, cell division, hormonal storage and release, neurotransmission, memory, and visual process (Hambidge 2010; Bhowmik et al. 2010). It also has a specific role in enzyme functions – some of them are alkaline phosphatase, alcohol-dehydrogenases, Cu–Zn superoxide dismutase, dipeptidyl carboxypeptidase, DNA polymerase, RNA polymerase, and reverse transcriptase (Kumari et al. 2011), involved in most of the major metabolic pathways and consequently is necessary for a wide range of biochemical, immunological, and antioxidant functions (Maret 2009; Prasad 2014). The role of zinc as an antioxidant has gained importance as it prevents free radical formation, protects biological structures from damage, and functions against oxidative stress (Bhowmik et al. 2010; Kumari et al. 2011). This mineral stabilizes the quaternary structures of enzymes and structures of RNA, DNA, and ribosomes. Zinc finger proteins, the largest class of DNA binding proteins, provide a scaffold that organizes protein subdomains for the interaction with either DNA or other proteins (Kumari et al. 2011). From prokarya to eukarya, between 4–10% of the genome encodes zinc proteins, and in human cells this percentage corresponds to the remarkable number of about 3000 zinc proteins (Bhowmik et al. 2010; Hambidge et al. 2010). Zinc plays an important role in regulating the production and secretion of proteins at transcriptional and translational level. It is vital for a variety of hormonal activities including glucagon, insulin, growth hormone, as well as sex hormones. Its role in immune function is evident from thymic hormone, thymulin, which is zinc dependent and is required for T-cell maturation and differentiation (Bhowmik et al. 2010). It is also known for its anti-inflammatory (antiviral, antibacterial, and antifungal) and anticancerous properties and has been found to protect animals against otherwise lethal irradiation by neutrons (Bhowmik et al. 2010). The therapeutic roles of zinc in acute inflammation, diarrhea, acrodermatitis enteropathica, cognitive impairment, type 2 diabetes (Bhowmik et al. 2010; Maret 2013), prevention of blindness in patients with age-

related macular degeneration, and treatment of common cold have also been reported.

Zinc deficiency has become a global health problem that is generally recognized (Bhowmik et al. 2010; Hambidge et al. 2010; Hambidge 2010), and can be due to inadequate dietary intake, decreased absorption, increased requirements, increased loss, or genetic disease (Bhowmik et al. 2010). The ubiquitous nature of zinc in the human biological system indicates the widespread consequences and complexity of inadequate dietary supply of zinc and zinc depletion (Lowe et al. 2009).

The concentration of zinc in plasma is approximately 15 mM/L of which 84% is bound to albumin, 15% is tightly bound to a-2 macroglobulin, and 1% to amino acids (Seiler et al. 1988). Zinc deficiency is associated with a wide variety of clinical features such as growth impairment, alopecia, hypogeusia, hyposmia, diarrhea, dementia, delayed sexual development and impotency, eyes and skin lesions, emotional disorders, immune dysfunction, susceptibility to infections, impaired appetite, abnormal pregnancy, reduced glucose tolerance, and increased carcinogenesis (Tuerk and Fazel 2009; Hambidge et al. 2010).

It is estimated that more than 20% of individuals worldwide are zinc deficient, especially in developing countries. Zinc deficiency can be found in premature infants, children with poor nutritional intake, elderly patients, and in individuals with sickle cell anemia, anorexia nervosa, cystic fibrosis, liver and renal disease, diabetes, HIV infection, and chronic alcoholism (Hambidge et al. 2010; Hambidge 2010).

The RDA-recommended dietary intake of Zn is approximately 12 mg/day and this is obtainable from protein-rich foods, seafood, fresh fruit and vegetables, and dairy products.

Zinc possesses two main properties, which make it an ideal component in biological systems. First, Zn is virtually nontoxic as the homeostatic mechanism by which it is regulated is so efficient that no chronic disorders are known to be associated with excessive accumulation (Hambidge et al. 2010). Second, its physical and chemical properties enable it to interact with a variety of enzymes and other proteins that participate in cellular metabolism as well as in the control of gene transcription. In the body Zn exists in two main states: (i) a bound form that is held on to tightly by metalloproteins and Zn finger proteins and (ii) a more loosely bound labile form that participates in intracellular Zn fluxes and is readily depleted in Zn deficiency. Although all organs contain labile intracellular Zn, the following tissues are particularly labile Zn rich: hippocampus, testis, and secretory cells (e.g., pancreatic β cells and mast cells).

Zinc Metabolism

Zinc is tightly regulated within the body by transporters that work primarily in the duodenum, jejunum, and nephron (Hambidge et al. 2010; Hambidge 2010; Kaur et al. 2014). Zinc absorption occurs predominantly in the jejunum via the specific transporter Zip4 (Hambidge et al. 2010; Kaur et al. 2014) by passive diffusion or

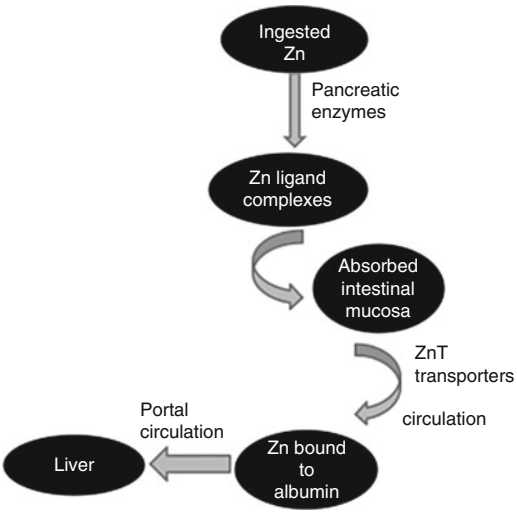

Fig. 1 Zinc metabolism: ingestion, absorption, and circulation up to the liver. Zinc-ligand complexes are absorbed into the intestinal mucosa, where ZnT transporters promote their release into the circulation; zinc is then bound to albumin and taken to the liver through the portal circulation

attached to the apical membrane of enterocytes, where transports are aided by metallothionein and cysteine-rich proteins (Hambidge et al. 2010; Hambidge 2010). It is then taken into the cell and either released into the blood or back into the intestine.

Absorption can be reduced through ingestion of zinc-binding substances such as phytates and fiber. The resulting insoluble complexes remain in the gastrointestinal tract and are excreted in the stool. Consumption of high amounts of iron and/or copper can potentially decrease zinc absorption (King et al. 2000). In the absence of these substances, ingested zinc is released from food by pancreatic enzymes (e.g., proteases, lipases) and forms complexes with amino acids, phosphates, and organic acids (King et al. 2000). These zinc-ligand complexes are absorbed into the intestinal mucosa, where ZnT transporters promote their release into the circulation (Liuzzi et al. 2004). The majority of zinc is then bound to albumin and taken to the liver through the portal circulation (Tuerk and Fazel 2009) (Fig. 1). Approximately 80–85% of zinc is stored in skeletal muscle and bone and has a slow turnover (Tuerk and Fazel 2009). Most zinc is lost through pancreatic secretions, feces, urine, sweat, menstrual fluid, semen, epithelial cells, and hair (Bridges and Zalups 2005). Because there is no specialized organ to regulate zinc in vivo, daily dietary intake is required to maintain a steady state.

Transport of Zinc and its Family Members

Zn belongs to the family of transition metals, which have low ionization energies and a wide range of oxidation states, or positively charged forms. Zn, cadmium (Cd), and mercury (Hg) have been classified as “group 12” metals. They share their way of

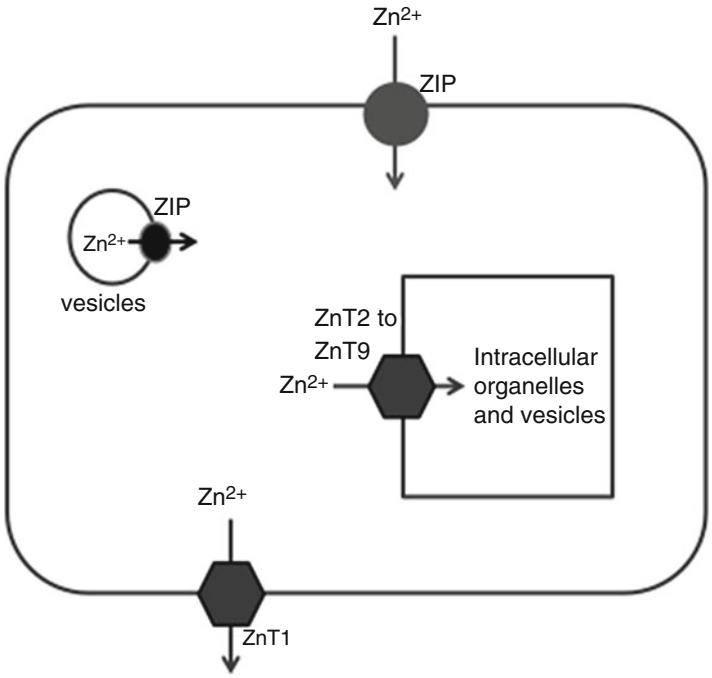

Fig. 2 Zinc transport: import by zip family transporters and export by ZnT family transporters. ZIP transporter import zinc from the extracellular fluid or from intracellular vesicles into the cytoplasm and ZnT family (ZnT1 to ZnT9) export zinc out to the extracellular space or sequestrate cytoplasmic Zn into intracellular compartments

transport in mammalian cells. They are taken up across cell membranes by active (MacDonald 2000) or facilitated diffusion, and this mode of transport in cells has been described as "ion mimicry" (Bridges and Zalups 2004).

There are two types of zinc transporters, coded from solute-linked carrier (SLC) gene families, which possess competing roles in zinc homeostasis. ZnT transporters (SLC30) function by reducing intracellular zinc, whereas Zip transporters (SLC39) function to increase intracellular zinc (Tuerk and Fazel 2009; Wang and Zhou 2010). There are 9 known ZnT and 14 Zip transporters in human beings identified to date with both transporter families being upregulated or downregulated based on zinc levels in vivo (Tuerk and Fazel 2009) and intracellular binding proteins, notably metallothioneins (MTs) are the main controllers of intracellular Zn concentration (Fig. 2).

Entry (Import)

Zn is taken up as a divalent cation and it has a single oxidation state and cannot be oxidized or reduced. The Zn2+ ions are hydrophilic, so they need specialized transporters to get into the cytoplasm. The ZIP family, in mammals, consists of 14

isoforms (ZIP1 to ZIP14) of transporters, which promote metal ion passage from the extracellular fluid or from intracellular vesicles into the cytoplasm (Liuzzi and Cousins 2004; see Fig. 2).

Most ZIP members have a similar protein structure with eight transmembrane domains and a cavity through which metals are transported (Eide 2006). Despite such similarities, different ZIP transporters are expressed on different cell types (Taylor et al. 2005). The absorption of Zn is reduced by increased levels of other cations, such as cadmium, copper, magnesium, calcium, nickel, and iron (Abdel-Mageed and Oehme 1990).

Exit (Export)

Flux of Zn away from the cytosol is needed to balance the input. Zn export is controlled by ZnT proteins. ZnT family consists of nine isoforms (ZnT1 to ZnT9) which contribute to the cytoplasmic Zn balance by exporting Zn out to the extracellular space or by sequestrating cytoplasmic Zn into intracellular compartments when cellular Zn levels are too elevated (Fig. 2). ZnT-1 is the member of the SLC30 family which is ubiquitously expressed and the only Zn transporter involved in Zn efflux across the plasma membrane in many different cells, thus conferring resistance to Zn (Qin et al. 2009). Moreover, among all transporters, ZnT-1 is the most highly regulated, with expression levels increased up to 20-fold during Zn supplementation. Low-dose of Cd induces ZnT1, while ZnT1 silencing enhances Cd toxicity (Fernandez et al. 2007). The other members of the ZnT family are localized on the membrane of intracellular organelles and secretory vesicles/granules. They sequester cytoplasmic Zn into various compartments for secretion, storage, or for supplying proteins that require Zn for their structure and function. For example, different ZnTs working together are necessary to supply Zn to alkaline phosphatases and other enzymes important in the early secretory pathway of proteins (Suzuki et al. 2005).

Homeostasis

Zn homeostasis is maintained by the regulation of uptake/elimination but also by intracellular sequestration in the so-called zincosome. Metallothioneins, which behave as Zn chaperones, are a major tool of this process. Zn is extensively chelated by MTs in the cytosol thanks to their large Zn-binding capacity (Maret and Krezel 2007), (Fig. 2). MTs have the capacity to bind heavy metals and Cd–MT complexes are 100- to 1000-fold more stable than Zn–MT complexes, and MTs were initially considered as Cd detoxification molecules (Carpene et al. 2007; Bell and Vallee 2009).

Zn acts indirectly when inducing the production of metallothionein (MT), which can bind metals with known pro-oxidant activity. Our groups showed that MT levels in lung were significantly higher in comparison with control rats of Zn-deficiency (ZD) diet, during two and 4 months of treatment (Gomez et al. 2003). We proposed

that the higher levels of MT in ZD lung probably reflect a protective response to low concentration of Zn. We were suggesting that high levels of MT are a response to Zn deficiency and exacerbated due to the direct contact of the lung with the environment (Gomez et al. 2003). The same work group determined gene transcription of MTs I and II. MT II mRNA transcription increased in the ZD group as compared to the control group. During the supplementation period, MT II gene transcription was decreased compared to the control group. The gene transcription of MT I was not significantly different among all groups (Biaggio et al. 2010).

It now appears that MTs are involved in, at least, two major types of reactions with Zn: Zn buffering and Zn muffling. Zn buffering is, under steady state conditions, a primary function of cytosolic Zn-binding proteins to buffer the Zn content in the picomolar range. The process of muffling differs from buffering process because it is slow compared with thermodynamic buffering process (Günzel et al. 2001). MTs, as well as some exporters, are transcribed via the metal responsive transcription factor-1 (MTF-1) (Gunther et al. 2012). MTF-1 is localized in both cytoplasm and nucleus. It is involved in cellular adaptation to various stress conditions, primarily exposure to heavy metals, but also to hypoxia and oxidative stress.

Antioxidant Effects of Zinc

Zinc has been shown to be an important antioxidant as excellently reviewed by Powell (2000) and this is best demonstrated in animal studies where there is increased organ susceptibility, such as: the lung (Taylor et al. 1997), liver (Parsons and Di Silvestro 1994), and testes. Recent studies in a rat model of Zn deficiency enhanced epithelial lesions in the gastrointestinal epithelium, which were blocked by a nitric oxide synthase inhibitor (Cui et al. 2000).

Zinc can act as an antioxidant by a number of mechanisms (Fig. 3), which may also be important in the respiratory system. First, Zn can directly act as an antioxidant by stabilizing and protecting sulfhydryl-containing proteins that are important in lung function (e.g., ciliary tubulin, kinases/phosphatases, and Zn finger transcription factors). This ion may protect proteins from thiol oxidation and disulfide formation. Second, Zn can displace Fe and Cu from cell membranes and proteins, which can otherwise cause lipid peroxidation and destruction of membrane protein lipid organization due to their ability to promote the generation of hydroxyl ion (OH) from H_2O_2 and superoxide. This is important as Zn has only one oxidation state (II) and therefore cannot undergo these redox reactions. In addition, Zn can accept a spare pair of electrons from oxidants, hence neutralizing their reactivity.

Zn is an important component of the major antioxidant enzyme Cu–Zn superoxide dismutase (Cu–Zn SOD), located in airway and alveolar epithelial cells cytoplasm. Cu–Zn SOD plays an important role removing superoxide anions. Larsen et al. (2000) recently demonstrated the important protective effect of Cu–Zn SOD in airway. Elevated levels of Cu–Zn SOD in lungs were found to be more resistant to allergen-induced hyperresponsiveness than their wild-type counterparts.

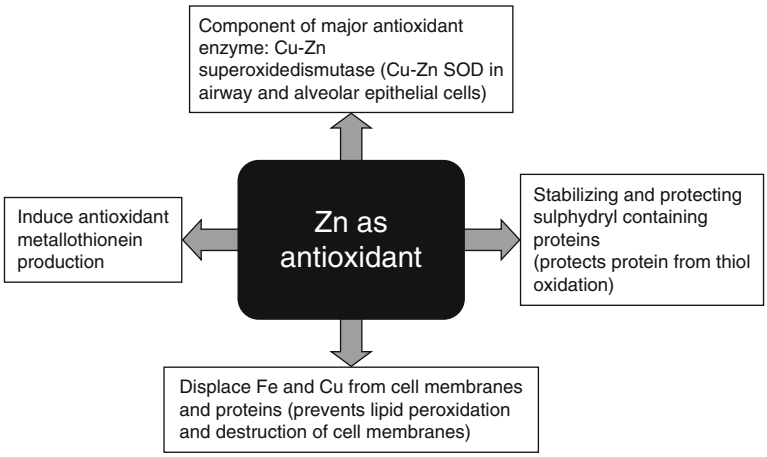

Fig. 3 Zinc and the function as antioxidant. Zinc is an important antioxidant in the respiratory system. Zinc acts as a component of the antioxidant enzyme Cu-Zn SOD (Cu-Zn superoxide dismutase), stabilizes and protects proteins, and induces the production of metallothionein while zinc stored in cells prevents lipid peroxidation and stabilizes membranes

It is known that Zn has a protective role in preventing cell death by apoptosis, in Zn deficiency. Zn and the protein Bcl-2 protect cells from oxidative stress, Zn acts as a cytoprotector of lung epithelium integrity during inflammatory stress and cellular depletion of Zn enhances susceptibility to apoptosis. During the apoptotic process, the molecular targets for Zn are the antiapoptotic Bcl-2-like and proapoptotic Bax-like, among others. Bax showed an increased expression in ZD group, suggesting the activation of apoptosis in the lung, whereas during the supplementation period Bax mRNA levels decreased (Biaggio et al. 2014) (Fig. 4).

Reactive oxygen species produce oxidative damage and have been shown to contribute to aging, neurodegeneration, carcinogenesis, and atherosclerosis (Lachance et al. 2001; Prasad et al. 2009). Zinc acts to prevent ROS formation by inhibiting enzymes that catalyze the formation of superoxide (Lachance et al. 2001). Further, it is a key component in superoxide dismutase, an enzyme capable of reducing hydroxide (Ho et al. 2001) and upregulates MTs (Lachance et al. 2001; Prasad et al. 2009).

Zinc Anti-Inflammatory Properties

Labile Zn plays a major role in inflammation control via a number of mechanisms. First, many inflammatory diseases, such as arthritis and asthma, are associated with an increase in the inducible form of nitric oxide (NO) synthase resulting in enhanced NO formation. Zn is able to inhibit lipopolysaccharide and IL-1β induced NO formation. Second, Zn is anti-inflammatory as it is also able to inhibit the activation of Nuclear Factor-κβ (NF-κβ), a transcription factor implicated in the expression of

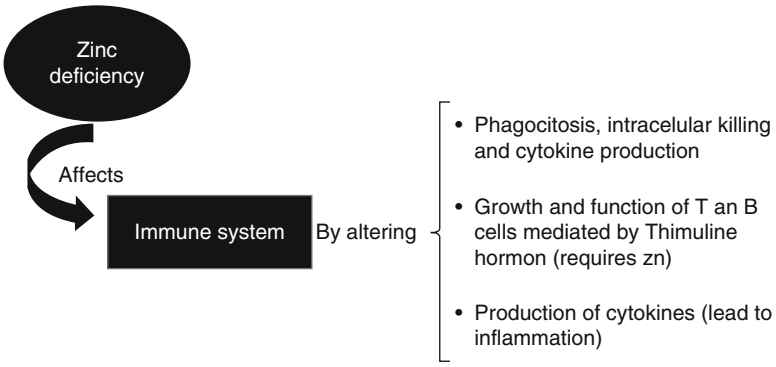

Fig. 4 Influence of zinc deficiency on immune system. Zinc deficiency affects immune system by altering phagocytosis, intracellular killing, and cytokine production. Deficiency leads to changes in growth and maturation of lymphocytes T and B

many pro-inflammatory genes. Zinc inhibits NF-κβ activation by blocking the phosphorylation and degradation of the inhibitory proteins Iκ (Jeon et al. 2000).

Other mechanisms, by which Zn may be anti-inflammatory in the respiratory tract, include: (i) blocking the binding of leucocytes to endothelial cells via the interaction between leucocyte-associated antigen 1 and intercellular adhesion molecule-1 (ICAM-1); (ii) blocking the docking of human rhinovirus on ICAM-1 of somatic cells, thereby preventing viral infections in the respiratory tract; and (iii) inhibiting the release of preformed mediators from mast cells and basophils (e.g., histamine) and eosinophils (e.g., eosinophil cationic protein).

While acknowledging that dietary changes over the past several decades have resulted in a decreased intake of fresh foods containing antioxidants, several intrinsic factors may contribute to a low Zn status in inflammatory diseases. Redistribution in plasma Zn to the liver can occur during excessive stress. This has been attributed to the release of leucocyte endogenous mediator from activated phagocytes, which then stimulates movement of Zn from plasma to hepatocytes, in allergic reactions. Second, the immune system is extremely dependent on the availability of Zn for maintaining its homeostasis. Inflammatory diseases can cause an increase in the demand for Zn as: (i) Zn is essential for producing the thymic hormone, thymulin, necessary for regulating T-cell development and activation; and (ii) Zn is crucial for the activation of natural killer cells, phagocytic cells and for granulocytes, such as mast cells and eosinophils. As a result, greater demand for Zn by the immune system could be a contributing factor to the Zn deficiency noted in inflammatory diseases.

Thymulin binds to high affinity receptors on T cells, induces several T-cell markers, and promotes T-cell function, including allogenic cytotoxicity, suppressor functions, and interleukin-2 (IL-2) production. After a mild Zn deficiency, serum thymulin activity, and mRNAs of IL-2 and IFNγ decreased. Thus, there is a shift from Th1 to Th2 functions affecting cell-mediated immunity adversely. A switch

from an initial cellular (Th1) to a more humoral and more pro-inflammatory (Th2) immune response occur in inflammatory diseases, such as asthma and can be reversed with Zn supplements.

Altered production of cytokines during Zn deficiency can lead to inflammation. It induces IL-1β release and subsequently inhibits the inflammation depending on the transcription factor NF-κβ (Summersgill et al. 2014). Moreover, simultaneous evaluation of circulating cytokines and Zn status showed that the reduced circulating Zn correlates with increased IL-6, IL-8, and TNFα level. In addition, the proliferative response of T and B lymphocytes following IL-6 and IL-2 stimulation increases in Zn deficiency, whereas it adversely influences the IL-4 signaling, causing an impairment of the immune system (Gruber et al. 2013).

Zinc deficiency itself is detrimental for inflammation as it results in dramatic increases in the number, size, and activation state of mast cells. This further exacerbates damage via increasing chemotaxis of eosinophils and neutrophils, which creates a continuous cycle of oxidative damage.

Zinc as an Antioxidant and Anti-Inflammatory Agent

Zn deficiency may increase oxidative and nitrosative stress in lung, which release several pro-inflammatory factors and provoke an infiltration of inflammatory cells (Gomez et al. 2006; Biaggio et al. 2010).

It is an important reminder at this point that zinc deficiency increased oxidative damage in the airways by causing infiltration of inflammatory cells and increased superoxide and nitric oxide production (Zalewski 2006; Gomez et al. 2006; Biaggio et al. 2010). Although reactive oxygen species are formed as a normal component of cellular respiration, in asthma and other inflammatory processes there is a reported imbalance between the flux of oxidants generated and the presence and/or activation of cellular antioxidant defense mechanisms. This especially relates to Cu-Zn SOD, and at least three studies have demonstrated a significant decrease in Cu-Zn SOD activity in erythrocytes (Tekin et al. 2000) and respiratory epithelial cells (Gomez et al. 2006; Biaggio et al. 2010). When zinc deficiency occurs in conjunction with acute lung injury or asthma, a more intense inflammation is produced. In addition, zinc is also able to restore chloride secretion in cystic fibrosis models (Zalewski 2006).

Oxidative stress and chronic inflammation are important contributing factors in several chronic diseases such as atherosclerosis and related vascular diseases, mutagenesis and cancer, neurodegeneration, and immunologic disorders. In addition, the aging process zinc deficiency per se resulted in increased generation of interleukin-1β (IL-1β) from the monocytes–macrophages. Zinc-deficient elderly and sickle cell disease patients also showed increased oxidative stress and they generated increased levels of inflammatory cytokines that decreased on zinc supplementation (Prasad et al. 2007; Bao et al. 2010).

Inflammation generates oxidative stress by increasing ROS, which results in oxidation of LDL. Oxidized LDL activates the NF-kβ-inducible kinase/IK-β kinase/NF-kβ signaling pathway and upregulates its downstream target genes such

as inflammatory cytokines, CRP, adhesion molecules, inducible nitric oxide synthase cyclooxygenase 2, fibrinogen, and tissue factor. These cytokines and molecules attract neutrophils, monocytes, macrophages, and platelets; induce coagulation; and initiate development of atherosclerosis. Zinc supplementation increased plasma antioxidant power, decreased inflammatory cytokines and oxidative stress biomarkers.

The NF-kβ pathway is known for its specific genes expression in response to inflammatory cytokines and oxidative stress. This pathway is also implicated in ROS perpetuation. Zinc decreased NF-kβ activation and its target genes such as TNFα, IL-1β, and VCAM increased the gene expression of A20 and PPAR-α. These zinc finger proteins have anti-inflammatory properties in HL-60 and THP-1 cells after ox-LDL stimulation. Thus, zinc decreased the expression of these cytokines and molecules by inhibition of NF-kβ activation via A20 and PPAR-α pathway.

Role of Zinc in Diseases

Malnutrition is one of the major public health challenges and the most common immune deficiency disease. Micronutrient deficiencies (as Zn and vitamin A) are the major risk factors for malnutrition, which are responsible of more than one third of death in children under five in developing countries. Moreover, malnutrition increases the risk of infections and affects every part of the immune system. Although dietary Zn deficiency was originally thought to be of rare occurrence, it is now estimated to affect more than 25% of the world's population. According to a World Health Organization report (WHO 2002), Zn deficiency ranks fifth among the most important health risk factors in developing countries and eleventh worldwide (Chandel et al. 2010). As Zn is widely required in cellular functions, abnormal Zn homeostasis causes a variety of health problems reaching different levels of severity. If chronic, severe and untreated, Zn deficiency can be fatal through immune defects leading to infections. Less drastic symptoms include infections, hypogonadism, weight loss, growth defects, dermatitis, alopecia, and delayed wound healing (Evans 1986).

Unfortunately, the importance of Zn in humans was only appreciated in the 1960s; before, only animal studies were conducted on this subject. An increased susceptibility to infections in patients was associated with Zn deficiency, indicating its importance for host immunity. Zn deprivation is associated with a decline of the immune system with increased inflammation leading to chronicity (Foster and Samman 2012). Several Zn supplementation studies were then conducted in Zn-deficient patients affected by different disease types (viral, bacterial, and parasitic infections or autoimmune diseases) (Prasad 2009).

Acrodermatitis enteropathica is one of the first diseases to provide the hallmarks of Zn importance. This rare genetic disorder is due to a recessive mutation in the gene encoding ZIP4, responsible for Zn uptake (Andrews 2008). This mutation leads to low plasma Zn concentration and to hyper-pigmented skin lesions, defective growth and, of major importance, to thymic atrophy and lymphopenia. Several

other diseases including infections, cancer, chronic diseases such as asthma, Alzheimer, and autoimmune diseases are related to alterations in Zn status.

Between others, rheumatoid arthritis (RA), characterized by a chronic inflammatory reaction, has been associated with deficiencies of Zn homeostasis. The first study linking Zn to RA reported improvements in joint swelling, morning stiffness, and walking in RA patients taking Zn supplements. However, these results on the antirheumatic effect of Zn were not confirmed by two other studies. But Zn supplementation was shown to modulate ex vivo phagocytosis and oxidative burst in phagocytes from RA patients (Filippin et al. 2008). Nevertheless, patients affected by RA show reduced Zn levels in sera, which negatively correlate with the levels of pro-inflammatory cytokines (TNFα and IL-1β) secreted by monocytes. Also, Zn deficiency increases the levels of TNFα, IL-1β, and IL-8 in a monocyte–macrophage cell line and Zn supplementation inhibits the LPS-mediated release of TNFα and IL-1β in monocytes (Filippin et al. 2008).

Besides its effects on the immune system, Zn regulates several other pathways involved in the development and perpetuation of RA. Zn is a component of matrix metalloproteases (MMPs), which are responsible for matrix remodeling and have a central role in bone destruction in RA. Lack of Zn and the related increase in IL-1β production stimulate the production of MMPs with consequent degradation of extracellular matrix components (Burrage et al. 2006). Lack of Zn has also been associated with an increased oxidative stress and an increased ROS production. Furthermore, Zn deficiency leads to an absence of SOD production and, subsequently, to a reduction in MT induction. Interestingly, local control of RA has been obtained following intraarticular administration of SOD. Zn also inhibits the activation of the transcription factor NF-κβ resulting in a decrease in the transcription of pro-inflammatory cytokines and adhesion molecules. However, the beneficial effects of Zn have not yet been directly demonstrated in RA patients.

In summary, Zn deficiency affects all aspects of the immune system indicating that the availability of Zn is essential for the proper development and function of the immune system, even if some mechanisms of action are not yet decrypted. Consequently several pathologies are characterized by imbalanced Zn homeostasis.

Conclusions and Perspectives

The nutritional importance of Zn is well known. Zn requires daily intake, and to achieve a steady-state level, the homeostasis of Zn inside the cells is tightly regulated by different transporters and regulators. Zn functions as a key structural or catalytic component and it is implicated at all levels of cellular signal transduction. In this way, Zn regulates also communication between cells, cell proliferation, differentiation, and survival. Furthermore, Zn involvement in the regulation of immune cells contributes to pathologies in which inflammation are presented. However, several mechanisms about Zn action on the immune system are still unclear. Further studies on the expression and regulation of transporters or on the interactions of Zn with other ions will also help to better understand the level of Zn and the evolution of

diseases, leading to potential new and innovative therapeutic avenues in the immunological field.

Policies and Protocols

To determine the dietary zinc requirement for a given age/gender group, it is necessary to define the relationship between absorption and intestinal losses and adjust by a constant for the nonintestinal losses in order to calculate the minimum quantity of absorbed zinc necessary to offset total endogenous losses. The factorial calculations used are based on metabolic/tracer studies in which participants are fed diets from which the bioavailability of zinc is likely to be representative of typical diets in Australia and New Zealand (NRVs -2006).

There are not many studies of this type in other parts of the world, so the available data do not take into account the food habits of many populations, nor the ethnicity.

For the above, we can say that a greater number of investigations on this subject are necessary.

Percentage of zinc required per day according to sex and stages of life

Age	AI (Adequate intake)	EAR (Estimated average requirement)	RDI (Recommended dietary intake)
Infant (0–6 months) (7–12 months)	2.0 mg/day	2.5 mg/day	3 mg/day
Children and adolescents			
All			
1–3 year 4–8 year		2.5 mg/day 3.0 mg/day	3 mg/day 4 mg/day
Boys			
9–13 year 14–18 year		5 mg/day 11 mg/day	6 mg/day 13 mg/day
Girls			
9–13 year 14–18 year		5 mg/day 6 mg/day	6 mg/day 7 mg/day
Adults			
Men			
19–30 year 31–50 year 51–70 year >70 year		12 mg/day 12 mg/day 12 mg/day 12 mg/day	14 mg/day 14 mg/day 14 mg/day 14 mg/day
Women			
19–30 year 31–50 year 51–70 year >70 year		6.5 mg/day 6.5 mg/day 6.5 mg/day 6.5 mg/day	8 mg/day 8 mg/day 8 mg/day 8 mg/day

Age	AI (Adequate intake)	EAR (Estimated average requirement)	RDI (Recommended dietary intake)
Pregnancy			
14–18 year		8.5 mg/day	10 mg/day
19–30 year		9.0 mg/day	11 mg/day
31–50 year		9.0 mg/day	11 mg/day
Lactation			
14–18 year		9 mg/day	11 mg/day
19–30 year		10 mg/day	12 mg/day
31–50 year		10 mg/day	12 mg/day

Dictionary of Terms

- **Oxidative and nitrosative stress** – produced when there is an imbalance between antioxidant and pro-oxidant. The most important free radicals (pro-oxidant) are oxygen reactive species (ROS) and nitrogen reactive species (RNS).
- **Antioxidant** – enzymatic and nonenzymatic antioxidants are molecules that protect cells against free radicals because they can damage cell structures. Organisms have an antioxidant defense system.
- **Inflammation** – this is induced by mediators produced by damaged cells as: cytokines, on the other. Pro-inflammatory cytokines increased during zinc deficiency and decreased on zinc supplementation.
- **Metalothionein** – belongs to the group of intracellular cysteine-rich, metal-binding proteins which are involved in diverse intracellular functions. They have high affinity for metals, like Zn and Fe, and whatever facilitates their detoxification and maintenance of metal homeostasis.
- **Zinc deficiency** – when the body does not absorb or get from food the necessary amount of zinc. This amount depends on age, sex, and physiological state. Zinc deficiency could be mild or moderate, likewise acute or chronic. Any of them can lead to a health problem.

Summary Points

- Zinc is an essential trace element important in human nutrition and health especially for the growth and development of infants and young children, elderly, and in pregnancy.
- It serves as a catalytic, structural, and protein interface component for diverse biological functions.
- The role of zinc in immune modulation has been lately studied.

- This chapter centers on mechanisms involved in regulation of zinc homeostasis and their effects on the immune response focusing on those that are implicate in the inflammation.
- Zinc, cadmium, and mercury share their way of transport in mammalian cells, taking up across cell membranes by active or facilitated diffusion.
- There are different types of zinc transporters, which possess competing roles in zinc homeostasis.
- Zinc homeostasis is maintained by the regulation of uptake/elimination but also by intracellular sequestration in the so-called zincosome with a key participant, the zinc chaperones: metallothioneins.
- Zinc has been shown to be an important antioxidant by a number of mechanisms, which may also be important in the respiratory system.
- Zinc deficiency may increase oxidative and nitrosative stress in lung parenchyma, which release several pro-inflammatory factors and provoke an infiltration of inflammatory cells.
- Zinc deficiency causes a decrease in innate and adaptive immunity.
- During zinc deficiency, the production of pro-inflammatory cytokines increases, influencing the outcome of a large number of inflammatory diseases.
- Zinc involvement in the regulation of immune cells and inflammation produced by zinc deficiency contributes to human pathologies.

Zinc Deficiency and Stunting

101

Valeria Galetti

Contents

Abstract

This chapter reviews key aspects of human zinc nutrition providing an insight on the etiology of zinc deficiency and current policies on the assessment of the risk of zinc deficiency in populations using stunting rates and other indicators. Zinc is an essential trace element in human nutrition, and it is critical to various basic molecular functions. Zinc depletion of the organism thus virtually affects any organ system in the human body, and it encompasses a number of diverse biochemical changes resulting in a generalized metabolic dysfunctions. Marginal

zinc deficiency mainly occurs when zinc intakes from the diet are inadequate to provide for increased requirements, increased losses, decreased absorption, or decreased utilization. This form of zinc deficiency carries most of the public health significance of zinc deficiency. Marginal zinc deficiency adversely affects physiological, biochemical, and immunological functions. Typical signs are growth retardation, hypogonadism in male adolescents, rough skin, poor appetite, mental lethargy, abnormal dark adaptation, abnormal neurosensory changes, and delayed wound healing. A more severe form of zinc deficiency can be inherited or acquired due to iatrogenic-induced zinc-free diet or severely impaired intestinal uptake. Acrodermatitis enteropathica is a rare autosomal recessive genetic disorder that results in impaired zinc absorption. In population surveys, the risk of zinc deficiency is considered to be elevated and of public health concern when the prevalence of low serum zinc concentrations is greater than 20%, the prevalence of inadequate intakes is greater than 25%, or the prevalence of stunting is at least 20%. In such cases, an intervention to improve population zinc status or increase dietary zinc intake is recommended. Approximately 17.3% of the world's population are at risk of inadequate intake of absorbable zinc, with the highest risk carried by countries in South and Southeast Asia, sub-Saharan Africa, and Central America. The global mortality burden due to zinc deficiency is of 116,000 deaths per year, the second most important cause of mortality due to micronutrient deficiency after vitamin A deficiency.

Keywords

Zinc · Zinc metabolism · Zinc requirements · Zinc deficiency · Zinc intake · Inadequate zinc intake · Zinc status · Plasma zinc · Serum zinc · Dietary zinc · Stunting · Height-for-age

Abbreviations

AE	Acrodermatitis enteropathica
CI	Confidence interval
DALY	Disability-adjusted life year
EAR	Estimated average requirement
EDTA	Ethylenediaminetetraacetic acid
EFZ	Endogenous fecal zinc
FAO	Food and Agriculture Organization
HAZ	Height-for-age z-score
IAEA	International Atomic Energy Association
IL	Interleukin
IOM	Institute of Medicine
IZiNCG	International Zinc Nutrition Consultative Group
PZn	Plasma/serum zinc
RCT	Randomized controlled trial
RDA	Recommended dietary allowance
RR	Relative risk *or* rate ratio

SD	Standard deviation
UFZ	Unabsorbed fecal zinc
UL	Tolerable upper level of intake
UNICEF	United Nations Children's Emergency Fund
WAZ	Weight-for-age z-score
WHO	World Health Organization
WHZ	Weight-for-height z-score
ZIP	Gene expressing for a Zip transporter
Zip	Zinc transporter, transports zinc into the cytoplasm
ZnT	Zinc transporter, transports zinc out of the cytoplasm

Introduction

In 1961, Prasad et al. described a clinical picture featuring dwarfism, hypogonadism, hepatosplenomegaly, and iron deficiency anemia in 11 Iranian boys (Prasad et al. 1961). The boys were aged 14–21 years, but their appearance was that of 8–15-year-old boys due to shorter-than-normal height; the absence of pubic, axillary, and facial hair; and infantile genitalia. Other key features of the disease included edema and skin and hair changes. Prasad pointed out that the clinical picture was not that of kwashiorkor, previously observed in populations of Africa, Jamaica, and India, because of missing salient features characterizing the newly observed syndrome. In addition, dietary patterns were dissimilar: while subjects developing kwashiorkor consumed a predominantly high-carbohydrate diet low in protein, both animal and vegetable, the Iranian boys consumed large quantities of wheat, which is one of the best cereals in respect to both quantity and quality of proteins. Conversely, these subjects' diet was deficient in animal proteins only. In one subject, Prasad and colleagues were able to determine a distinctly low plasma zinc (PZn) concentration, and by acknowledging similarities in the clinical manifestations of zinc-deficient rats, they concluded that the newly discovered syndrome might have been explained by zinc deficiency (Prasad et al. 1961). Further studies by Prasad and colleagues in other populations in Egypt and Iran described the clinical patterns in more detail and established that its primary cause was zinc deficiency (Prasad 1991; Prasad et al. 1963a, b). The discovery that patients with the syndrome acrodermatitis enteropathica (AE), an inherited autosomal recessive disorder causing zinc deficiency, had low PZn levels was the next key finding that allowed to identify the phenotypic symptomatology of the zinc deficiency syndrome without the presence of other nutritional deficiencies, such as iron deficiency like in the observed cases in Iran and Egypt.

The scope of this literature review is to provide an insight on the role of zinc as an essential trace element in human nutrition, on the etiology of zinc deficiency, and on the assessment of the risk of zinc deficiency using stunting rates and other indicators.

Zinc Metabolism

It is estimated that the human genome encodes for more than 3000 zinc proteins (Andreini et al. 2006). Zinc interacts with proteins in three ways: (1) as central atom in the catalytic center of metalloenzymes that participate in the synthesis and metabolism of molecules (proteins, nucleic acids, lipids, among others) and in cellular proliferation, differentiation, and growth, (2) in the maintenance of tertiary and quaternary structure of proteins (Maret 2013) (tertiary and quaternary structure of proteins), and (3) in the regulation of gene expression and protein synthesis, where zinc interacts with zinc metalloregulatory proteins (Maret 2006). Within the human body, zinc is present in all organs, tissues, fluids, and secretions, with a total body zinc of about 2500 mg in adult men (Iyengar 1998). Most of the zinc is found in the skeletal muscle mass (1400 mg), in the liver (700 mg), and in the bones (400 mg). The highest concentration of zinc is found in teeth (250 mg/kg), hair (200 mg/kg), and prostate (100 mg/kg). Plasma provides zinc to all tissues; therefore, maintenance of homeostasis and constant PZn level is essential to sustaining normal biological functions. The maintenance of homeostasis is achieved by efficiently regulated mechanisms of gastrointestinal absorption and excretion, at the organism level, and import and export, at the cellular level (King et al. 2000). Body zinc balance is the net yield of ingested zinc minus excreted zinc. Chronically low zinc intakes, generic disorders such as AE, or disease states can alter this balance. A physiological model for zinc homeostasis has been proposed (Fig. 1).

The process of absorption is considered as the influx of zinc from the intestinal lumen (mainly the distal duodenum or the proximal jejunum) into the enterocyte via a saturable active carrier mechanism mediated by zinc transporter Zip4 (found along the apical membrane and promoting import into the cytoplasm) and further through the basolateral membrane of the enterocyte via zinc transporter ZnT1 (promoting the export from the cytoplasm) into the portal circulation (Krebs 2000). At lower luminal zinc concentrations (i.e., up to an amount of about 7–9 mg of ingested zinc), import is mainly carried out by Zip4 (King 2010). In a mice model, it was observed that in conditions of zinc restriction, ZIP gene expression is upregulated, suggesting that efficiency of absorption increases with reduction in zinc intakes or reduction of zinc availability in the intestinal lumen (Dufner-Beattie et al. 2004). At higher zinc luminal concentrations, like in case of supplementation therapy, a non-saturable absorption mechanism possibly involving paracellular passive zinc diffusion becomes prominent (King 2010).

Although zinc absorption seems to be capable of coping with large fluctuations in intake, its response is slow. Rapid "fine-tuning" of net retention is guaranteed by a further level of homeostatic control through secretion, reabsorption, and excretion (King et al. 2000). Secretion of endogenous zinc occurs mainly from the pancreas, followed by bile, duodenum, and transepithelial flux from enterocytes and from mucosal cells that are sloughed into the gut (Krebs 2000). Maintenance of zinc balance intrinsically depends on the amount of secreted zinc that is reabsorbed, although it is not clear if this reflects a reduction in the amount of secreted zinc into the intestinal lumen and/or an increased reabsorption rate of endogenous zinc due to upregulation of the carrier-mediated process (King et al. 2000). A study of intestinal

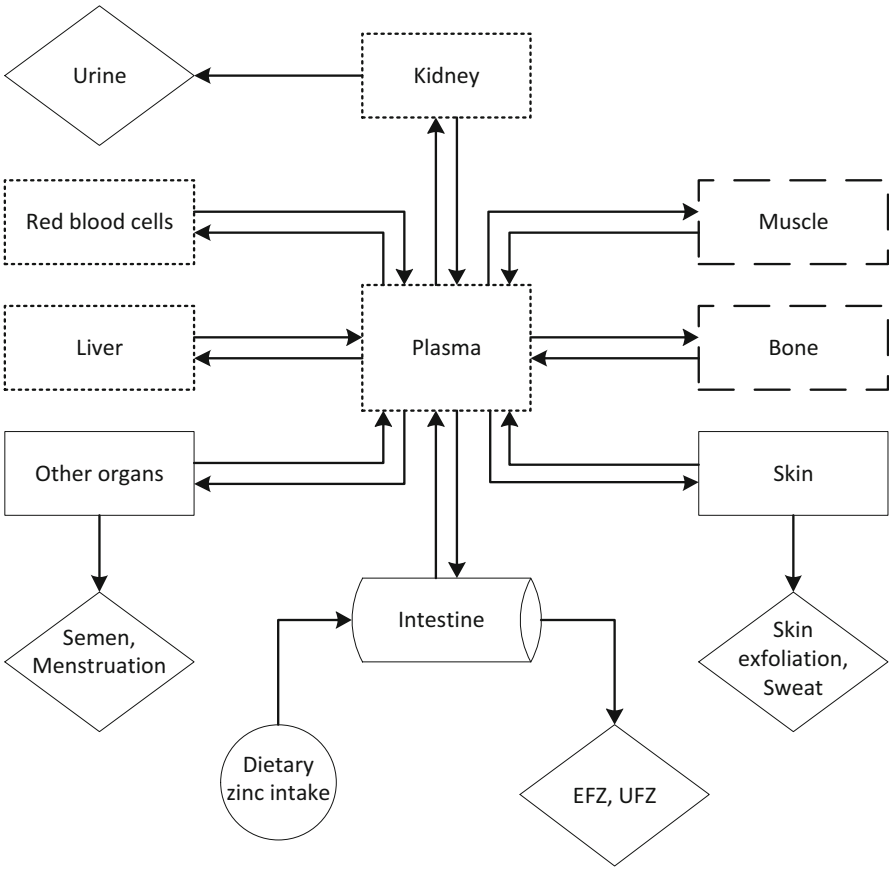

Fig. 1 Physiological model of zinc homeostasis. Dietary zinc is mainly absorbed in the duodenum and jejunum and transferred to plasma. From the plasma, zinc is distributed to the rapid turnover zinc pool tissues (dotted lines) and the slow turnover zinc pool tissues (dashed lines). Zinc is excreted through the intestine (*EFZ* endogenous fecal zinc, *UFZ* unabsorbed fecal zinc) and urine. Other zinc losses occur through skin exfoliation, semen, and menstruation

intubation showed that reabsorption of endogenous zinc continues more distally in the small intestine than absorption of exogenous zinc; however the mechanism of reabsorption remains unknown (Krebs 2000). The potential suggested route for the release of endogenous zinc into the gut is a Zip5-mediated zinc transport from the bloodstream to the enterocyte, with eventual release into the intestinal lumen via the apical transporter ZnT5 (Wang and Zhou 2010). Total zinc excretion represents the net gastrointestinal excretion (secretion minus reabsorption) plus the unabsorbed dietary zinc. The major route of excretion is feces (1–5 mg/day), but other losses include urinary excretion (0.4–0.6 mg/day) and surface losses (desquamation of skin, hair outgrowth, and sweat). Contribution from semen (1 mg) and menstrual losses (0.1–5 mg) is not negligible (Holt et al. 2012).

Dietary Sources of Zinc and Requirements

Zinc is found widely in the food supply. Zinc content is closely correlated with protein content, and rich sources include red meat, liver, kidney, heart, shellfish, crustacean, and cheese, with the highest concentration being found in oysters with 160 mg/100 g. Plant protein sources such as nuts and legumes (beans, chickpeas, peas, and lentils) are also good sources of zinc. In cereals, zinc is found in the bran and germ tissues. Highly refined cereal products, such as white rice or white breads, are poor sources of zinc because zinc-rich bran and germ are normally lost through the milling process. Dairy products and poultry are moderate sources of zinc, whereas poor sources are fruits, tubers, fats, and oils. Zinc-rich foods are not necessarily good contributors to dietary zinc intake. While zinc from animal sources is highly bioavailable, zinc from vegetable sources is generally less bioavailable due to the presence of phytate. Bioavailability describes the degree to which a nutrient in any food is absorbed, transported, and used physiologically. Bioavailability depends on the total zinc content in the diet as well as the food-matrix composition and interactions with other components of foods. Amino acids (e.g., histidine, methionine), organic acids (e.g., citrate), and low-molecular-weight chelators (e.g., EDTA) facilitate absorption by acting as zinc ligands (Lonnerdal 2000). Organic compounds such as phytate, the principal storage form of phosphorus in plants, form stable chelating complexes with zinc at intestinal pH reduce absorption. Certain levels of calcium and possibly iron increase zinc bioavailability by binding phytate and making it unavailable for chelating zinc (Miller et al. 2013). The content of phytate in the diet (also expressed as the phytate-to-zinc molar ratio), however, is the most important food-matrix factor determining zinc absorption (Lonnerdal 2000; Miller et al. 2013) (Fig. 2).

Different algorithms are proposed for estimating dietary zinc bioavailability by the WHO, US Institute of Medicine (IOM), International Zinc Nutrition Consultative Group (IZiNCG), and European Food Safety Authority (EFSA). WHO classifies diets into low, moderate, and high bioavailability with estimated zinc absorption of 15%, 30%, and 50%, respectively, irrespective of life stage and sex. IOM provides an estimated zinc bioavailability for mixed diets for children and adults. IZiNCG proposes revised estimates for mixed and unrefined diets for children, men, and women. EFSA differentiates between lactating women and other life stages (Table 1).

Dietary reference intake values include estimated average requirements (EARs), recommended daily allowances (RDAs), and tolerable upper levels of intake (ULs). The EAR is the median of the distribution of requirements for a specific sex and life-stage group of healthy individuals, and it meets the requirements of half the individuals in that population. The RDA, set at two standard deviations above the EAR, is the zinc intake level at which, theoretically, 97.5% of the population would meet the daily requirements of healthy individuals. The UL is defined as the highest level of zinc intake that is likely to pose no risk of adverse health effects for almost all individuals. The range between the RDA and the UL is considered as the range of safe intakes. Different sets of dietary reference intakes are proposed by WHO, IOM, IZiNCG, and EFSA (Tables 2, 3, and 4).

Risk Factors of Zinc Deficiency and At-Risk Populations

Risk factors for zinc deficiency include (1) dietary or socioeconomic factors that contribute to insufficient zinc intakes or interfere with absorption and bioavailability of dietary zinc, (2) physiological factors that contribute to increased demand owing to growth, and (3) pathological or genetic factors that contribute to increased zinc losses or impaired zinc absorption or utilization. Risk of zinc deficiency thus occurs during periods when zinc intakes from the diet are inadequate to provide for increased requirements, increased losses, decreased absorption, or decreased utilization. Population subgroups generally regarded to be at high risk of zinc deficiency are infants, children, adolescents, pregnant and lactating women, elderly, or any individual with a particular pathological condition, especially among populations from low-income strata or rural settings in developing countries but also among certain Western population subgroups (Brown et al. 2004).

Inadequate dietary intake of absorbable zinc is likely the primary cause of zinc deficiency in most situations (Brown et al. 2004). Risk factors, typical to most low-income rural settings, include poverty, limited food availability, or food choice driven by socioeconomic, cultural, or religious constraint (Gibson 2006). Geogenic factors can also contribute to low zinc content in locally grown foods (Nriagu 2011). In Western societies, reduction in total food intake in elderly (Brown et al. 2004) and consumption of vegetarian or vegan diets (Foster et al. 2013) might result in insufficient zinc intakes.

Table 1 Estimates of dietary zinc absorption as developed by the World Health Organization (WHO/FAO/IAEA 1996), US Institute of Medicine (IOM 2006), International Zinc Nutrition Consultative Group (IZiNCG) (Brown et al. 2004), and European Food Safety Authority (EFSA 2014)

Increased requirements occur during the intense anabolic phase in periods of organism rapid growth due to the critical role of zinc in nucleic acid synthesis and protein metabolism (Gibson 1994). Requirements are thus increased during pregnancy for accrual zinc in fetal and maternal tissues (from 0.1 mg/day in the first quarter to 0.7 mg/day in the fourth quarter, totaling ≈100 mg for the whole gestation period), during lactation for the secretion of zinc in breast milk (4 mg/day in the first days, 1 mg/day at 1 month, and 0.7 mg/day at 6 months for exclusive breastfeeding), and during catch-up growth of premature infants or infants with a smaller content of zinc metallothionein at birth as a consequence of low birth weight or poor maternal zinc status (Brown et al. 2009; Gibson 2006; Swanson and King 1987). Increased demand for zinc is also suggested for weaning infants, children, and adolescents at the time of the pubertal growth spurt (Brown et al. 2004). Stress, trauma, obesity, and rehabilitation after starvation can also incur in increased requirements due to increased anabolism (Nriagu 2011).

Excessive zinc loss occurs via feces, urine, skin, and blood. Fecal losses, which can be of endogenous or exogenous origin, are mainly due to alteration of integrity, permeability, and absorptive capacity of the gastrointestinal mucosa or to increased chyme transit time. Gastrointestinal diseases such as diarrhea, parasitic infections

(i.e., hookworm), celiac disease, inflammatory bowel disease, and Crohn's disease and genetic disorders such as mucoviscidosis (cystic fibrosis), AE, and Wilson's disease can cause malabsorption or sustained loss of intestinal secretions (Holt et al. 2012). Morphological alterations of the intestine through surgical interventions as a strategy against obesity, such as gastric bypass, can promote malabsorption (Salle et al. 2010). Physiological mucosal changes in the intestine occurring during aging also affect zinc absorption and increase losses (Holt 2007). Chelating drugs such as phenytoin and tetracycline and pharmacologic doses of iron reduce zinc absorption (Solomons 1986; Weismann 1986). Increased zinc excretion through urine has been reported in a number of conditions, including liver diseases and cirrhosis, alcoholism, kidney diseases, diabetes mellitus, and chronic (i.e., thalassemia, sickle cell disease) or parasitic hemolysis (i.e., schistosomiasis, malaria) (Gibson 1994). Iatrogenic increase in urinary zinc excretion has been observed during treatment with some chelating agents such as penicillamine (Nriagu 2011). Conditions that induce catabolism are also associated with increased endogenous zinc losses: surgery, burns, multiple injuries, major fractures, and bone or muscle atrophy (Nriagu 2011). Increased losses can also occur through blood (i.e., excessive bleeding or menstruation) and semen (i.e., excessive ejaculation) and through exfoliation of skin and increased perspiration as a result of hot and humid climate or excessive exercise (Gibson 1994). Impaired utilization of zinc may occur in the presence of infection, which generally results in zinc sequestration by the liver, thus reducing levels of circulating zinc and availability to other tissues (Cousins and Leinart 1988).

Clinical Spectrum of Zinc Deficiency

Given zinc ubiquitous nature and implication in various basic molecular functions, zinc depletion virtually affects any organ system in the human body. Zinc deficiency, rather than manifesting a specific clinical condition, encompasses a number of diverse biochemical changes resulting in a generalized metabolism dysfunction (King 2011). Indeed, the variety of clinical manifestations exhibited by zinc deficiency illustrates the numerous roles that zinc plays in the body. Zinc deficiency ranges from marginal to severe: while marginal zinc deficiency is mainly due to suboptimal zinc intakes, severe states are consequent to disease-induced impaired absorption or iatrogenic-induced zinc-free diet. If unrecognized and not corrected, zinc deficiency can turn fatal (Dibley 2001).

Marginal zinc deficiency may occur during periods of increased zinc requirement, such as increased growth in infancy, childhood, adolescence, and pregnancy, mainly due to insufficient dietary zinc intakes. Typical signs of marginal zinc deficiency are growth retardation, hypogonadism in male adolescents, rough skin, poor appetite, mental lethargy, abnormal dark adaptation, abnormal neurosensory changes, and delayed wound healing (Tuerk and Fazel 2009). Depletion/repletion studies conducted by Prasad on male healthy volunteers aged 20–45 years revealed that marginal zinc deficiency in humans is characterized by decreased taste acuity (hypogeusia), decreased sperm count, decreased serum testosterone concentration,

hyperammonemia, decreased lean body mass, decreased serum thymulin activity, decreased IL-2 activity, decreased natural killer cell activity, and alterations in the T-cell subpopulations. The manifestations occurred during an experimental regime of zinc restriction (3–5 mg/day), which induced a total imbalance of ≈180 mg over the 6-month depletion period. All manifestations were corrected by zinc supplementation in the repletion period (27 mg/day) (Prasad 1991). These studies clearly established that even a marginal deficiency of zinc in humans adversely affects physiological, biochemical, and immunological functions.

Severe zinc deficiency can be inherited or acquired due to virtually no zinc in the diet or severely impaired intestinal uptake. Acquired zinc deficiency was observed in patients receiving total parenteral nutrition without zinc supplementation, whereas inherited zinc deficiency refers to subjects affected by AE. AE is a lethal rare autosomal recessive genetic disorder that results in a mutation of the Zip4 gene that encodes for the Zip4 zinc transporter (Wang et al. 2002). Zinc absorption thus results impaired as demonstrated in tracer studies (Weismann et al. 1979). AE occurs worldwide with an estimated incidence of 1 per 500,000 children, with no apparent predilection for race or sex (van Wouwe 1995), and usually develops days to weeks after weaning from breastfeeding or, if an infant is bottle-fed, within days from birth. It is likely that zinc is bound to different molecules in breast milk versus cow milk and that this might have an impact on absorbability; however reasons for this well-characterized difference in onset have not yet been clarified (Cousins and Smith 1980). Subjects affected by AE develop dermatologic manifestations (skin lesions in the acral and periorificial areas), ophthalmic manifestations (conjunctivitis, photophobia, and corneal opacities), neuropsychiatric manifestations (irritability, emotional instability, tremors, and occasional cerebellar ataxia), as well as growth retardation, anorexia, delayed puberty, and male hypogonadism (Maverakis et al. 2007). AE patients also show increased susceptibility to infections and severe gastrointestinal disturbances such as diarrhea, malabsorption, and lactose intolerance (Prasad 2013). Symptoms other than dermatitis seem to vary with age (Vanwouwe 1989). Before the beneficial effect of zinc therapy was recognized, AE was often a fatal disease. Patients on zinc-free total parenteral nutrition for prolonged periods commonly show manifestations similar to those by AE: severe dermatitis, alopecia, weight loss, wound healing problems, and intercurrent infections due to cell-mediated immune dysfunctions.

Assessment of Population Zinc Status

Nutritional indicators are dietary, biochemical, functional, or clinical indices that allow measuring the level of nutrient intake, nutrient exposure, nutrient status, or nutrient functional effects. Used either alone or in combination, they can characterize the stages of development of a nutritional deficiency (Gibson 2005). Several biochemical indicators of zinc status have been proposed and measured in a number of studies (such as zinc concentration in serum or plasma, erythrocyte, leukocyte, urine, hair, nails, to name a few), but the search for a reliable, sensitive, and specific

Table 5 Lower plasma zinc (μg/dl) cutoffs by age, sex, time of day, and fasting status as proposed by the International Zinc Nutrition Consultative Group (IZiNCG) (Brown et al. 2004)

	Children <10 years	Females ≥10 years	Males ≥10 years
Morning fasting	–	70	74
Morning nonfasting	65	66	70
Afternoon	57	59	61
		Pregnancy	
First trimester		56	
Second/third trimester		50	

biochemical index of zinc status at the individual level has been problematic and is still ongoing. Anthropometric or clinical indices, such as stunted growth, immune dysfunction, and skin lesions, are indicative of the functional effects of prolonged low zinc status (Lowe et al. 2009).

The functional outcome of choice for estimating the risk of zinc deficiency in populations is stunting (de Benoist et al. 2007). It is recommended to use the stunting prevalence in children under 5 years of age, i.e., the prevalence of children with height-for-age (HAZ) below-2SD of the age-specific median of the reference population based on the WHO Child Growth Standards (WHO 2006). The risk of zinc deficiency is considered to be of elevated public health concern when the prevalence of stunting among children aged <5 years is at least 20%. Although stunting may be associated with zinc status, it may also be caused by inadequate intakes of other nutrients including energy, protein, or micronutrients such as iron, zinc, and vitamins D, A, or C (singly or in combination). Consequently, HAZ is a valid qualificator of the likely risk of zinc deficiency ("high" versus "low" risk) but has limited value in quantifying the extent of the prevalence of zinc deficiency. Therefore, this assessment should be used as evidence suggestive for an increased likelihood that zinc deficiency is of public concern, whereby further assessment of zinc status using direct indicators is required, such as biochemical assessment of PZn and/or dietary assessment of zinc intake (Brown et al. 2004).

The biochemical indicator of choice is PZn, and lower cutoffs by age, sex, time of day, and fasting status have been proposed by IZiNCG (Brown et al. 2004) (Table 5). For population assessment, the percentage of individuals with PZn below the appropriate cutoff is calculated: <10% suggests that zinc deficiency is not of public health concern, 10–20% suggests that segments of the population may be at high risk of zinc deficiency and that stratified analysis for identification of at-risk groups is necessary, and >20% suggests that the population is at high risk of zinc deficiency, and programs at national level may be considered (Brown et al. 2004).

To assess the adequacy of population zinc intake as based on dietary surveys, IZiNCG suggests calculating the percentage of individuals with intakes below the EAR, using the EAR cut-point method: <15% suggests a likely low risk, 15–25% suggests an intermediate level of risk for zinc deficiency, and ≥25% suggests that there is an elevated risk of zinc deficiency in that population and that zinc deficiency is of public health concern (Brown et al. 2004).

Global Prevalence of Zinc Deficiency

Data is insufficient to classify many countries' national zinc status based on the population distribution of PZn or zinc intakes. In the absence of these direct indicators, in 2004 IZiNCG developed a method to derive estimates for a country's likely risk of zinc deficiency derived from two indirect indicators: (1) the national prevalence of stunting in children aged <5 years and (2) the national prevalence of inadequacy of zinc intakes based on the amount of absorbable zinc in each country's national food supply (Brown et al. 2004). The national prevalence of stunting in children aged <5 years is regularly assessed in most countries during surveys, and the national stunting prevalence is well documented in the WHO Global Database on Child Growth and Malnutrition. Estimated national and global prevalence of inadequate zinc intakes were estimated in 2005 and revised in 2012 (Wessells et al. 2012; Wuehler et al. 2005). Using these data, IZiNCG classified each country into one of the three categories of likely risk of zinc deficiency ("high," "moderate" and "low") using a composite index based on both indirect indicators: (1) prevalence of stunting ≥20% *and* estimated prevalence of inadequate zinc intake ≥25% to be suggestive evidence for "high" risk of zinc deficiency, (2) prevalence of stunting >20% *or* estimated prevalence of inadequate zinc intake >25% to be suggestive evidence for "moderate" risk of zinc deficiency, and (3) prevalence of stunting <20% *and* estimated prevalence of inadequate zinc intake <25% to be suggestive evidence for "low" risk of zinc deficiency. The global risk of zinc deficiency was thus estimated in 2004 (Brown et al. 2004) and was then revised in 2012 (Wessells and Brown 2012) (latest estimates are mapped in Fig. 3).

Absorbable zinc content of national food supplies may be inadequate to meet zinc requirements for approximately 15–20% of the world's population, with an estimate of 17.3% of global inadequacy of absorbable zinc intakes. Countries in South and Southeast Asia (22–29%), Sub-Saharan Africa (25%), and Central America (17%) were identified as being at highest risk of inadequate zinc intake. The mean prevalence of stunting in countries identified as being at low, moderate, and high risk of inadequate zinc intake was 19.6%, 28.8%, and 43.2%, respectively. The estimated prevalence of inadequate zinc intake significantly and positively correlated with the prevalence of stunting in children <5 years of age, although it was generally lower than stunting rates. This was explained by the fact that prevalence of zinc deficiency is indeed higher in young children than in adults and that prevalence of inadequate zinc intakes derived from food balance sheets is more likely to be reflective of adult dietary intakes than children (Wessells and Brown 2012).

The methodology applied in this approach has not yet been validated and should therefore be regarded as an interim measure. In fact, risk factors of stunting are not only limited to zinc deficiency but also include other micronutrient deficiencies and other forms of malnutrition, such as protein-energy deficiency, whereas national food balance sheet may not be representative for population groups in rural settings that are most vulnerable to stock price variation and meteorological conditions affecting subsistence farming. National health and nutrition surveys, although expensive and requiring a skilled staff, should be encouraged for the determination

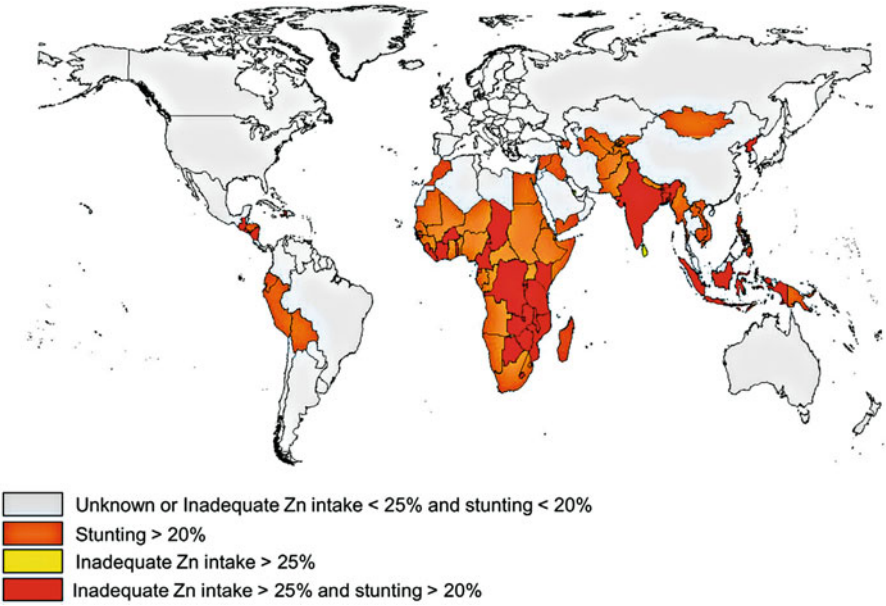

Fig. 3 National risk of zinc deficiency based on the prevalence of childhood stunting and the estimated prevalence of inadequate zinc intake. Stunting data (low height-for-age) are for children less than 5 years of age in 138 low- and middle-income countries. The estimated prevalence of inadequate zinc intake is based on the Food and Agriculture Organization national food balance sheet data from 188 countries (Source: Wessells and Brown 2012 with permission from PLOS under the Creative Commons license)

of prevalence of low PZn and inadequate zinc intake in nationally representative population strata. In recent years, more information has become available from national surveys in low- and middle-income countries on the distribution of PZn in nationally representative samples. A decent agreement was recently found comparing zinc deficiency risk estimation based on PZn with the estimation based on the IZiNCG methodology (Hess 2017).

Public Health Significance of Zinc Deficiency

Marginal zinc deficiency seems to carry most of public health significance of zinc deficiency, as it is more prevalent than more severe states but still shows clinically important manifestations (Hambidge 2000). The main cause of marginal zinc deficiency is dietary, thus due to the nature of diets prevalently consumed in settings of lower socioeconomic status more common to most developing countries. Results from several systematic reviews suggest that zinc deficiency substantially contributes to the morbidity and mortality of young children worldwide. A meta-analysis revealed that zinc deficiency in children aged <5 years is associated with a relative

risk (RR) of incidence of diarrheal disease of 1.28 (95% CI: 1.10–1.50), pneumonia of 1.52 (95% CI: 1.20–1.89), and malaria of 1.56 (95% CI: 1.29–1.89) and was estimated to yearly cause 176,000 diarrhea deaths, 406,000 pneumonia deaths, and 207,000 malaria deaths (Caulfield and Black 2004). The associated loss of disability-adjusted life years (DALYs) was estimated at more than 28 million, with the biggest share of disease burden found in countries in Africa, Eastern Mediterranean, and Southeast Asia. Revised estimates were proposed in 2008 by Black and colleagues in a meta-analysis of RCTs carried out in countries estimated to be at medium-high risk of zinc deficiency (Black et al. 2008). The pooled RR for morbidity associated with zinc deficiency was 1.09 (95% CI: 1.01–1.18) for diarrhea, 1.25 (95% CI: 1.09–1.43) for pneumonia, and 1.56 (95% CI: 1.29–1.89) for malaria. The RR for mortality in children aged 1–59 months associated with zinc deficiency was 1.27 (95% CI: 0.96–1.63) for diarrhea, 1.18 (95% CI: 0.90–1.54) for pneumonia, and 1.11 (95% CI: 0.94–1.30) for malaria. Zinc deficiency was estimated to yearly cause 450,000 deaths (4.4% of total death in children aged <5 years), and the associated loss of DALYs was estimated at more than 16 million (3.8% of total DALYs in children aged <5 years), more than iron and iodine deficiencies pulled together but less than vitamin A deficiency. These estimates were about 40% lower than those previously reported because included additional studies reporting lower RR. More recent estimates by Black and colleagues reported even lower figures with a total of 116,000 deaths attributable to zinc deficiency, mainly because the risk of pneumonia and diarrheal mortality was estimated starting at 12 months of age rather than 6 months of age, as previously done (Black et al. 2013). Although the share of global mortality burden due to zinc deficiency is only second to that of vitamin A deficiency among micronutrient deficiencies, zinc deficiency is responsible for the least proportion of global deaths when compared to other nutritional disorders: stunting (14.7%), underweight (14.4%), wasting (12.6%), fetal growth restriction (11.8%), suboptimum breastfeeding (11.6%), vitamin A deficiency (2.3%), and zinc deficiency (1.7%) (Black et al. 2013).

Policies and Protocols

WHO Policies

Stunting

Low HAZ occurs when an individual is short for his/her age and reflects either normal variation or a pathological process. When shortness is pathological, an individual is said to be "stunted." Stunting reflects a process of failure to reach linear growth potential as a result of long-term suboptimal health and/or nutritional conditions (WHO 1995). In contrast, low WHZ is referred to as "wasting" and describes the condition of gaining insufficient weight relative to height, implying recent severe weight loss. Low WAZ, or "underweight," refers to the gaining of insufficient weight relative to age implying stunting and/or wasting (WHO 1995). Since height deficit results from a long-term cumulative effect of socioeconomic,

health, and nutrition inadequacies, it was chosen as the operational anthropometric indicator of choice for predicting the level of risk with which these inadequacies occur, ultimately reflecting the level of development. When low HAZ is observed in children below 2–3 years, it probably reflects a continuing process of "failing to grow," whereas when observed in older children, it reflects a state of "having failed to grow" (WHO 1995). For these reasons, a current picture of the level of development of a population is given by the prevalence of stunting, i.e., HAZ <-2SD of the WHO Child Growth Standards (WHO 2006), in children below 5 years of age. Four ranges have been defined by WHO to classify levels of stunting for global monitoring purposes: <20%, 20–29%, 30–39%, and ≥40% representing low, moderate, high, and very high prevalence of stunting, respectively (de Onis et al. 1993). Stunting rates exceeding 20% are considered a public health concern (WHO 1995).

Zinc Status Indicators

In 2007, WHO/UNICAF/IAEA/IZiNCG, in an interagency meeting on zinc status indicators, reviewed methods of assessing population zinc status and endorsed the following recommendations for the use of specific biochemical, dietary, and functional indicators of zinc status in populations (de Benoist et al. 2007).

- The risk of zinc deficiency is considered to be elevated and of public health concern when the *prevalence of low serum zinc concentrations is greater than 20%*. In this case, an intervention to improve population zinc status is recommended.
- The risk of zinc deficiency is considered to be elevated and of public health concern when the *prevalence or probability of inadequate intakes is greater than 25%*. In this case, an intervention to increase population dietary zinc intake is required.
- The risk of zinc deficiency is considered to be of elevated public health concern when the *prevalence of stunting is at least 20%*. In this case, an intervention to improve population zinc status is recommended.

Dictionary of Terms

- Stunting. A form of failure to growth, also known as pathological shortness, occurring when an individual is short for his/her age, specifically when his/her height-for-age z-scores are below -2SD of the WHO Child Growth Standards.
- Kwashiorkor. A form of severe protein-energy malnutrition characterized by edema and an enlarged liver.
- Acrodermatitis enteropathica. A rare, lethal if untreated, inherited autosomal recessive genetic disorder causing zinc deficiency.
- Iatrogenic disease. An illness inadvertently induced by medical diagnostic procedures or treatment.

Summary

- This chapter reviews key aspects of human zinc nutrition providing an insight on the etiology of zinc deficiency and current policies on the assessment of the risk of zinc deficiency in populations using stunting rates and other indicators.
- Zinc is an essential trace element in human nutrition, and it is implicated in various basic molecular functions.
- Zinc depletion virtually affects any organ system in the human body, and it encompasses a number of diverse biochemical changes resulting in a generalized metabolism dysfunction.
- Zinc deficiency occurs when zinc intakes from the diet are inadequate to provide for increased requirements, increased losses, decreased absorption, or decreased utilization.
- Marginal zinc deficiency is mainly due to suboptimal zinc intakes and carries most of public health significance of zinc deficiency.
- Marginal zinc deficiency adversely affects physiological, biochemical, and immunological functions. Typical signs are growth retardation, hypogonadism in male adolescents, rough skin, poor appetite, mental lethargy, abnormal dark adaptation, abnormal neurosensory changes, and delayed wound healing.
- Severe zinc deficiency can be inherited or acquired due to virtually no zinc in the diet or severely impaired intestinal uptake. Acrodermatitis enteropathica is a rare autosomal recessive genetic disorder that results in impaired zinc absorption.
- The risk of zinc deficiency is considered to be elevated and of public health concern when the prevalence of low serum zinc concentrations is greater than 20%, the prevalence of inadequate intakes is greater than 25%, or the prevalence of stunting is at least 20%. An intervention to improve population zinc status or increase dietary zinc intake is recommended.
- Approximately 17.3% of the world's population are at risk of inadequate intake of absorbable zinc, with the highest risk carried by countries in South and Southeast Asia (22–29%), sub-Saharan Africa (25%), and Central America (17%).
- The global mortality burden due to zinc deficiency is of 116,000 deaths per year, only second to that of vitamin A deficiency among micronutrient deficiencies.

Contents

Abstract

Zinc (Zn) is an essential micronutrient element. This element in relation with the structure and function of many proteins and enzymes is important for a variety of biological activities, including epigenetic regulations. Zinc deficiency is common in many parts of the world and particularly in poor populations. Accumulating evidence has demonstrated that several key enzymes and zinc finger proteins with

zinc atom(s) in the reactive center and binding site play important roles in DNA methylation and histone modifications. Therefore, zinc deficiency may disrupt the functions of these enzymes and proteins and result in epigenetic dysregulation. Furthermore, zinc deficiency may enhance inflammatory response and subsequently alter DNA methylation status of the genes involved in inflammation. In this chapter, we first describe zinc dietary sources and deficiency, and then discuss direct and indirect effects of zinc deficiency in DNA and chromatin methylation alteration. Finally, we prospect a new zinc biomarker and further investigation on the effects of zinc deficiency in epigenetics.

SLC	solute-linked carrier
WHO	World Health Organization
ZFP	zinc finger protein

Introduction

Zinc is a chemical element with the symbol Zn^{2+} and atomic number 30. This chemical element is present in all body tissues and fluids as an essential component for approximately 1000 proteins (Dreosti 2001; Ho 2004; Chasapis et al. 2012). Of them, more than 300 enzymes participate in the synthesis and degradation of carbohydrates, lipids, proteins, and nucleic acids as well as in the metabolism of other micronutrients (Frassinetti et al. 2006; Prasad 2012, 2013). Except these enzymes, the rest mainly includes the proteins with a zinc atom in the reactive center and zinc finger proteins (ZFPs) (Laity et al. 2001). Therefore, zinc, in relation with the structures and functions of these proteins, is of importance in a variety of biological activities such as

apoptosis, signal transduction, transcription, differentiation, and replication in all organ systems and during embryonic development. Since zinc is involved in such fundamental and extensive biological activities, it most likely accounts for the essentiality of zinc for all life forms.

As an essential mineral, zinc has been perceived by the public as being of "exceptional biologic and public health importance." However, many peoples particularly in the developing countries consume less than the recommended nutrient intakes (RNIs) for dietary zinc (WHO and FAO 2004). Epidemiological study has reported that zinc deficiency affects about 2.2 billion people around the world and has been ranked 11th among global risk factors for mortality and 12th for burden of disease (Lopez et al. 2006). Clinical observation has demonstrated that zinc deficiency is associated with pathologic changes in many diseases (Frassinetti et al. 2006; Prasad 2012, 2013). Dysregulation of epigenetics due to zinc deficiency may be involved in the pathogenesis of the diseases.

Epigenetics is involved in many cellular processes. Within cells, there are three systems that can interact with each other to silence genes: DNA methylation, histone modifications, and noncoding RNA-associated silencing (Du et al. 2015). Zinc has been found to affect the activities of some key enzymes such as methionine synthase (MTR, also known as MS) and betaine homocysteine methyltransferase (BHMT) in the reaction of DNA methylation (Castro et al. 2008; Jing et al. 2015). ZFPs are the most abundant proteins in eukaryotes and fundamentally contribute to multiple layers of epigenetic regulation such as DNA methylation and histone modifications (Laity et al. 2001; Shimbo and Wade 2016). Furthermore, zinc homeostasis is involved in the immune cell signaling and activation. Zinc deficiency may enhance inflammatory response and subsequently alter DNA methylation status of the genes involved in the induction of a pro-inflammatory response (Wong et al. 2015). In this chapter, we briefly describe zinc dietary sources and deficiency, and then intensively discuss direct and indirect influences of zinc deficiency in DNA methylation changes. Finally, we prospect a new zinc biomarker and further investigation on the effects of zinc deficiency in epigenetics.

Zinc Food Sources and Deficiency

Zinc deficiency can occur not only in humans but also in soil, plants, and animals. In general, zinc deficiency is defined either qualitatively as insufficient zinc to meet the requirements of the body and thereby causing clinical manifestations or quantitatively as a serum zinc level below the normal range. In humans, the most common cause of zinc deficiency is reduced dietary intake, while other reasons include inadequate absorption, increased loss, or increased use (Wessells and Brown 2012; Wessells et al. 2012). Therefore, it is necessary to know the sources of zinc from foods.

A wide variety of foods contains zinc and the selected food sources of zinc are listed in Table 1. To help the consumers for comparison of the nutrient contents of products within the context of a total diet, the daily values of foods (DVs) in this table have been developed by the U.S. Food and Drug Administration. Oysters

Table 1 Selected food sources of zinc

Food	Mg per serving	Percent DV
Oysters, cooked, breaded, and fried, 85.05 g	74.0	493
Beef chuck roast, braised, 85.05 g	7.0	47
Crab, Alaska king, cooked, 85.05 g	6.5	43
Beef patty, broiled, 85.05 g	5.3	35
Breakfast cereal, fortified with 25% of the DV for zinc, ¾ cup serving	3.8	25
Lobster, cooked, 85.05 g	3.4	23
Pork chop, loin, cooked, 85.05 g	2.9	19
Baked beans, canned, plain or vegetarian, ½ cup	2.9	19

Mg milligrams; *DV* daily value. DVs were developed by the U.S. Food and Drug Administration to help the consumers for comparison of the nutrient contents of products within the context of a total diet

contain more zinc per serving than any other food. Oysters are unusual and delicious mollusks that provide the human body with a number of unique nutrients and minerals, particularly zinc (Murphy et al. 1975). The edible components are the meat inside the oyster, and once the shells have been cracked, we can cook this meat in a variety of ways, but they can also be eaten raw. The valves in oysters can actually cleanse entire ecosystems of pollutants and are a major benefit to the environment. In recent years, however, the oyster population of the world has dropped significantly, resulting in weaker overall ecosystems in the areas where oysters once flourished (Páez-Osuna et al. 2002; Lacerda and Molisani 2006). Red meat and poultry provide the majority of zinc in the diet. Other food sources, including beans, nuts, certain types of seafood (such as crab and lobster), whole grains, fortified breakfast cereals, and dairy products, are also good (WHO and FAO 2004). Comparatively, the bioavailability of zinc from animal foods is higher than that from grains and plant foods, because phytates are present in whole-grain breads, cereals, legumes, and other foods from plants and bind zinc and inhibit its absorption in foods (Wise 1995; Sandstrom 1997).

Table 2 RDAs for dietary zinc (mg/day) and the normative storage requirements from diets differing in zinc bioavailability

Group	Age	Assumed body weight (kg)	High bioavailability	Moderate bioavailability	Low bioavailability
Infants and children	0–6 months	6	l.l[a]	2.8[b]	6.6[C]
	7–12 months	9	0.8[a], 2.5[d]	4.1	8.4
	1–3 years	12	2.4	4.1	8.3
	4–6 years	17	2.9	4.8	9.6
	7–9 years	25	3.3	5.6	11.2
Adolescents	10–18 years (F)	47	4.3	7.2	14.4
	10–18 years (M)	49	5.1	8.6	17.1
Adults	19–65 years (F)	55	3.0	4.9	9.8
	19–65 years (M)	65	4.2	7.0	14.0
	65+ years (F)	55	3.0	4.9	9.8
	65+ years (M)	65	4.2	7.0	14.0
Pregnant women	First trimester	–	3.4	5.5	11.0
	Second trimester	–	4.2	7.0	14.0
	Third trimester	–	6.0	10.0	20.0
Lactating women	0–3 months	–	5.8	9.5	19.0
	3–6 months	–	5.3	8.8	17.5
	6–12 months	–	4.3	7.2	14.4

Source: Adapted from WHO and FAO 2004. Unless otherwise specified, the interindividual variation of zinc requirements is assumed to be 25%. Weight data interpolated from FAO, *Food and Nutrition Series,* No. 23, 1988). RNIs: recommended nutrient intakes; *Mg*: milligrams; *Kg*: kilograms; *F*: females; *M*: males; a: Exclusively human-milk-fed infants. The bioavailability of zinc from human milk is assumed to be 80%; assumed co-efficient of variation 12.5%. b: Formula-fed infants. Applies to infants fed whey-adjusted milk formula and to infants partly human-milk-fed or given low-phytate feeds supplemented with other liquid milks; assumed coefficient of variation 12.5%. c: Formula-fed infants. Applicable to infants fed a phytate-rich vegetable protein-based formula with or without whole-grain cereals; assumed coefficient of variation 12.5%. d: Not applicable to infants consuming human milk only

The current recommended dietary allowance (RDA) is the average daily level of intake sufficient to meet the nutrient requirements of nearly all (97%–98%) healthy individuals. The RDAs for zinc are summarized in Table 2. For infants aged 0–6 months, the food nutrition board at the Institute of Medicine of the National Academies established an adequate intake (AI) that is equivalent to the mean intake

of zinc in healthy, breastfed infants (Institute of Medicine 2001; WHO and FAO 2004; Ackland and Michalczyk 2016). AI is generally established when evidence is insufficient to develop an RDA and is set at a level assumed to ensure nutritional adequacy.

One previous report has demonstrated that zinc deficiency affects about 2.2 billion people around the world and is often caused due to poor diet consumption (Prasad 2001). Another recent study based upon on WHO growth standards has indicated that an estimated 17.3% of the world's population is at risk of inadequate zinc intake (Wessells et al. 2012). Country-specific estimated prevalence of inadequate zinc intake is negatively correlated with the total energy and zinc contents of the national food supply and the percent of zinc obtained from animal source foods (Wessells and Brown 2012; Wessells et al. 2012). Pregnant and nursing women are considered at higher risk of zinc deficiency, as are those with gut problems, babies born prematurely, or those who have consumed a high-grain or vegetarian diet (especially for a long period of time) (Ackland and Michalczyk 2016). The symptoms of zinc deficiency can vary and is often associated with the following problems: poor memory, weakened immune system or constant minor illnesses like colds, loss of taste or smell, sleep problems (zinc is needed to make melatonin), hair loss, loss of appetite, low libido, diarrhea, brain fog, slow wound healing, white spots on fingernails, and growth retardation in children (WHO and FAO 2004). However, most severe symptoms of zinc deficiency result from other factors including excessive alcohol use, liver diseases, malabsorption syndromes, renal disease, enteral or parenteral alimentation, administration of sulfhydryl-containing drugs, and sickle cell diseases (Evans 1986). Moreover, zinc deficiency is an important factor in the development and progression of cancers (Dhawan and Chadha 2010; Gumulec et al. 2011; Sharif et al. 2012**)** and metabolic disorders (Lin and Huang 2015; Wilson et al. 2016; Grüngreiff et al. 2016). Recent studies have provided evidence that zinc deficiency and zinc transports are involved in the pathogenesis of diabetes and diabetic complications (Gu 2015; Zhang et al. 2016a; Maret 2017). Taking together, the symptoms resulting from zinc deficiency are as diverse as the enzymes with which the element is associated. Although clinical observation of the symptoms caused by zinc deficiency is well documented, our knowledge concerning the mechanisms of zinc deficiency in relation with epigenetics is still limited. Herein, we mainly discuss the proteins, which are related with zinc in biological structure and function and possible problems in epigenetics caused by zinc deficiency.

Zinc Deficiency and the Oocyte Epigenetic Programming

It is well known that human pregnancy outcome is significantly influenced by the nutritional status of the mother and an optimal uterine environment. Quality of the maternal epigenome significantly contributes to promoting optimal embryonic development and postnatal health (Corry et al. 2009; Hales et al. 2011). The epigenome of the oocyte is dramatically remodeled during oogenesis. As the

oocyte nears ovulation, major changes in chromatin structure and biochemistry take place to prepare for fertilization and embryonic development (Debey et al. 1993; Zuccotti et al. 1995). Chromatin methylation is an important component of epigenetic programming during oogenesis.

Zinc deficiency during pregnancy causes abnormal embryo and fetal development and poor progeny health (Apgar 1985; Keen et al. 2003; Uriu-Adams and Keen, 2010). Several studies have implicated that zinc is an important factor necessary for regulating the meiotic cell cycle and ovulation (Kim et al., 2010; Bernhardt et al. 2011; Tian and Diaz, 2013). To investigate the effects of acute in vivo zinc deficiency before ovulation on oocyte epigenetic programming and embryonic development, Tian and Diaz (2013) have developed an animal model with zinc deficiency. Newly weaned 18-day-old female CD1 mice were given the zinc-deficient diet (zinc omitted from the mineral mix <1 mg zinc/kg), while the control mice have the diet of 29 mg zinc/kg. Diets are given for 3 or 5 days before ovulation. Results demonstrate that feeding a zinc-deficient diet (ZDD) for 3–5 days before ovulation (preconception) dramatically disrupts oocyte chromatin methylation and preimplantation development. Histone H3K4 trimethylation and global DNA methylation in zinc-deficient oocytes are significantly decreased. Furthermore, the H3K4 trimethylation can be restored by using supplementation of a methyl donor (s-adenosylmethionine) during in vitro maturation in oocytes from zinc-deficient mice. Methyl donor supplementation partially restores fertilization potential of zinc-deficient oocytes (Tian and Diaz 2013). Therefore, this study provides evidence that zinc deficiency leads to decreased oocyte chromatin methylation, and implicates that oocyte epigenetic programming during the period of final oocyte growth is important to perturbation in whole body zinc homeostasis.

Zinc Deficiency and the DNA Methylation Pathway

DNA methylation is one of epigenetic marks that regulates gene expression and suppresses transposon activity. The DNA methylation pathway is a process by which carbons are added onto folic acid from amino acids and redistributed onto other compounds throughout the body. Figure 1 illustrates the homocysteine recycling for DNA methylation. In the cycle, several key enzymes, including MTR and BHMT, are responsible for the formation of methionine, S-adenosyl methionine (SAMe), and thymidylate monophosphate (dTMP), and subsequently facilitate virtually every DNA methylation reaction in the body (Matthews and Goulding 1997; Smith and Denu 2009; Shimbo and Wade 2016). Zinc deficiency may disrupt their biological activities and consequently result in the decreased DNA methylation levels.

BHMT is mainly present in kidneys and liver (http://www.genecards.org/cgi-bin/carddisp.pl?gene=BHMT&keywords=BHMT). This enzyme and BHMT2 are the only enzymes that can catalyze the conversion of betaine and homocysteine to dimethylglycine and methionine, respectively. This reaction is considered the alternate or short route for methylation. BHMT uses zinc as a cofactor to catalyze the

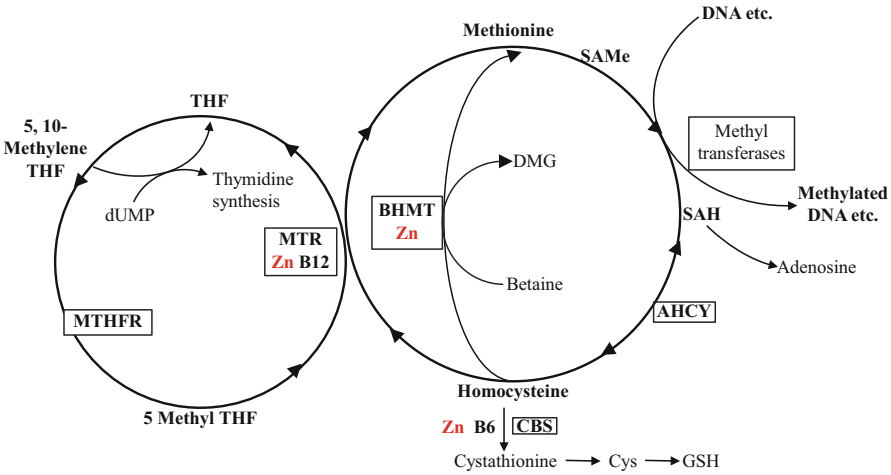

Fig. 1 Homocysteine recycling: involvement of zinc in MTR and BHMT for DNA methylation. This figure illustrates that methionine synthase (*MTR*) and betaine homocysteine methyltransferase (*BHMT*) are responsible for the formation of methionine, S-adenosyl methionine (*SAMe*), and thymidylate monophosphate (*dTMP*), and subsequently facilitate virtually every DNA methylation reaction in the homocysteine recycling. These two key enzymes are zinc-dependent methyltransferases. Zinc deficiency may disrupt their biological activities and consequently result in the decreased DNA methylation levels

transfer of a methyl group from betaine to homocysteine. Several studies have demonstrated that mutations in the BHMT gene may decrease the activity of this enzyme in the homocysteine recycling and DNA methylation. BHMT mutations in mothers may increase the risk of Down syndrome for their children. BHMT mutations may result in fatty liver and hepatocellular carcinomas (Matthews and Goulding 1997; Castro et al. 2008; Shimbo and Wade 2016).

MTR (also known as 5-methyltetrahydrofolate-homocysteine methyltransferase) is widely expressed in different organs and tissues. This enzyme facilitates the transfer of a methyl group from 5-methyltetrahydrofolate to homocysteine using zinc, cobalamin (B12), and MTRR enzyme as a catalyst. The end products of this reaction are the amino acid methionine and the vitamin tetrahydrofolate. Dysfunction of this enzyme due to mutations in the gene or disruption of zinc deficiency may lead to a lack of methionine and the accumulation of homocysteine in the body (hyperhomocysteinemia) (Matthews and Goulding 1997; Castro et al. 2008; Shimbo and Wade 2016). The pathological consequence of the gene mutation depends on how profoundly these methylation pathways are affected and the degree of homocysteine accumulation in the body.

Interestingly, Jing et al. (2015) have investigated the effects of dietary zinc (Zn) supply on homocysteine levels and expression of these two enzymes in the growing rats. Male weanling rats Sprague-Dawley are randomly assigned to four dietary groups for 3 weeks: Zn deficient (ZD; <1 mg Zn/kg); Zn control (ZC; 30 mg Zn/kg); pair fed (PF; 30 mg Zn/kg), and Zn supplemented (ZS; 300 mg Zn/kg). As expected,

several parameters, including feed intake, body weight gains, kidney weights, and serum and femur Zn concentrations, in the ZD rats are lower than those of ZC rats but not significantly different from the PF controls. The mRNA expression levels of the MTR gene are lower in liver and kidney of ZD rats compared to PF rats. However, hepatic and renal BHMT mRNA expression levels in ZD rats are not altered compared to controls. This study provides evidence suggesting that homocysteine homeostasis is disturbed by zinc deficiency but not zinc supplementation, and elevated serum homocysteine may be due to reduced expression of MTR but not BHMT during zinc deficiency.

Zinc Deficiency and Zinc Finger Proteins

Three classes of mammalian proteins recognize methylated DNA: MBD proteins, SRA proteins, and ZFPs. ZFP are a massive, diverse family of proteins and serve a wide variety of biological functions (Laity et al. 2001; Blattler et al. 2013). It is difficult to simply define what unites ZFPs due to their diversity. However, the common character of all ZFPs is that the functional domains of ZFPs require the coordination by at least one zinc ion. In general, the second structures (α-helix and β-sheet) of a ZFP, which are referred as "fingers" are joined by the zinc ion. For example, the Cys2His2 was the first domain discovered (also known as Krüppel-type). Figure 2 represents the structure of the Cys2His2 zinc finger motif consisting of α-helix and antiparallel β-sheet. The zinc ion (green) is located in the center and coordinated by two histidine residues and two cysteine residues. The Cys2His2 zinc fingers that bind DNA tend to have 2–4 tandem domains as part of larger protein. Cys2His2 proteins are the biggest group of transcription factors in most species. Lack of the zinc ion in the ZFP will result in the structural damage and functional

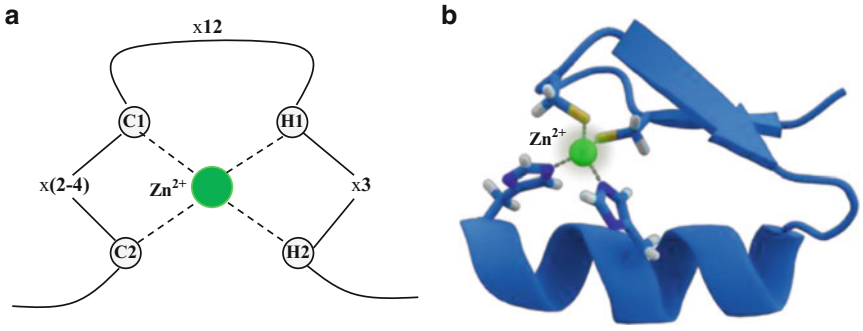

Fig. 2 A cartoon representation of the Cys2His2 zinc finger motif. The Cys2His2 zinc finger motif consists of α-helix and antiparallel β-sheet. Two histidine residues and two cysteine residues are coordinated by the zinc ion (in the *center* and labeled in *green*). (**a**): a schematic outline of the Cys2His2 type zinc finger domain. The number of x shows the intervals between the zinc binding residues. (**b**): a crystal of structure of the Cys2His2 zinc finger motif

Table 3 Zinc finger proteins, their recognition of methylated and specific DNA sequences

Protein name	Size molecular mass	Gene symbol	Aliases	DNA-binding specificity	
				Methylated sequence	Nonmethylated consensus
Zinc finger and BTB domain containing 33	672 AA 74484 Da	ZBTB33	KAISO	5′-CGCG-3’	5′-TCCTGCNA-3’
Zinc finger and BTB domain containing 4	1013 AA 105114 Da	ZBTB4	KAISO-L1	5′-CGCG-3’	5′-CTGCNA-3’
Zinc finger and BTB domain containing 38	1195 AA 134257 Da	ZBTB38	Croz	5′-CGCG-3’	5′-CATGTG-3’

loss (Wu 2002). Therefore, zinc serves to stabilize the integration of ZFP itself but is not involved in binding targets. Subsequently, zinc finger-containing domains typically act as interactors, binding DNA, RNA, protein, or small molecules (Laity et al. 2001; Wu 2002; Blattler et al. 2013).

Kaiso, ZBTB4, and ZBTB38 are three ZFPs can bind either methylated DNA in a sequence-specific manner or unmethylated consensus sequences. They may use a mode of binding common to other zinc-finger proteins, suggesting that many other sequence-specific methyl-binding proteins may exist. Table 3 represents the methylated DNA and unmethylated consensus sequences of Kaiso, ZBTB4, and ZBTB38.

Kaiso is originally described as a BTB/POZ zinc finger transcription factor and a p120-catenin-binding partner. This protein functions as a DNA methylation-dependent transcriptional repressor by binding to sequence-specific Kaiso-binding sites or to methyl-CpG dinucleotides (Blattler et al. 2013). Kaiso represses the expression of glucocorticoid receptor via a methylation-dependent mechanism and attenuates the antiapoptotic activity of glucocorticoids in breast cancer cells. Kaiso promotes cell migration and invasiveness through regulation of miR-31 expression in prostate cancer cells (Wang et al. 2016; Zhou et al. 2016). ZBTB4 (also known as Kaiso-L1) is found to be downregulated in breast cancer patients, and that its expression is significantly correlated with relapse-free survival. ZBTB4 functions as a novel tumor-suppressor gene with prognostic significance for breast cancer survival. CIBZ, was discovered to implicate in the spinal cord injury process for the first time. Further studies indicate that CIBZ is extensively distributed in various tissues, and the expression level is highest in muscle, followed by spinal cord, large intestine, kidney, spleen, thymus, lung, cerebrum, stomach, ovary, and heart, respectively. CIBZ gene is involved in secondary injury process and triggers the activation of apoptotic caspase-3 and bax genes independent of p53 (Cai et al. 2012). To date, the precise factors contributing to ZFPs-related zinc deficiency remain poorly defined.

Zinc Deficiency and Inflammation

As an essential micronutrient, zinc is required for many cellular processes, especially for the normal development and function of the immune system. There are remarkable similarities between the hallmarks of zinc deficiency and age-related immunological dysfunction because both are characterized by impaired immune responses and systemic chronic inflammation (Mocchegiani et al. 2000; Foster and Samman 2012; Prasad 2014). Moreover, zinc has anti-inflammatory properties and low zinc status is associated with increased susceptibility to infections and exaggerated inflammatory responses.

Interleukin 6 (IL-6) is an interleukin that acts as both a proinflammatory cytokine and an anti-inflammatory myokine. Wong et al. (2015) have recently demonstrated that zinc deficiency induces a progressive demethylation of the IL6 gene promoter in human monocytic cell line THP-1. The decreased IL6 gene methylation levels are correlated with increased IL6 expression. Evidence from this study suggests that zinc deficiency may have the effects in promoting inflammation and subsequently disrupt DNA methylation of the genes involved in the inflammation process. IL6 promoter methylation may also be reduced with age in human population. Most likely, there is a potential epigenetic link between zinc deficiency and age-related chronic inflammation (Bonaventura et al. 2015). However, it is necessary to include other proinflammatory cytokines such as IL1β, IL8, and tumor necrosis factor alpha (TNFα) for analysis before a conclusion is drawn.

Zinc Deficiency and Epigenetics

The effects of zinc deficiency in epigenetics are summarized in Fig. 3. *Zinc deficiency directly affects the key enzymes involved in the reaction of DNA methylation such as MTR and BHMT, and the proteins, in which zinc iron are constructed, including ZFPs, and consequently disrupts the DNA methylation and histone modification. Zinc deficiency also indirectly induces inflammation response and subsequently causes epigenetic alteration.*

Zinc transporters play an important role in regulating cellular zinc homeostasis. Members of Zip and ZnT zinc transporter families exhibit tissue- and cell-specific expression and possess differential responsiveness to dietary zinc, as well as to physiologic stimuli, including cytokines (Liuzzi and Cousins 2004; Bonaventura et al. 2015). Zinc transporters may also be involved into the indirect influence in epigenetics under the condition of zinc deficiency. Intrauterine growth retardation causes hypomethylation and hyperacetylation of genomic DNA while zinc deficiency is found to accompany fetal growth retardation in the patients with diabetes (Miao et al. 2013; Lin and Huang 2015). In alpha- and beta-cells of the islets of Langerhans, zinc has specific functions in the biochemistry of insulin and glucagon. When zinc ions are secreted during vesicular exocytosis, they have autocrine, paracrine, and endocrine roles. Solute carrier family 30 member 8 (SLC30A8, also known as ZnT8) is a zinc efflux transporter in the cell membrane and transports zinc

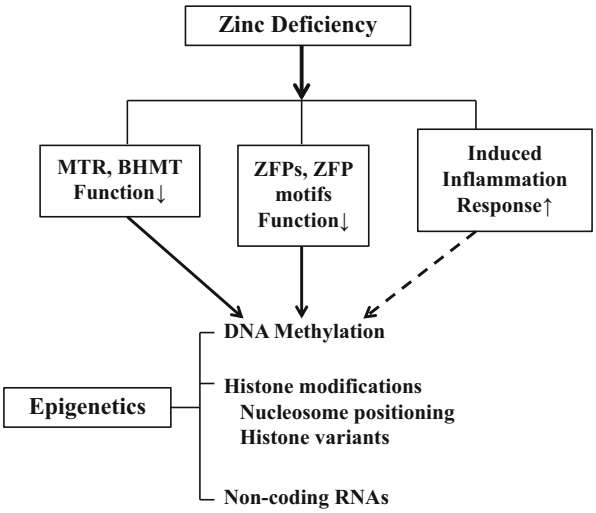

Fig. 3 Effects of zinc deficiency in epigenetics. Zinc deficiency can directly affect the activities of key enzymes such as MTR and BHMT and zinc finger proteins and consequently disrupt the DNA methylation and histone modification. Moreover, zinc deficiency can also indirectly induce inflammation response and subsequently cause epigenetic alteration. Other proteins such as zinc efflux transporters may also be involved into the indirect influence in epigenetics under the condition of zinc deficiency

ions into the insulin and glucagon granules and the subsequent crystallization of hexameric insulin. Pathological studies have demonstrated that the SLC30A8 gene expression levels are downregulated in pancreatic islets of diabetic mice (Fu et al. 2009). The downregulation of the SLC30A8 gene expression results in the reduction of insulin content and glucose-inducible insulin secretion (Chimienti et al. 2004; Gu 2016; Katsarou et al. 2017). Seman et al. (2015) have analyzed SLC30A8 DNA methylation with a bisulfite pyrosequencing protocol and found that DNA methylation levels of the SLC30A8 gene in type 2 diabetes patients are significantly higher compared to nondiabetic subjects. Interestingly, the average DNA methylation levels of the SLC30A8 gene in all studied subjects are high (~81.4%). However, the relationship between DNA methylation changes in this gene and zinc deficiency is still unknown. Furthermore, the recent studies have provided evidence that zinc deficiency enhanced albuminuria and extracellular matrix protein expression, associated with diabetic renal interstitial fibrosis by activation of renal interstitial fibroblasts and regulation of the expression of fibrosis-associated factors, which may be mediated by the activation of fibroblasts via the TGF-β/Smad signaling pathway (Zhang et al. 2016a). Zinc supplementation significantly inhibited the pathway (Zhang et al. 2016b). Therefore, zinc is one of the many factors in multiple gene-environment interactions that cause the functional demise of pancreatic beta-cells and renal interstitial fibrosis. Further epigenetic study is necessary to better understand between nutritional or conditioned zinc deficiency, environmental

exposures, and pathobiochemistry of the diabetes and diabetic complications including diabetic nephropathy.

Currently, the serum zinc concentration is used for evaluation of zinc deficiency. This biomarker for zinc status, however, may not be reliable because a decrease in serum concentration is only detectable after long-term or severe depletion. Therefore, it is necessary to develop new biomarker and protocol to more accurately detect dietary zinc deficiency. Dietary zinc deficiency affects blood linoleic acid: dihomo-γ-linolenic acid (LA:DGLA) ratio. The erythrocyte LA:DGLA ratio as a new zinc biomarkers has shown promise in preclinical and clinical trials and can be developed to more accurately detect dietary zinc deficiency (Knez et al. 2016). Consequently, the precise determination of zinc status will improve the basic and translation medicine researches on the effects of zinc deficiency in epigenetics.

Zinc is one of the many factors in multiple gene-environment interactions that cause the epigenetic alteration. Further investigation is of importance to better understand the inactive mechanisms of nutritional or conditioned zinc deficiency with zinc metabolism, environmental exposures and epigenetic regulation. Based upon the advanced knowledge concerning the relationship between zinc deficiency and epigenetic alteration, the possible interventions may include personalized nutrition, bioactive food, and pharmaceuticals targeting the control of cellular zinc in precision medicine.

Key Facts

Zinc is a chemical element with the symbol Zn^{2+}. The atomic number of zinc in periodic table of elements and chemistry is 30.

Zinc is publically considered as an essential micronutrient element because it exists in all body tissues and fluids and is included in the reactive centers and/or binding sites of many proteins and enzymes.

Zinc deficiency is defined either qualitatively as insufficient zinc to meet the requirements of the body and thereby causing clinical manifestations or quantitatively as a serum zinc level below the normal range.

An estimated global prevalence of inadequate zinc intake is 17.3% according to the data analysis based upon WHO growth standards. Zinc deficiency is actually common in many parts of the world and particularly in poor populations.

Zinc deficiency may lead to decreased oocyte chromatin methylation. The subsequent oocyte epigenetic programming during the period of final oocyte growth is important to perturbation in whole body zinc homeostasis.

Zinc deficiency may cause decreased DNA and chromatin methylation mainly due to dysfunction of MTR and BHMT in the reaction of DNA methylation.

Some zinc finger proteins (ZFPs) such as Kaiso, ZBTB4, and ZBTB38 bind either methylated DNA in a sequence-specific manner or unmethylated consensus sequences. These ZFPs may have the effects in epigenetic regulations under the condition of zinc deficiency.

Zinc deficiency is associated with immunological dysfunction, and may induce inflammation response and subsequently cause epigenetic alteration in the related genes.

Zinc transporters play an important role in regulating cellular zinc homeostasis. DNA methylation changes of some genes encoded for zinc transporters for example SLC30A8 has been found to be involved in the pathogenesis of diabetes.

Dietary zinc deficiency affects blood LA:DGLA ratio. This ratio can be used as a new zinc biomarker to more accurately detect dietary zinc deficiency.

Dictionary of Terms

- **Zinc deficiency** – It is defined either qualitatively as insufficient zinc to meet the requirements of the body and thereby causing clinical manifestations or quantitatively as a serum zinc level below the normal range. Zinc deficiency can occur in soil, plants, and animals. In humans, the most common cause of zinc deficiency is reduced dietary intake, while other reasons include inadequate absorption, increased loss, or increased use.
- **Homocysteine recycling** – Homocysteine is a sulfhydryl-containing amino acid, an intermediate product in the normal biosynthesis of the amino acids methionine and cysteine. In the methylation cycle, homocysteine is methylated to methionine, which undergoes S-adenosylation and forms S-adenosylmethionine (SAM). SAM is the principal methyl donor for all methylation reactions in cells. The reactions are controlled by two key enzymes named as methionine synthase (MTR) and betaine homocysteine methyltransferase (BHMT). MTR and BHMT are both zinc-dependent methyltransferases. Zinc deficiency may disrupt the biological activities of these two enzymes in the reaction of DNA methylation and consequently result in the decreased DNA methylation levels.
- **Zinc finger proteins** – They are a massive, diverse family of proteins that serve a wide variety of biological functions. These types of proteins are structured with a zinc finger, which is a small protein structural motif and characterized by the coordination of one or more zinc ions in order to stabilize the fold.
- **Zinc transports** – These proteins are encoded by two solute-linked carrier (SLC) gene families: SLC30 (ZnT) and SLC39 (Zip), and all have transmembrane domains. There are at least 9 ZnT and 15 Zip transporters in human cells. ZnT transporters reduce intracellular zinc availability by promoting zinc efflux from cells or into intracellular vesicles, while Zip transporters increase intracellular zinc availability by promoting extracellular zinc uptake and, perhaps, vesicular zinc release into the cytoplasm. Both ZnT and Zip transporter families exhibit unique tissue-specific expression, differential responsiveness to dietary zinc deficiency.
- **LA:DGLA ratio** – Linoleic acid (LA) is a polyunsaturated omega-6 fatty acid. Dihomo-γ-linolenic acid (DGLA) is a 20-carbon ω-6 fatty acid. The LA:DGLA in blood samples is closely responsible for dietary zinc deficiency. Thereby, this ratio is a potential new zinc biomarker for determination of dietary zinc deficiency.

Summary Points

- Current studies concerning the effects of zinc deficiency in diseases and in the relation with proteins or enzymes are extensive but our knowledge regarding the relationship between zinc deficiency and epigenetic dysregulation is still limited. Further basic and clinical investigation is necessary to better understand the roles of zinc and effects of its deficiency in epigenetic regulations. To summarize what we have discussed above, several points are listed as below: Zinc is an essential micronutrient element for health. Zinc deficiency is common in the developing countries and in the poor populations of the developed countries. The global prevalence of zinc deficiency is estimated by approximately 17.3%.
- MTR and BHMT are two key enzymes in the reaction of DNA methylation. Both are zinc dependent. Therefore, zinc deficiency leads to decreased DNA and chromatin methylation zinc finger proteins (ZFPs), mainly including Kaiso, ZBTB4, and ZBTB38, bind either methylated DNA in a sequence-specific manner or unmethylated consensus sequences. All these proteins are structured with a zinc finger, which is a small protein structural motif and characterized by the coordination of one or more zinc ions. Zinc deficiency may influence the function of ZFPs and subsequently result in epigenetic alteration.
- Zinc deficiency is found to induce inflammation response and subsequently cause epigenetic alteration in the genes encoded for inflammatory factors.
- Zinc transporters, including 9 members of SLC30 family and 15 members of SLC39 family in human play the important roles in regulating cellular zinc homeostasis. DNA methylation levels of these zinc transporter genes may be associated with dietary zinc deficiency.

Abstract

Studies in experimental animals and in groups of humans and epidemiological studies have shown that the sodium chloride or salt (sodium, Na, NaCl) plays an important role mainly in the regulation of blood pressure and represents an important environmental factor involved in the genesis of cardiovascular diseases. Therefore, salt intake in the population has been a constant concern. Variable blood pressure responses to different content in sodium intake are found in experimental hypertension models and in humans, and the reasons for such heterogeneity are not fully elucidated. The reduction of dietary sodium intake is recommended by public health as one of the non-medicated treatments for hypertension and consequently reducing the risk of cardiovascular diseases. However, some studies have demonstrated side effects of salt dietary restriction,

RAAS	Renin angiotensin aldosterone system

Introduction

High dietary intake of sodium associated with elevated blood pressure is a major risk factor for cardiovascular disease (He and MacGregor 2009; WHO 2007). The United Nations, World Health Organization, Centers for Disease Control and Prevention, and other organizations have emphasized the relationship between dietary sodium and cardiovascular outcomes (He and MacGregor 2002, 2003; Moher et al. 1999; Alderman et al. 1997).

Studies conducted in many countries observed that 99.2% of adult population have estimated mean levels of sodium intake exceeding the World Health Organization recommendation of 2.0 g per day of sodium, and 88.3% of adult population exceed this recommended level by more than 1.0 g per day of sodium. Figure 1 shows estimated cardiovascular death related to exceeding sodium intake by 2 g per day in many countries in the world.

Based on this evidence, a lower intake of dietary sodium is recommended, expecting a reduction in cardiovascular morbidity and mortality.

Evidence Between Sodium Intake Reduction and Blood Pressure

Over the past years, it has been published several population and trial studies from centers of many countries around the world, and they have shown the effects of reduced sodium intake on blood pressure (Graudal et al. 2012). Therefore, huge data are available to analysis and generate other important consistent information.

Studies from Global Burden of Diseases Nutrition and Chronic Diseases Expert Group (NUTRICODE) found strong evidence of a linear dose-response relationship

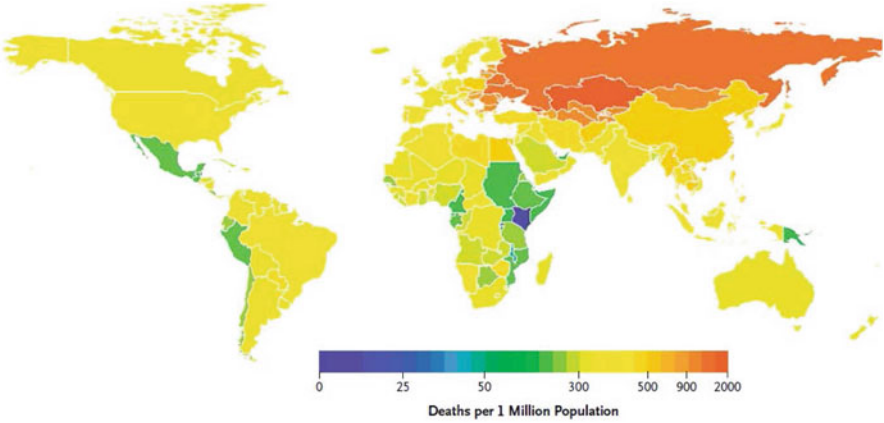

Fig. 1 Cardiovascular mortality (per one million of people) in each nation attributed to sodium consumption more than 2.0 g per day (Figure derived from Mozaffarian et al. 2014 Copyright © (2017) Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society)

between reduced sodium intake and blood pressure, where each reduction of 2.30 g of sodium per day was associated with a reduction of 3.82 mm Hg (95% confidence interval (CI), 3.08–4.55) in blood pressure (Fig. 2). They also observed that effects of reduction of sodium intake on blood pressure modify according to the population characteristics, for example, larger reduction on blood pressure among older than younger persons, among blacks than whites, and among hypertensive than normotensive persons. For a white and normotensive population of 50 years old, each reduction of 2.30 g per day in sodium intake lowered systolic blood pressure by 3.74 mm Hg (95% CI, 2.29–5.18). They did not find evidence of substantial blunting of the blood pressure-lowering effects of sodium restriction by antihypertensive drugs (Mozaffarian et al. 2014).

The evidence of a significant decrease in blood pressure of 1% (normotensive) and 3.5% (hypertensive) related to sodium reduction was demonstrated in randomized controlled trials allocating persons with normal or elevated BP irrespective of race and age to either a low- or a high-sodium diet and in which the sodium intake was estimated by the 24-h urinary sodium excretion (either measured on the basis of a 24-h urine collection or estimated from a sample of at least 8 h). However, this study also showed a significant increase in plasma renin, plasma aldosterone, plasma adrenaline, and plasma noradrenaline, a 2.5% increase in cholesterol, and a 7% increase in triglyceride. These biochemical changes usually correlate with reduction of sodium intake (Graudal et al. 2012).

In another study involving non-ill adult and children, a significant decrease of systolic and diastolic pressure levels with reduction of sodium intake was observed. Indeed, the decreased sodium intake had no significant adverse effect on blood lipids, catecholamine levels, or renal function in adults, a different result from the above study. Probably non-ill adult is less susceptive to sodium intake changes related to these biochemical parameters (Aburto et al. 2013).

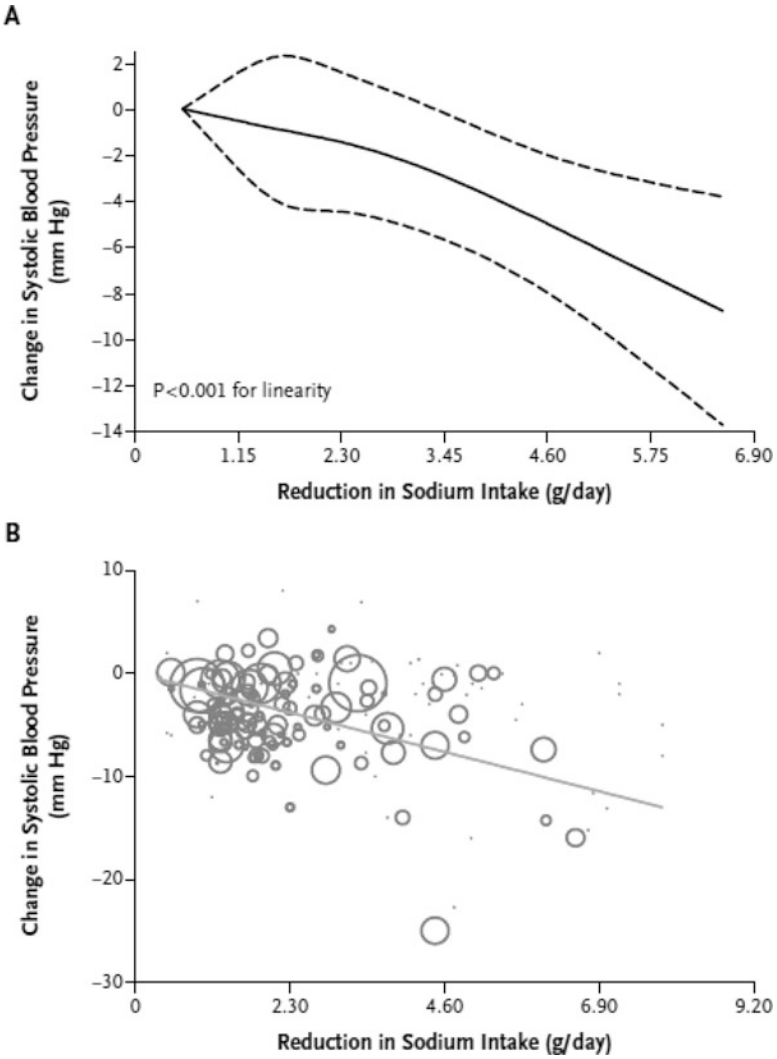

Fig. 2 Effects of sodium intake reduction on systolic blood pressure. Data are from 103 trials and included 6,970 persons. The reductions in sodium intake ranged from 0.53 to 6.56 g per day, the duration of the intervention ranged from 7 to 1,100 days, and the age of the participants ranged from 13 to 73 years. In (**a**) the effect of reduced sodium intake on systolic blood pressure was linear ($P < 0.001$ for linearity). The *solid line* represents the central estimate and the *dotted lines* the 95% confidence intervals [CIs]. The model is based on inverse-variance – weighted, restricted-cubic-spline regression adjusted for age, race, and presence or absence of hypertension. In (**b**) the inverse-variance is shown – weighted linear meta-regression. Each *circle* represents one randomized comparison of the intervention with the control group in each trial, and the size of the *circle* corresponds to its inverse-variance weight. The *fitted line* represents the effect of reduced sodium intake across all trials. Each reduction in sodium intake of 2.30 g (100 mmol) per day was associated with a reduction of 3.82 mm Hg (95% CI, 3.08–4.55) in systolic blood pressure (Graph derived from Mozaffarian et al. (2014) Copyright © (2017) Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society)

Effects of Sodium Intake Reduction on Cardiovascular Health and Kidney Disease

Most people with diabetes and chronic kidney disease (CKD) have hypertension characterized by enhanced sodium retention. Because blood pressure control is a key objective in management of diabetic kidney disease, antihypertensive agents, including angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, are used to treat hypertension. In addition, reducing dietary sodium is critical to optimize the effectiveness of medication used for blood pressure control (KDOQI 2007). Patients with CKD have diminished their capacity to excrete sodium more than those with normal kidney; due to this, the blood pressure of these patients is more sensitive to high sodium intake (Johnson et al. 2002).

Many studies have shown decrease on blood pressure following reduction on sodium intake; however, it is not possible to quantify promptly its effect on cardiovascular health and kidney disease because in order to obtain these data, a long-term follow-up of the patients is necessary. Usually, cohort studies are followed for the maximum of 10 or 15 years; the reduced sodium intake is not habitual for the general population, and then, this reduction does not stand longer enough to measure the cardiovascular morbidity and mortality. Due to these factors, it drives researchers to evaluate cardiovascular and kidney disease based on a median of sodium urine excretion of individual participants measured during the study.

The study, based on sodium urine 24 h excretion and corrected by urinary creatinine, found a continued decrease in cardiovascular disease (CVD) events among those with sodium levels as low as 1,500 mg per day. The risk reductions among those at the lowest levels of sodium excretion were substantial, with a 32% reduction among those excreting less than 2,300 mg per day (Cook et al. 2014).

A low-salt diet physiologically activates the RAAS in kidney and elsewhere (Ingert et al. 2002).

Short- and long-term effects with sodium intake reduction on efficacy of renin angiotensin aldosterone system (RAAS) blockade to reduce blood pressure and proteinuria in patients with hypertension and nondiabetic and diabetic chronic kidney disease are observed (Fig. 3) (Vogt et al. 2008; Slagman et al. 2011; Ekinci et al. 2009; Kwakernaak et al. 2014).

Recent reviews have pointed that data are reliable and enough to confirm the strong association between high sodium intake and cardiovascular and renal disease risk. Furthermore, the beneficial effects of dietary salt reduction on pressure-independent effects on the heart, blood, vessels and kidney are being increasingly recognized (Susic and Frohlich 2012). A prospective cohort study of patients with CKD and with follow-up from May 2003 to March 2013 observed that among patients with CKD, a higher urinary sodium excretion was associated with increased risk of CVD. These findings, if confirmed by clinical trials, suggest that moderate sodium reduction among patients with CKD and high sodium intake may lower CVD risk (Mills et al. 2016). In addition, there is a study which could propose a projection that modest reduction in dietary sodium will reduce substantially the cardiovascular events and medical costs and potentially be a public health target.

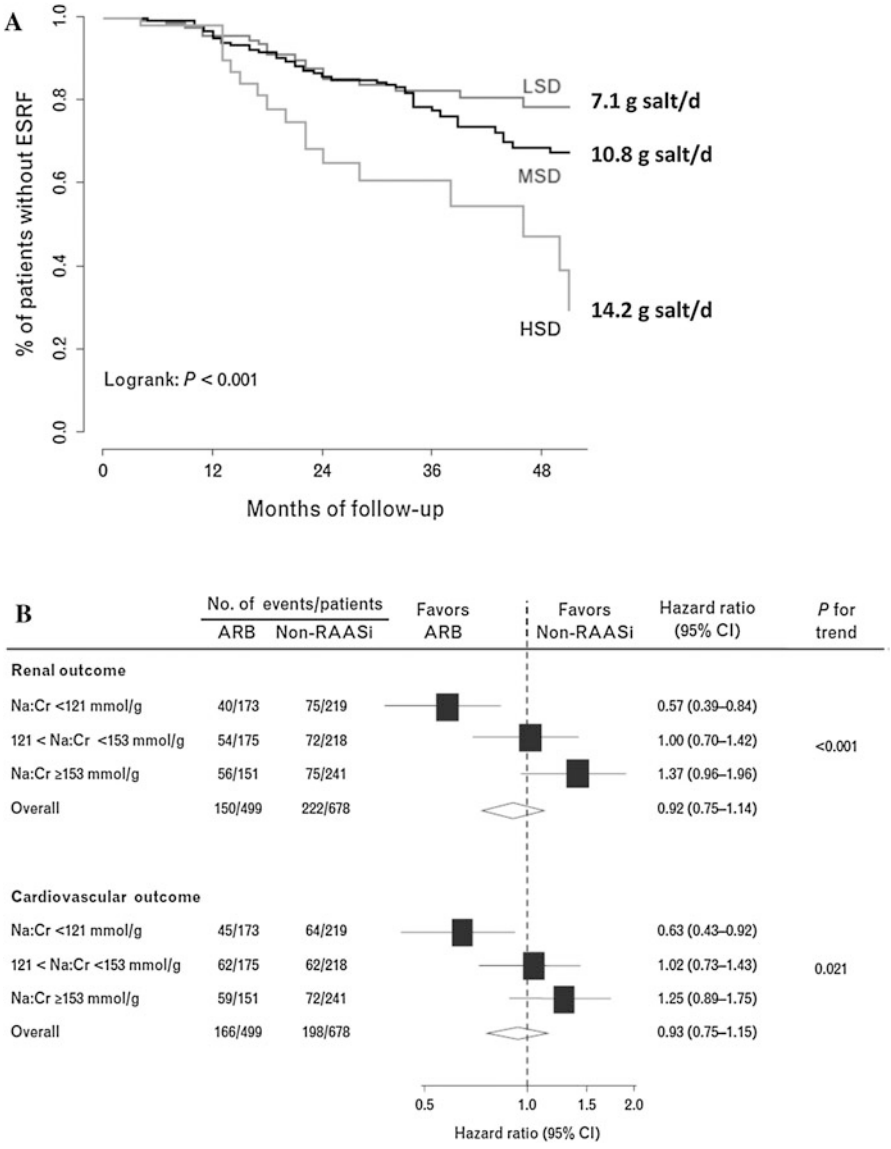

Fig. 3 Short- and long-term effects of sodium intake reduction. (**a**) End-stage renal failure (ESRF)-free survival according to high- (HSD), medium- (MSD), or low-sodium diet (LSD) in patients on angiotensin-converting enzyme inhibitor (ACEi) treatment, followed by 48 months. (**b**) Effect of sodium intake on renal and cardiovascular outcomes. *Na:Cr* sodium/creatinine, *ARB* angiotensin II receptor blocker, *Non-RAASi* non-renin angiotensin aldosterone inhibitor (Graph derived from Borst and Navis (2016) Copyright (2017), with permission from Elsevier)

They used the Coronary Heart Disease (CHD) Policy Model to quantify potentially achievable benefits in reducing dietary salt of up to 3 g per day (1,200 mg of sodium per day) on population-wide. They estimated the rates and costs of cardiovascular disease in subgroups defined by age, sex, and race; compared the effects of salt reduction with those of other interventions intended to reduce the risk of cardiovascular disease; and determined the cost-effectiveness of salt reduction as compared with the treatment of hypertension with medications (Fig. 4) (Bibbins-Domingo et al. 2010).

Negative Aspects of Reduction Sodium Intake

Although several studies have shown the benefits of reducing sodium intake on blood pressure and cardiovascular and kidney disease, there are some studies that demonstrate results with negative aspects of this intervention.

Some researchers are concerned about biochemical parameters, which are found increased in individuals submitted to reduction sodium intake. Renin angiotensin aldosterone activation and an increase in plasma adrenaline, noradrenaline, cholesterol, and triglyceride are observed and could interfere with blood pressure regulation and metabolic mechanism, contributing to the increase of cardiovascular risk (Graudal et al. 2012) and mortality (Cook et al. 2014).

Healthy subjects were submitted to low-sodium diet and high-sodium diet. After 7 days of low-/high-sodium diet, increased serum aldosterone, plasma renin activity, angiotensin II, and urine norepinephrine levels on individuals who received low-salt diet during 7 days compared to those that received 7 days of high-sodium diet are observed (Garg et al. 2011). The activated renin angiotensin aldosterone and sympathetic nervous systems were compared between low- and high-salt diet groups; however, it is not an adequate comparison because the sodium concentration of the high-sodium diet is extreme. Maybe, a plausible comparison of renin angiotensin aldosterone and sympathetic nervous systems activate would be between normal- and low-/high-sodium diet.

The increase of ANG II level is mainly to conserve sodium and regulates other natriuretic factors, including prostaglandins and bradykinin, under low-salt diet conditions (Kittikulsuth et al. 2012; Hocherl et al. 2002; Sivritas et al. 2008).

It is so important to pay attention at these findings because we still do not know the consequences of long-term sodium intake restriction in general population, considering people are accustomed to a high sodium intake for generations due to food industries, facility access to packaged and restaurant foods, etc.

In conclusion, high sodium intake is associated with high cardiovascular and kidney disease risk. However, the relation between low sodium intake and cardiovascular and kidney disease risk is not uniform and solid, because some are

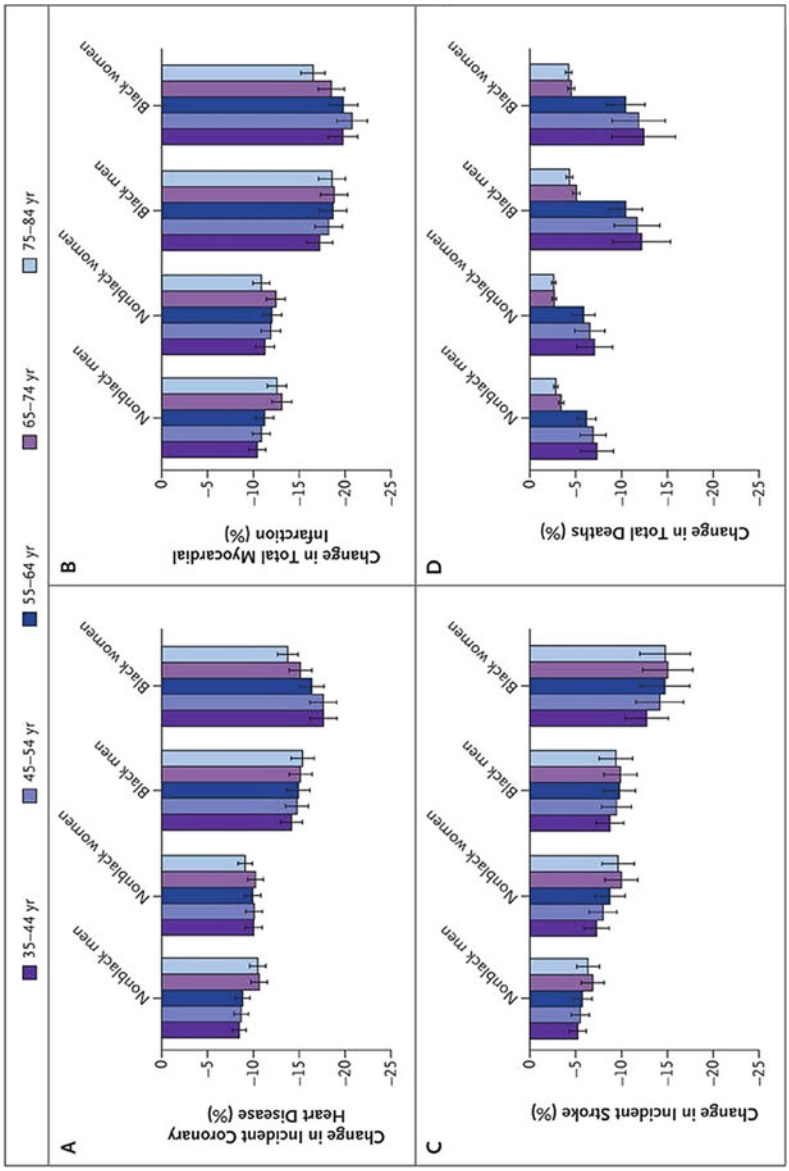

Fig. 4 (continued)

demonstrating awareness due to activation of renin angiotensin aldosterone and sympathetic nervous system and metabolic alteration; obstacle to decrease the sodium content from package food and restaurants is found; there is necessity of large public campaign.

Therefore, it will be interesting to program for long term to decrease little by little the sodium diet intake, until the minimum sodium intake related to low cardiovascular and kidney disease risk is reached.

Restriction of Salt from Childhood to Adulthood: Experimental Models

High sodium intake is associated with increased blood pressure levels in both normotensive and hypertensive individuals, as well as in laboratory animals. Likewise, lower intake of dietary sodium is related to a reduction in blood pressure levels. Persistent high blood pressure levels are associated with increased morbidity and mortality due cerebrovascular accident and coronary insufficiency. Several governmental organizations have recommend reduction of dietary salt intake. However, some changes in glucose, insulin, and lipid metabolism are found due to lower salt intake in the diet.

Decreased insulin sensitivity and lower glucose uptake are changes observed in animal models exposed to a low-sodium diet (0.06%) for 9 weeks compared to rats that received normal-sodium diet (0.50%) (Ruivo et al. 2006; Prada et al. 2000). In addition, animals submitted to salt restriction exhibited increased sympathetic nervous system activity and decreased nitric oxide-mediated vasodilatation (Ruivo et al. 2006). Also, it was observed that chronic salt restriction increased body weight and adipose tissue mass (Prada et al. 2000; Xavier et al. 2003; Okamoto et al. 2004). The decreased insulin sensitivity observed during chronic salt restriction is evidenced even when body weight is matched with animals fed with different salt contents (normal-salt and high-salt diet), suggesting that, in these animals, body weight is not a mechanism involved in insulin resistance.

It is well known that circulating renin angiotensin, a system is activated by low salt intake and plays an important role in blood pressure regulation, renal hemodynamics, fluid/electrolyte homeostasis, and cellular growth. In addition, angiotensin II is a well-characterized vasoconstrictor in systemic and uterine blood vessels.

Fig. 4 Annual projection of reduction in cardiovascular events defined a dietary salt reduction of 3 g per day (1,190 mg sodium) according to age group in nonblack men, nonblack women, black men, and black women. (**a**) shows changes in incident coronary heart disease, (**b**) changes in total myocardial infarctions, (**c**) changes in the incidence of stroke, and (**d**) changes in the rate of death from any cause. The projections were based on a reduction in dietary salt of 3 g per day (1,190 mg sodium) and on the high estimate for the effect of salt reduction on systolic blood pressure. Total myocardial infarction includes new and recurrent myocardial infarctions. I *bars* indicate standard errors of the Monte Carlo simulation (Graph derived from Bibbins-Domingo et al. (2010) Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society)

Rats fed with low-salt diet and treated with angiotensin-converting enzyme inhibitor (captopril) showed improvement in insulin sensitivity; however, treatment with angiotensin II AT1 receptor antagonist (losartan) did not change insulin sensitivity (Prada et al. 2000). The increased fasting blood glucose and plasma insulin levels and consequently the increase of HOMA-IR, which characterizes insulin resistance induced by low-salt restriction, are tissue-specific (Prada et al. 2005; Coelho et al. 2006). A possible mechanism by which low salt intake induces insulin resistance in the liver and muscle is through activation of protein JNK (protein kinase – c-jun N-terminal kinase) associated with a higher serine 307 phosphorylation of IRS-1 (insulin receptor substrate) (Prada et al. 2005). The likely mechanism for altering insulin signaling pathway in the liver and muscle is the higher serine 307 phosphorylation of the IRS-1 that is involved in inducing insulin resistance (Fig. 5). It is known that activation of the JNK protein induces IRS-1 serine 307 phosphorylation by blocking the interaction of the insulin receptor with its substrates and inhibiting the action of insulin in the cell (Aguirre et al. 2002).

Low-salt diet induced higher plasma concentrations of triacylglycerols and total cholesterol in Wistar rats, probably due to a 55% slower removal rate of triacylglycerols containing lipoproteins. Additionally low-salt diet increased plasma nonesterified fatty acid concentration, probably due to impaired lipoprotein lipase enzyme activity provoked by salt restriction (Catanozi et al. 2001). Similar finding was also demonstrated in LDL-receptor knockout mice and in apolipoprotein E knockout mice, indicating that low-salt diet elicits premature arterial lipid storage in hyperlipidemic normotensive animals. This finding leads to the speculation that low-

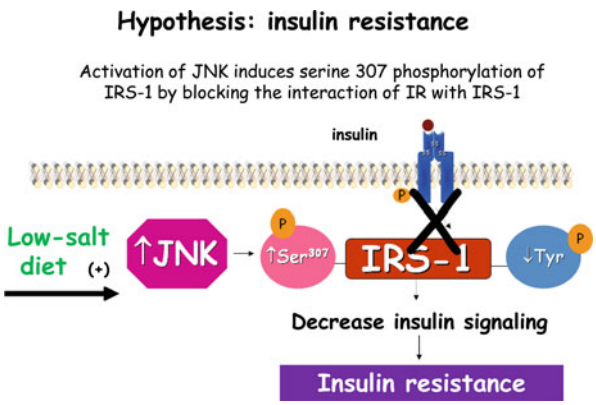

Fig. 5 Schematic representation of the molecular mechanism by which chronic salt restriction in the diet can induce insulin resistance in adult Wistar rats. The insulin receptor (IR) is a glycoprotein with intrinsic tyrosine kinase activity, and when activated by insulin, it autophosphorylates on tyrosine residues in the cytoplasmic domain. However, phosphorylation can occur on IR serine residues, which blocks the IR tyrosine kinase activity. The activation of the JNK protein may be one of the mechanisms of this block, since it stimulates IRS-1 serine 307 phosphorylation by decreasing the interaction of IR with its substrates and consequently impairing insulin signaling and contributing to insulin resistance

salt diet might have a greater impact on the development of atherosclerosis in hypertensive than normotensive animals (Catanozi et al. 2003). Recently, in a murine model of simultaneous hypertension and hyperlipidemia, the pleiotropic effect of chronic and severe sodium restriction (0.15% sodium chloride) elicited aortic damage even with reduced blood pressure. These negative effects on arterial wall were reduced by AT1 receptor antagonism, demonstrating the influence of angiotensin II in atherogenesis induced by a severely low-sodium diet (Fusco et al. 2017).

Salt Restriction During Pregnancy: Effects on Offspring

Many studies have demonstrated a link between the intrauterine environment and diseases in adult. The maternal diet is an essential factor for the health of offspring up to adulthood. Several experimental studies observed metabolic alterations on offspring at early after birth and at adulthood in response to maternal low-salt diet during pregnancy. These metabolic alterations depend on when maternal low-salt diet was administrated during the pregnancy. Sodium restriction during pregnancy induces low birth weight in both male and female offspring and alters lipid metabolism, and it is responsible for insulin resistance in adulthood offspring. Sexual dimorphism on some metabolic parameters is one of the consequences of maternal low-salt diet during pregnancy, and additional studies are necessary to clarify this phenomenon.

Wistar rats fed with low-salt diet (0.06% sodium – 0.15% NaCl) from the eighth week of life, during the gestational period until the end of lactation, showed an association between maternal sodium restriction diet and low birth weight of offspring and higher plasma levels of cholesterol and triacylglycerols in adulthood offspring (Vidonho et al. 2004). The insulin resistance that was observed in adulthood males, but not in female offspring, was assessed by hyperinsulinemic-euglycemic clamp method (Vidonho et al. 2004). In another study using the same experimental model described above, increased circulating leptin in males, while decreased in female adulthood offspring, and increased adiposity index only in female offspring were observed (Lopes et al. 2008). These data suggest that the level of dietary salt during intrauterine development can permanently alter mechanisms that regulate metabolism and body weight.

These effects might be related to the impact that sodium status has on hemodynamic and metabolic factors involved in uterine and placental perfusion, which has consequences for fetal nutrition. Although there were no significant changes in maternal food intake neither in uteroplacental blood flow, the placental and fetal weight were lower in response the maternal low salt intake during pregnancy. It was observed that inflammation and placental oxidative stress are not involved in the mechanisms of lower fetal and placental weights (Leandro et al. 2008).

There is evidence that low birth weight is due the low-salt diet intake during the second half of pregnancy that corresponds to the period of most rapid growth and

differentiation of key structures. One of the reasons that low-salt diet during pregnancy induces low birth weight appears to be an epigenetic mechanism. There is a negative correlation between low *Igf1* expression and high *Igf1* methylations levels in offspring with low birth weight (Siqueira et al. 2015).

The association between low birth weight and insulin resistance in adult offspring from mothers fed low-salt diet during gestation is related to maternal insult timing and the offspring's age as well as glucose intolerance (Siqueira et al. 2015). The amount of sodium consumed may alter glucose metabolism, while insulin concentrations or tissue sensitivity to this hormone may also interfere in the renal sodium control. The maternal low-salt diet intake during pregnancy does not modify the total renal volume, the volume of renal compartments, or the number of glomeruli in the newborns (Seravalli et al. 2016). However, when the maternal low-salt diet intake (0.07%) extends from gestation to lactation, the total number of glomeruli per kidney is lower in offspring with 1 and 12 weeks of age, probably due to a lower FGF-10 expression. Since removal of FGF-10 by knockout, the setting of GDNF signaling (Glial cell-derived neurotrophic factor vital for kidney development) stops kidney development.

In another experimental model, in which a maternal salt restriction of only 0.03% Na was given during the last 7 days of pregnancy, body, kidney, and cardiac ventricle weights were lower compared to the offspring of mothers fed with normal diet. At 12 weeks old, the body weight of the male offspring remained low, while high systolic blood pressure was present in both genders, starting at eighth week of age (Battista et al. 2002).

Unlike the maternal high-salt diet during pregnancy, which the transverse diameter of the nuclei of cardiomyocytes was higher in the left and right ventricles in the newborns, the maternal low-salt diet (0.06%) showed no cardiac and hemodynamic changes in the adult offspring even when they were submitted to high-salt diet in adult life (Seravalli et al. 2016; Alves-Rodrigues et al. 2013).

Therefore, maternal low-salt diet intake during pregnancy might have a protective effect on heart disease in adulthood. However, a lower expression of AT1 receptor in the kidneys and heart of males and lower renal expression of AT2 receptor in male and female offspring was shown.

Therefore, other studies are necessary to confirm if the observed results are reproducible in human beings in order to recommend low sodium level consumption during pregnancy.

Policies and Protocols

In this chapter we have described how dietary salt restriction is associated with metabolic and hemodynamic changes. The following protocols describe in detail the time, period, and diet concentration of salt in Wistar rats.

Male Wistar rats were fed a low-salt diet (0.06% Na or 0.15% NaCl), normal-salt diet (0.5% Na or 1.3% NaCl), and high-salt diet (3.12% Na or 7.94% NaCl) from weaning (3 weeks old) to adulthood (12 weeks old), in total 9 weeks of low-salt

dietary intake. All diets had 25% protein content and the only difference between the three diets was their sodium content. All animals were housed in a room with a controlled temperature and a 12 h light/dark cycle (with the lights on from 7 AM to 7 PM). They were given free access to food and water.

The maternal low-salt diet was also intake during pregnancy and lactation, and the offspring were studied after birth (first day of birth) or adulthood (12 weeks old). Twelve-week-old female Wistar rats were fed a low-salt (LS – 0.15% NaCl) or normal-salt (NS – 1.3% NaCl) diet during gestation (from first day of gestation until delivery) or a LS diet during either the first (LS10) or second (LS20) half of gestation.

Dictionary of Terms

- **Sodium urine 24-h excretion** – Urine collection for 24 h. Sodium from the diet is eliminated by the kidneys being excreted in varying daily amounts of 1–150 mEq, depending on the intake and total body sodium. Sodium is freely filtered by the glomeruli, and about 60% is reabsorbed in the proximal tubule. Sodium reabsorption also occurs along other segments of the nephrons. Urinary sodium dosage is important for the evaluation of hyponatremia due to renal loss (polycystic kidneys, proximal tubular acidosis), pre-renal, and renal oliguria. Indications: evaluation of hydroelectrolytic and basic acid disorders and differential diagnosis between pre-renal and renal oliguria. Clinical interpretation: increased urinary levels are found in adrenal insufficiency, salt-losing nephritis, and excessive sodium content in the diets, renal tubular acidosis, use of diuretics, and syndrome of inappropriate diuretic hormone secretion. Decreased urinary levels may exist in dehydration, congestive heart failure, liver disease, and nephrotic syndrome, situations that lead to a decrease in the glomerular filtration rate and in diets low in sodium.
- **Renin angiotensin aldosterone system (RAAS) –** Is closely related to the control of blood pressure and the regulation of the hydroelectrolyte balance. However, in the last decades, the alteration of the RAAS has been considered the main factor related to the development and the progression of diverse cardiovascular pathologies. The classic view of RAAS begins with the release of angiotensinogen from the liver, which undergoes the enzymatic action of renin, a proteolytic enzyme, secreted under conditions of hypotension and hypovolemia, originating the angiotensin I, which is then cleaved by the angiotensin-converting enzyme (ACE) in an octapeptide, angiotensin II (Ang II). The main physiological effects triggered by RAAS, such as vasoconstriction, synthesis and release of aldosterone, release of catecholamines, and control of water intake, cell proliferation, cardiac hypertrophy, oxidative stress, and inflammation, are mainly due to the classic actions of Ang II, through stimulation of the AT 1 receptor.
- **Angiotensin II** – Ang II is one of the main effector products of RAAS, which in turn plays its role through its angiotensin receptors, called AT1r and AT2r.

- **AT1 receptor** – AT1 is a G protein-coupled receptor responsible for triggering the activation of various intracellular signaling pathways, including phospholipase C, phospholipase D, phospholipase A2, adenylyl cyclase, ion channels, and others.
- **AT2 receptor** – The AT2 receptor, which is also a G protein-coupled receptor, induces vasodilation, inhibition of cardiomyocyte growth, inhibition of fibroblast proliferation, and extracellular matrix synthesis. Although the AT 2 receptor is highly expressed during fetal period, some pathological conditions increase its expression in the heart, such as ischemia, cardiac hypertrophy, hypertension, and heart failure.

Summary Points

- 99.2% of the adult population in the world have estimated mean levels of sodium intake exceeding the World Health Organization recommendation of 2.0 g per day of sodium.
- The reduction of sodium intake is recommended for the purpose of decrease cardiovascular morbidity and mortality.
- The evidence of a significant decrease in blood pressure of 1% (normotensive) and 3.5% (hypertensive) related to sodium reduction was demonstrated in randomized controlled trials.
- The reduction of sodium usually correlates with a significant increase in plasma renin, plasma aldosterone, plasma adrenaline, and plasma noradrenaline, a 2.5% increase in cholesterol, and a 7.0% increase in triglyceride.
- Systolic and diastolic pressure levels decrease significantly with reduction of sodium intake.
- Short- and long-term effects with sodium intake reduction on efficacy of RAAS blockade to reduce blood pressure and proteinuria in patients with hypertension are observed.
- There is a projection that modest reduction in dietary sodium will reduce substantially the cardiovascular events and medical costs.
- Some changes are found due to lower salt intake in the diet, such as glucose, insulin, and lipid metabolism.
- The low-salt diet induces to high plasma concentrations of triacylglycerols and total cholesterol in Wistar rats.
- Sodium restriction during pregnancy induces low birth weight in male and female offspring and alters lipid metabolism, and it is responsible for insulin resistance in adulthood offspring.

Modeling Systems, Cellular and Molecular Effects

The Role of the Central Nervous System in the Reduction of Food Intake During Infectious and Neoplastic Disease and in Eating Disorders: Experimental Approaches

104

Jan Pieter Konsman

Contents

Abstract

According to fixed set point models of energy balance, food intake increases when the organism is losing weight and decreases when it is gaining weight. Concomitantly reduced food intake and increased energy expenditure during infectious and neoplastic disease and in some eating disorders thus seem to contradict such models. Reduced food intake in infectious and neoplastic disease and anorexia nervosa may represent initially adaptive responses contributing to the organism's survival, even though chronically decreased food intake and increased energy expenditure lead to denutrition. The identification of cytokines and hormones mediating and the activation of brain structures in

situations of concomitant reduced food intake and increased energy expenditure suggest that these are actively put in place by the organism. Furthermore, lesions or inhibition of some of the activated cerebral structures and pathways alleviate reduced food intake in animal models of infectious and neoplastic disease and anorexia nervosa. Thus, organisms seem capable of defending several set points, rather than just one fixed set point, of energy balance.

Introduction

The Lipostat Model of Food Intake and Body Weight Regulation

Although the glucostat and lipostat hypotheses of energy balance differ relative to what variable is detected by the central nervous system, they both propose that a "defended" set point maintains the organism's energy balance. Accordingly, food intake should increase when the organism is losing weight and, conversely, decrease when it is gaining weight. The discovery of the fat-derived hormone leptin that reduces food intake and is lacking in genetically obese mice (Zhang et al. 1994; Campfield et al. 1995) corroborated the lipostat hypothesis. Interestingly, leptin receptors are present on neuropeptide Y- and melanocortin-containing neurons of the arcuate hypothalamus (Hakansson et al. 1998), known to respectively stimulate and reduce food intake (Levine and Morley 1984; Fan et al. 1997). Thus, the identification of peripheral hormones and hypothalamic mechanisms that can be considered a feedback signal and output generator, respectively, has probably reinforced the idea that energy balance is regulated in function of a fixed set point.

Anorexia Can be Accompanied by Increased Energy Expenditure

The relationships between food and water intake, body weight and composition, and thermogenesis provide some test cases for fixed set point theories of energy balance.

Intraperitoneal administration of so-called endotoxin bacterial lipopolysaccharide (LPS) reduces food intake and body weight irrespectively of whether water was applied into the stomach (Miller et al. 1962). Moreover, treatment with sodium salicylate was found, as expected, to alleviate fever, but not the suppression of food intake after LPS administration (Mccarthy et al. 1984). These findings provide evidence against the idea that a reduction in food intake during infection would simply occur as a consequence of lower water intake or increased body temperature. However, mounting a fever response does require an increase in energy expenditure for organisms (Jennings and Elia 1987; Cooper et al. 1992). Since clinical data also report the cooccurrence of fever and loss of appetite in many infectious diseases (Gelston and Jones 1977; Mok et al. 1979; Pereira and Begum 1987), bacterial LPS-induced thermogenesis and reduced food intake seem to model nonspecific symptoms of infectious disease.

Reduced food intake and catabolism, reminiscent of what is observed in bacterial sepsis, but different from simple starvation in that body protein is not preserved, can be encountered in cancer denutrition or cachexia (Brennan 1977; Van Eys 1985). The cancer-associated anorexia-cachexia syndrome accounts for 10–30% of cancer deaths and complicates treatments (Inagaki et al. 1974; Dewys 1979; Theologides 1979). Interestingly, cancer-associated anorexia-cachexia can be reproduced in animals without chemo- or radiotherapy (Morrison 1974; Garattini et al. 1980) indicating that host-tumor interactions are sufficient to induce it.

In addition, reduced food intake "occurs in association with incubation, migration, molting, and hibernation, even though food is sometimes readily available" (Mrosovsky and Sherry 1980). Among these "animal anorexias," "activity-based anorexia" and "food restriction-induced hyperactivity" have been the subject of intense study (Pierce et al. 1986; Broocks et al. 1990). In these experimental paradigms, rodents with free access to food engage in wheel running that is covered for by energy intake, whereas animals for which access to food is limited in time show excessive running resulting in denutrition. Since increased physical activity occurs in 30–80% of anorexia nervosa patients (Davis et al. 1994) and food restriction in these patients is a factor contributing to increased physical activity (Holtkamp et al. 2004), these paradigms have been proposed as animal models of anorexia nervosa (Siegfried et al. 2003) So, during infectious and neoplastic disease and in some eating disorders, as well as in animal models of these conditions, increased energy expenditure is accompanied by reduced food intake in normal-weighted or weight-losing individuals.

Reduced Food Intake as a Biological Response

Potential Adaptive Value of Reduced Food Intake

The cooccurrence of increased energy expenditure and reduced food intake during infection and cancer as well as in some eating disorders can easily lead to the conclusion that these are due to dysfunctioning set point mechanisms. However,

both field observations and experimental work indicate that feeding during infection can be harmful and increases mortality while prior starvation decreases mortality (Murray and Murray 1979; Wing and Young 1980). Interestingly, intravenous or intragastric feeding of anorectic tumor-bearing rats also increases tumor growth and mortality (Cameron and Pavlat 1976; Cameron et al. 1979). Anorexia during infection and cancer has been proposed to favor host survival by eliminating infected or transformed host cells (Legrand 2000). Indeed, in a mouse model of intestinal neoplasia food restriction limits polyp growth and increases apoptosis (Kakuni et al. 2002). Moreover, food restriction eliminates preneoplastic cells through apoptosis in a drug-induced animal of liver cancer (Grasl-Kraupp et al. 1994). Interestingly, recent research indicates that reduced food intake improves host survival in response to bacterial inoculation and administration of bacterial LPS, but not after exposure to influenza virus, by protecting host tissues against the effects immune cell-mediated production of reactive oxygen species (Wang et al. 2016). Thus, bacterial infection-associated reduced food intake would allow host tissues to tolerate free radical stress better than bacteria.

The exercising subtype of anorexia nervosa has been proposed to reflect an evolutionary ancient response to flee famine or nutrient-poor or nutrient-depleted environments (Guisinger 2003). Accordingly, the encounter of energy-rich sources should reduce locomotor activity and stimulate intake. Testing of this hypothesis by providing energy-rich sucrose or equally sweet energy-free saccharine to food-restricted rats with access to a running wheel showed indeed that animals increase their sucrose intake, which, in turn, prevents hyperactivity and weight loss (Duclos et al. 2013).

Peripheral Signals Reducing Food Intake and Increasing Energy Expenditure in Nonoverweight Animals

For reduced food intake and increased energy expenditure to be considered biological responses, endogenous mediators and mechanisms need to be identified. Phagocytosis of bacteria promotes "the release of endogenous pyrogen from leukocytes" (Berlin et al. 1964), which, in turn, causes a negative nutrient balance during infection (Powanda and Beisel 1982). Indeed, this "endogenous pyrogen" coined Interleukin-1beta (IL-1beta) both induces fever and reduces food intake (Mccarthy et al. 1995). Conversely, peripheral administration of the naturally occurring Interleukin-1 receptor antagonist alleviates fever (Smith and Kluger 1992; Luheshi et al. 1996) and attenuates the reduction in food intake and body weight after bacterial LPS injection in rodents (Bluthé et al. 1992; Swiergiel et al. 1997). The available literature thus clearly supports the idea that IL-1 is an endogenous mediator of fever and reduced food intake after exposure of host tissues to bacterial LPS.

Based on their anorectic and catabolic properties, IL-1 and its functionally related, but structurally different, Tumor Necrosis Factor-alpha (TNFalpha), initially known as cachectin, have been proposed to play a role in cancer-associated anorexia-cachexia (Moldawer et al. 1987). Indeed, TNFalpha activity was found to

be increased in the serum of cachectic sarcoma-bearing rats (Stovroff et al. 1989). Moreover, neutralizing TNF action increases food intake in weight-losing sarcoma-bearing Fischer 344 rats (Smith et al. 1993; Torelli et al. 1999). Although some studies have shown a slight benefit of TNF-blocking strategies in cancer patients, these were found to be ineffective against anorexia and weight loss in advanced disease (Dezube et al. 1993; Eisen et al. 2000; Jatoi et al. 2007).

However, in autologous animal models, such as Morris hepatoma in Buffalo rats, and in many patients with cancer-associated anorexia increased plasma concentrations of IL-1beta or TNFalpha have not been observed (Ruud and Blomqvist 2007; Pourtau et al. 2011; Ezeoke and Morley 2015). Other cytokines, such as Macrophage Inhibitory Cytokine-1 (MIC-1), may play a role in cancer anorexia. Increased MIC-1 expression is found in cancer cells and in serum in many aggressive cancers (Mimeault and Batra 2010). This cytokine not only stimulates tumor growth and modulates immune responses (Mitchell and Bucala 2000; Candido and Hagemann 2013) but also constitutes an endogenous regulator of food intake as mice genetically deficient in MIC-1 display increased food intake and become obese (Tsai et al. 2013). Interestingly, MIC-1 serum concentrations correlate with prostate cancer-associated anorexia-cachexia and administration of a MIC-1 antiserum attenuates the reduction in food intake induced by xenografts of prostrate cancer in immunodeficient mice (Johnen et al. 2007). In addition, during autologous tumor growth in immunocompetent animals increased MIC-1 plasma concentrations correlate negatively with food intake (Borner et al. 2016a). Tumor-derived MIC-1 thus seems to constitute a mediator of cancer-associated anorexia.

Several tumors, including the Morris hepatoma 7777, that reduce food intake in rat produce the anorectic cytokine-like hormone leptin (Howard et al. 2010; Pourtau et al. 2011). In the Morris hepatoma model, plasma leptin levels in anorectic tumor-bearing rats are lower than in free-feeding tumor-free animals, but still higher than in food-restricted weight-matched animals (Pourtau et al. 2011). Interestingly, circulating concentrations of the orexigenic hormone ghrelin display the exact inverse relationships (Pourtau et al. 2011). So, in cancer-associated anorexia increased concentrations of anorectic mediators such as MIC-1 can be observed along with the absence of the expected leptin and ghrelin responses to weight loss.

Even though ghrelin administration alleviates cancer-associated anorexia in the Morris hepatoma model (Borner et al. 2016b), cachectic animals bearing other tumors seem less sensitive to its appetite-stimulating effects (Wang et al. 2006; Chance et al. 2008). Moreover, the ghrelin agonist anamorelin increases lean body mass, but not handgrip strength, in patients with advanced non-small-cell lung cancer (Garcia et al. 2015; Temel et al. 2016). Ghrelin administration may therefore alleviate some aspects of cancer-associated anorexia, but its impact on patient functioning remains to be established.

Anorexia nervosa is accompanied by increased cortisol concentrations, which are associated with physical activity (Walsh et al. 1978; Klein et al. 2007). In the activity-based anorexia animal model, corticosterone is synergistically increased by food restriction, and exercise and has been proposed to contribute to body weight loss and suppression of food intake (Broocks et al. 1990; Burden et al. 1993).

Moreover, in rat lines known to differ in hypothalamic-pituitary-adrenal axis (re) activity, higher food restriction-induced hyperactivity was associated with increased prefeeding corticosterone levels (Duclos et al. 2005). Finally, hyperactivity during food restriction is suppressed by adrenalectomy and restored by acute administration of corticosterone (Duclos et al. 2009). Thus, increased corticosterone plays an important role in food-restriction-induced hyperactivity. Leptin concentrations are low in anorexia nervosa patients, as well as in animals displaying food restriction-induced hyperactivity, and correlate negatively with physical activity (Exner et al. 2000; Frey et al. 2000; Holtkamp et al. 2003). These observations, along with the finding that leptin treatment can reduce food restriction-induced hyperactivity (Exner et al. 2000), have led some authors to call for clinical trials evaluating leptin treatment of anorexia nervosa (Hebebrand and Albayrak 2012). So, in animal models of infectious and neoplastic disease and eating disorders, host mediators have been identified that reduce food intake and increase energy expenditure.

Brain Structures Activated During Concomitantly Reduced Food Intake and Increased Energy Expenditure in Nonoverweight Individuals

The activation of common brain structures during reduced food intake and increased energy in infectious and neoplastic disease and eating disorders provides additional weight to the idea that these symptoms are actively put in place rather than being due to a loss of function. While noninvasive functional neuroimaging techniques, such as deoxyglucose Positron Emission Tomography (PET) and blood oxygen-level dependent Magnetic Resonance Imaging (MRI) are employed in humans, postmortem detection of the transcription factor c-Fos has often been used in animals to assess activation of brain structures. c-Fos mRNA and protein expression peak, respectively, around 30 and 120 min after exposure to the excitatory neurotransmitter glutamate, growth factors or increases in intracellular calcium, thus making it a suitable cellular marker for transcription activation (Morgan and Curran 1990).

Several patterns of c-Fos induction are observed after intraperitoneal IL-1beta or LPS administration in rodents (Fig. 1). The first, 1–2 h after injection, includes midline brainstem structures, the paraventricular and preoptic hypothalamus, and the central amygdala (Brady et al. 1994; Konsman et al. 1999). Between 3 and 8 hours after IL-1beta or LPS administration c-Fos expression in these structures is accompanied by a wave of induction in brain circumventricular organs, such as the area postrema and median eminence that lack a functional blood-brain barrier. From these organs labeling seems to spread to adjacent brain structures, for example, the arcuate nucleus of the hypothalamus (Brady et al. 1994; Konsman et al. 1999). In addition, increased c-Fos expression is observed in the nucleus accumbens in the ventral striatum during this time window after peripheral LPS administration (Frenois et al. 2007).

Human brain imaging approaches lack the cellular resolution of c-Fos studies in animals and reveal metabolic rather than transcription activation. In spite of these differences, human brain imaging studies indicate activation of some brain structures

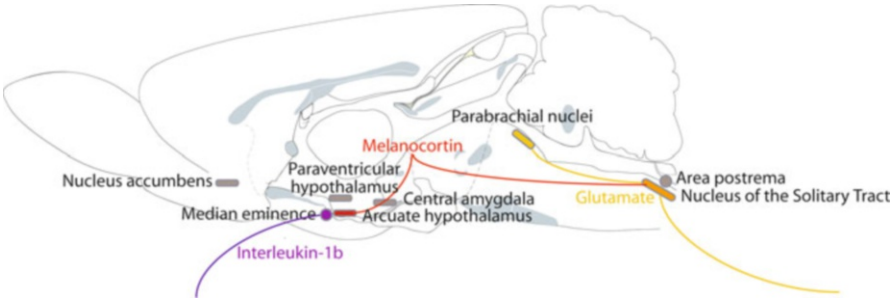

Fig. 1 Brain circuits associated with bacterial lipopolysaccharide-induced reduced food intake. Peripheral administration of bacterial lippolysaccharides results in the rapid systemic production of the pro-inflammatory cytokine Interleukin-1beta and induction of the cellular activation marker c-Fos in, among other structures, the brainstem nucleus of the solitary tract and parabrachial nuclei, the paraventricular hypothalamus, and the central amygdala as compared to saline injections. At later points, the area postrema, the arcuate nucleus of the hypothalamus, and the nucleus accumbens also show increased c-Fos expression. Brainstem glutamate-producing and brain melanocortin-containing circuits underlie early and sustained reduced food intake, respectively. Colors indicate different peripheral and central pathways reducing food intake

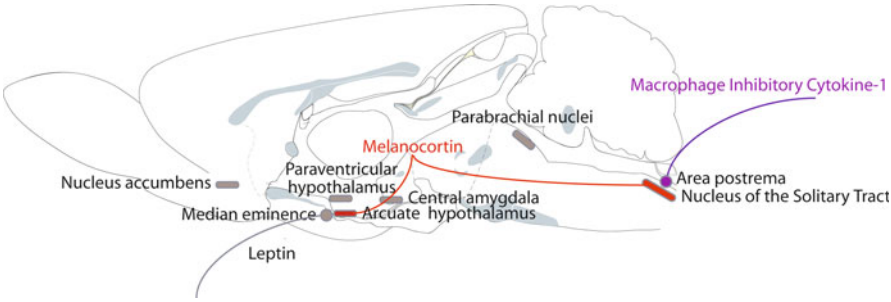

Fig. 2 Brain circuits associated with tumor-induced reduced food intake. Peripheral inoculation of tumor cells in rodents results in higher circulating leptin concentration, the systemic production of the macrophage inhibitory cytokine-1 and induction of the cellular activation marker Fos in, among other structures, the brainstem nucleus of the solitary tract, area postrema and parabrachial nuclei, the arcuate and paraventricular hypothalamus, the central amygdala, and nucleus accumbens as compared to food-restricted and free-feeding controls. Brain melanocortin-containing circuits play a role in reducing food intake. Colors indicate different peripheral and central pathways reducing food intake

that also showed increased c-Fos expression in animals after peripheral LPS administration. Indeed, volunteers receiving low doses of intravenous LPS show increased glucose and oxygen consumption in the pons and amygdala (Hannestad et al. 2012; Harrison et al. 2013; Labrenz et al. 2016). In addition, these human brain imaging studies have shown LPS-induced increases in metabolic activity in the cingulate and insular cortices (Hannestad et al. 2012; Harrison et al. 2013; Labrenz et al. 2016).

The pattern of c-Fos expression obtained during cancer-associated anorexia in the Morris hepatoma rat model (Fig. 2) is in part reminiscent of that observed after LPS

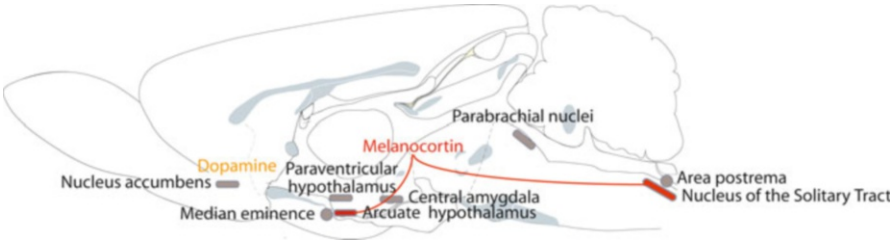

Fig. 3 Brain circuits associated with activity-based reduced food intake. Activity-based anorexia and food-restriction-induced hyperactivity paradigms result in increased c-Fos expression in, among other structures, the nucleus of the solitary tract; arcuate, supraoptic, and paraventricular hypothalamus; and nucleus accumbens. Dopamine-producing and melanocortin-containing circuits underlie reduced food intake in these paradigms. Colors indicate different peripheral and central pathways reducing food intake

injection (Konsman and Blomqvist 2005; Ruud and Blomqvist 2007). Interestingly, oxygen extraction measured by MRI was also found to be higher in the hypothalamus of lung cancer patients than that of healthy controls, but lower in anorexic compared to nonanorexic patients (Molfino et al. 2016). The distribution of c-Fos in the brains of rodents that display food restriction-induced hyperactivity or activity based anorexia (Fig. 3) also shows overlap with that observed after systemic LPS injection (Duclos et al. 2013; Scharner et al. 2016). Using PET imaging, striatal structures showed reduced glucose consumption in the activity-based anorexia animal model, but increased glucose consumption in anorexia nervosa patients (Herholz et al. 1987; Delvenne et al. 1999; Van Kuyck et al. 2007). So, in different animal models of concomitant decreased food intake and increased energy expenditure the same brainstem, hypothalamic, and ventral striatal structures display increased expression of the cellular activation marker c-Fos. Unfortunately, it is at present impossible to determine if the same structures are also activated in the clinical conditions these animal models are supposed to mimic as human brain imaging studies using different modalities.

Brain Circuits Mediating Reduced Food Intake and Increased Energy Expenditure

The brainstem mediates short-term regulation of food intake and activation of brainstem glutamatergic projections from the nucleus of the solitary tract to the parabrachial nuclei reduce food intake (Wu et al. 2012). We have shown that brainstem metabotropic glutamate receptor antagonism attenuates hypophagia and increases food intake after peripheral LPS injection to a greater extent than in vehicle-treated animals (Chaskiel et al. 2016). In parallel, intrafourth ventricle administration of the metabotropic glutamate receptor antagonist also reduces c-Fos expression in the nucleus of the solitary tract and lateral parabrachial nuclei (Chaskiel et al. 2016). These findings suggest that brainstem glutamatergic circuits

are part of the neuronal substrates that rapidly reduce food intake under inflammatory conditions (Fig. 1), but also negatively regulate food consumption in the absence of sickness.

In the hypothalamus, the arcuate nucleus expresses IL-1 receptors (Ericsson et al. 1995). Interestingly, neonatal excitotoxic lesions of arcuate neuropeptide Y/Agouti-related protein and proopiomelanocortin arcuate neurons exacerbate IL-1beta-induced hypophagia (Reyes and Sawchenko 2002). However, only part of the arcuate neuropeptide Y/Agouti-related protein containing neurons and none of the proopiomelanocortin-expressing neurons express IL-1 receptors (Scarlett et al. 2008; Chaskiel et al. 2014). But, even though proopiomelanocortin arcuate neurons do not express IL-1 receptors, central melanocortin antagonism has been found to attenuate hypophagia from 8 h onwards after the peripheral administration of either IL-1beta or LPS (Fig. 1) (Huang et al. 1999; Whitaker and Reyes 2008). In addition, our recent findings show that lesioning of arcuate IL-1 receptor-expressing cells alleviates the reduction in food intake after peripheral IL-1beta injection (Chaskiel et al. 2014). Therefore, besides the activation of brainstem glutamatergic projections between the nucleus of the solitary tract and the parabrachial nuclei mediating hypophagia after peripheral LPS injection, neurons in the arcuate nucleus of the hypothalamus seem to be target of systemic IL-1beta to reduce food intake.

The nucleus of the solitary tract and pontine parabrachial nuclei receive, among other sources, input from neurons in the area postrema, the brainstem circumventricular organ lacking a functional blood-brain barrier. Although lesions of the area postrema do not attenuate the reduction in food intake observed after LPS administration (Weingarten et al. 1993), its removal does alleviate cancer-associated anorexia in two rodent tumor models (Bernstein et al. 1985; Borner et al. 2016a). As neurons containing anorexigenic and catabolis melanocortins are present both in the brainstem nucleus of the solitary tract and hypothalamic arcuate nucleus, it is of interest to test their implication in cancer-associated anoxia cachexia. Several studies have shown that central administration of the endogenous melanocortin antagonist Agouti-related Protein or that of a synthetic antagonist attenuates anorexia and weight loss in experimental cancer models (Marks et al. 2001; Wisse et al. 2001). So, activation of brain circumventricular organs and melanocortin pathways plays an important role in cancer-associated anorexia (Fig. 2).

In the case of activity-based anorexia, central administration of Agouti-related Protein also increases food intake and decreases physical activity (Hillebrand et al. 2006). In addition, antagonizing dopaminergic neurotransmitter pathways also increases food intake and reduces physical activity in activity-based anorexia (Verhagen et al. 2009; Klenotich et al. 2015), whereas inhibition of serotinergic transmission lowers physical activity without improving food intake (Atchley and Eckel 2006; Klenotich et al. 2012). However, the selective serotonin reuptake inhibitor fluoxetine, but not the less serotonin-selective reuptake inhibitor imipramine, attenuates the reduction in food intake and the development of hyperactivity in acidity-based anorexia (Altemus et al. 1996). These findings indicate that CNS melanocortin and dopamine pathways mediate activity-based anorexia (Fig. 3),

whereas the exact role of serotonin remains to be elucidated. There is thus ample evidence to suggest that the activation of specific brain structures reduce food intake in different animal models of infectious and neoplastic disease or eating disorders. Although some brain pathways may be specific to a single condition, activation of melanocortin neurons seems to contribute to the reduction of food intake in several conditions of reduced food intake and increased energy expenditure in normal-weighted or weight-losing individuals.

Conclusion

Situations of concomitant reduced food intake and increased energy expenditure observed during infectious and neoplastic disease as well as in some eating disorders seem to contradict a fixed set point hypothesis of energy balance. Reduced food intake in infectious and neoplastic disease and anorexia nervosa may represent initially adaptive responses contributing to the organism's survival, even though chronically decreased food intake and increased energy expenditure lead to denutrition. The identification of cytokines and hormones mediating and the activation of common set of brain structures in these different situations of concomitant reduced food intake and increased energy expenditure suggest that these responses are actively put in place by the organism. Furthermore, lesions or inhibition of some of the activated brain structures and pathways alleviate reduced food intake in animal models of infectious and neoplastic disease and anorexia nervosa. Thus, organisms seem capable of defending several set points, rather than just one fixed set point, of energy balance.

Dictionary of Terms

- **Brainstem** – Ventrocaudal part of the animal brain that includes the midbrain, the pons, and the medulla, the latter of which controls respiration, heart rhythm, and blood glucose
- **Hypothalamus** – Ventromedian part of the animal brain containing "controllers" for thermoregulatory, ingestive, reproductive, and defensive behaviors
- **Neoplastic** – Pertaining to a tumorous condition or tumor formation

Summary Points

- Reduced food intake contributes to survival in experimental models of infection and cancer.
- Reduced intake of scarce energy-low food along with increased activity may favor the discovery of new energy-rich nutrients.
- Cytokines play an important role in reducing food intake in animal models of infection and cancer.

- Corticosteroids have been proposed to play a role in activity-based anorexia and mediate food restriction-induced hyperactivity in animals.
- The same brainstem and hypothalamic structures show increased expression of the cellular activation marker c-Fos in animal models of infection, cancer, and anorexia nervosa.
- Activation of brain melanocortin pathways contributes to the reduction of food intake in animal models of infection, cancer, and anorexia nervosa.

Abstract

Autophagy, a catabolic pathway that degrades cellular components not needed by or harmful to cells, enables nutrient recycling and is critical for cell survival in starvation conditions. Starvation-triggered signals, including diverse protein-protein interactions and numerous posttranslational modifications, modulate autophagy, and many of these signals regulate the vacuolar protein sorting (VPS34) complexes responsible for key stages of autophagy. Autophagy plays a major role in numerous human diseases including cancers, neurodegenerative diseases, heart diseases, and infectious diseases. Therefore, substantial ongoing research focuses on developing therapeutic methods to modulate autophagy. Short-term starvation may constitute a readily accessible mechanism to induce autophagy.

Keywords

Starvation · Autophagy · VPS34/PI3KC3 · BECN1/Beclin 1/VPS30/ATG6 · ATG14 · VPS38/UVRAG · VPS15/p150 · Posttranslational modification · Protein-protein interaction · Cancer · Neurodegenerative diseases · Heart diseases · Longevity

List of Abbreviations

ADP	Adenosine diphosphate
AMBRA1	Activating molecule in BECN1 regulating autophagy 1
AMP	Adenosine monophosphate
AMPK	AMP-associated protein kinase
ATG	Autophagy related protein
ATP	Adenosine triphosphate
BARAD	β-α repeated autophagy-specific domain
BATS	BARKOR/ATG14 autophagosome targeting sequence
BCL2	B-cell lymphoma 2
BECLIN 1/BECN1	BCL2-interacting, coiled-coil protein
BH3D	BCL2 homology 3 domain
BIF1	BAX interacting factor-1
CCD	Coiled-coil domain
DLC1	Dynein light chain 1
HMGB1	High mobility group box 1
IDR	Intrinsically disordered region
LC3	Microtubule-associated protein light chain 3
(m)TORC1	(Mammalian) target of rapamycin complex 1
NF-κB	Nuclear factor κ-light-chain-enhancer of activated B cells

PI	Phosphatidylinositol
PI3KC3	Class III phosphatidylinositol 3-kinase
PI3P	Phosphatidylinositol 3- phosphate
PTM	Posttranslational modification
ROS	Reactive oxygen species
RUBICON	Run domain Beclin 1-interacting and cysteine-rich domain-containing protein
SNAP29	Synaptosome-associated protein 29
STX17	Syntaxin 17
SUMO	Small ubiquitin-like modifier
TAB2/3	TAK1-binding proteins 2/3
TRIM28	Tripartite motif containing protein 28
ULK	UNC-51-like autophagy-activating kinase
UVRAG	UV radiation resistance associated gene protein
VPS	Vacuolar protein sorting protein
WASH	Wiskott-Aldrich syndrome protein and SCAR homolog

Introduction

Most organisms live in substantially harsher natural environments than that encountered by humans living in civilized societies. One of the most primitive and commonly encountered deficiencies in normal environments is the lack of nutrients. Therefore, eukaryotes have evolved mechanisms that enable them to survive starvation conditions. Key among these is autophagy, a lysosomal degradation pathway wherein cytoplasmic components not needed by or harmful to the cell, such as damaged organelles, aggregated proteins, or pathogens, are engulfed in membrane vesicles called autophagosomes which fuse with lysosomes to enable degradation of autophagosomal components and recycling of nutrients such as amino acids, nucleotides, and energy-providing molecules into the cytoplasm (Kroemer et al. 2010). Notably, extensive or unregulated autophagy can cause cell death.

Autophagy is accomplished by several autophagy-related (ATG) proteins in four distinct stages: (1) autophagy induction, (2) autophagosome nucleation, (3) autophagosome elongation, and (4) autophagosome maturation (Kroemer et al. 2010). Autophagy induction involves the UNC-51 like autophagy-activating kinase (ULK) 1 signaling complex composed of ULK1/2 kinase, ATG13, and focal adhesion kinase family interacting protein of 200 kD (Mizushima 2010). Vesicle nucleation requires vacuolar protein sorting protein 34 (VPS34), also called the Class III phosphatidylinositol 3-kinase (PI3KC3), which phosphorylates phosphatidylinositol (PI) to generate phosphatidylinositol-3-phosphate (PI3P). VPS34 lipid kinase activity and PI3P production is up-regulated by formation of VPS34 Complex I (Obara and Ohsumi 2008). Subsequently, autophagosome elongation enlarges and completes the autophagosome, while maturation involves fusion with lysosomes enabling degradation of autophagosomal contents. VPS34 Complex II plays a role in autophagosome-lysosome fusion (Liang et al. 2006).

Starvation-Triggered Upstream Signaling Mechanisms That Induce Autophagy

The availability or lack of nutrients activates several signaling pathways, many of which regulate autophagy. Nutrient levels sensed via altered cellular energy levels, amino acid availability, and starvation-induced oxidative stress impact autophagy levels. These signals are often transduced to VPS34 complexes via serine/threonine kinases such as AMP-activated protein kinase (AMPK), target of rapamycin complex 1 (TORC1), and the ULK1/2 complexes.

Cellular Energy Levels

ATP is the major energy-storing molecule in most living organisms and therefore is often called the energy currency of life. The availability of carbon sources such as glucose directly affects relative cellular concentrations of ATP, ADP, and AMP as the hydrolysis of glucose results in ATP biosynthesis from ADP/AMP. Elevated ADP and AMP levels reflect energetic stress; therefore, the ATP:ADP+AMP ratio is a key indicator of cellular energy levels. At high concentrations, ADP and AMP bind to and activate AMPK (Laderoute et al. 2006). Activated AMPK phosphorylates and activates ULK1, and both phosphorylate VPS34 complex proteins and VPS34 complex regulators, to up-regulate autophagy (Kim et al. 2011, 2013) (Fig. 1). Activated AMPK also up-regulates autophagy by phosphorylating and inactivating mammalian (m)TORC1, which prevents mTORC1-mediated phosphorylation and repression of ULK1 (Kimura et al. 2003; Kim et al. 2011) (Fig. 1).

Amino Acid Availability

TORC1 activation is also regulated by cellular levels of Leu, Gln, and Arg (Bauchart-Thevret et al. 2010; Duran et al. 2012; Han et al. 2012; Zhu et al. 2015). At high Leu concentrations, leucyl-tRNA synthetase interacts with and activates Rag GTPase which then activates mTORC1, leading to suppression of autophagy by phosphorylation of ULK1/2 and AMPK (Han et al. 2012) (Fig. 1). Gln and Arg are also implicated in mTORC1 activation, but how they are sensed is unknown (Duran et al. 2012; Zhu et al. 2015).

Starvation-Induced Mitochondrial Oxidative Stress

Nutrient depletion leads to malfunction of mitochondrial electron transport. Electrons leak from NADH-Coenzyme Q oxidoreductase and Coenzyme Q-Cytochrome c oxidoreductase, resulting in partial oxygen reduction to superoxide radicals ($O_2^{\bullet -}$), the precursor of most other reactive oxygen species (ROS). These superoxide radicals may be converted to hydrogen peroxide (H_2O_2) by mitochondrial

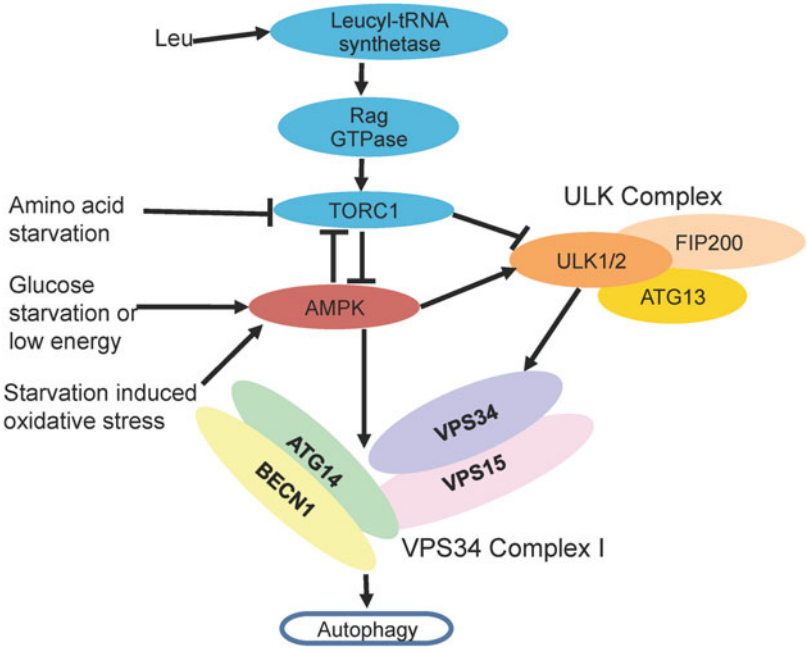

Fig. 1 Upstream signals that modulate autophagy in response to starvation. Proteins are represented as ovals, with VPS34 complex proteins in different colors

superoxide dismutase and released from the mitochondrial matrix to the cytoplasm. Starvation-induced H_2O_2 may activate AMPK, which may be redox-sensitive (Shao et al. 2014). Activated AMPK induces autophagy as discussed above (Fig. 1).

Organization of VPS34 Complexes

The availability or lack of nutrients activates many signaling pathways that directly or indirectly regulate function of the VPS34 complexes to regulate autophagy. These signals may regulate the assembly, cellular localization, and/or activity of VPS34 complexes, constituting major mechanisms by which starvation triggers autophagy. Human VPS34 is an 875-residue protein with three domains: an N-terminal C2 domain, an intrinsically disordered region (IDR), a central helical domain, and C-terminal lipid kinase domain (Backer 2008; Mei et al. 2014) (Fig. 2). VPS34 forms an obligate heterodimer with an N-terminally lipid-linked serine/threonine kinase, VPS15/p150, which consists of an N-terminal kinase domain, a central helical domain, an IDR, and a C-terminal WD40 domain (Rostislavleva et al. 2015; Mei et al. 2014) (Fig. 2). Interaction of the VPS34 C-terminal lipid kinase and C2 domains with the VPS15 N-terminal kinase and helical domains, respectively, mediates VPS34:VPS15/p150 heterodimerization. VPS34:VPS15 heterodimers,

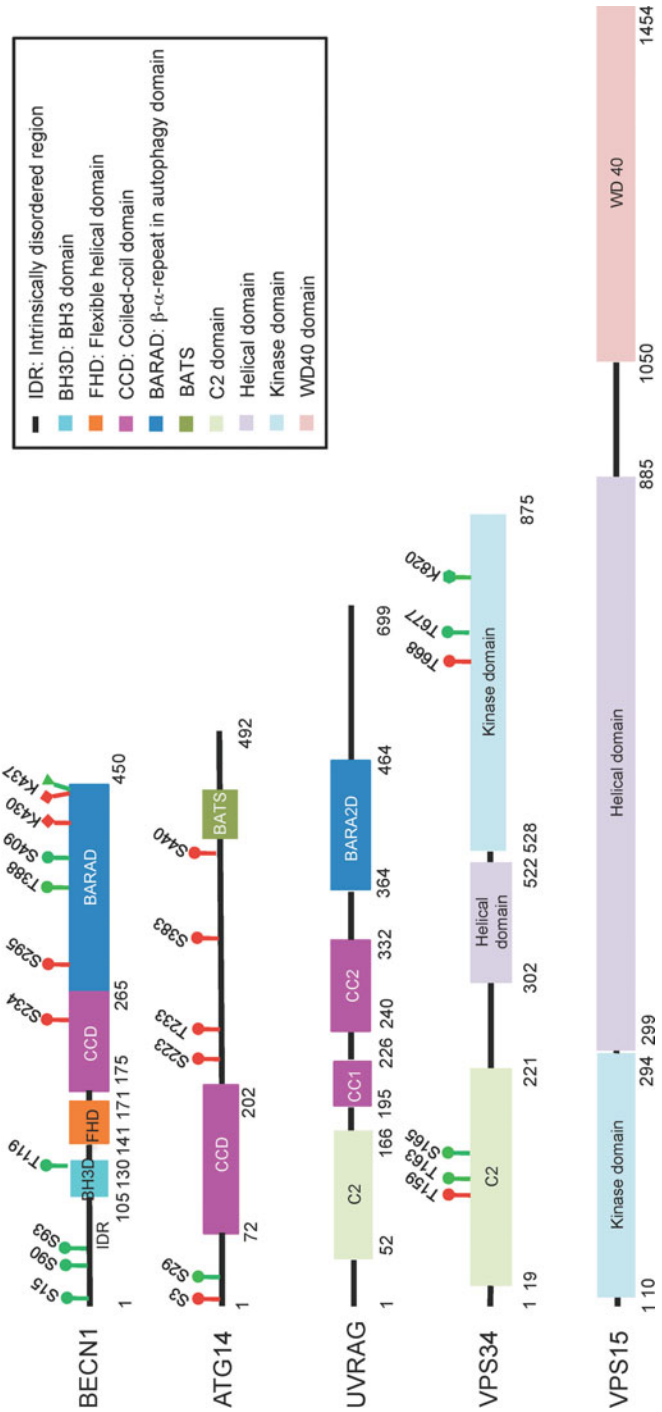

Fig. 2 VPS34 complex proteins: domain architecture and starvation-related PTMs. PTMs that promote or inhibit autophagy are colored green or red respectively. Small circles, diamonds, triangles, and hexagons indicate phosphorylation, acetylation, ubiquitination, and SUMOylation, respectively

often called non-autophagic VPS34 complexes, have basal PI3KC3 activity that likely enables low levels of autophagy.

PI3KC3 activity is substantially up-regulated by association of BECN1 and either ATG14 or UVRAG to form the autophagic complexes, Complex I or II, respectively (Itakura et al. 2008). Formation of these autophagic complexes is markedly up-regulated in starvation conditions.

BECN1, a core VPS34 complex component, is a 450-residue protein in humans. BECN1 homologs from diverse eukaryotes share between 29% and 99% identity. It consists of at least four domains/regions (Mei et al. 2016a): an intrinsically disordered region, a flexible helical domain, a coiled coil domain (CCD), and a β-α repeated, autophagy-specific domain (BARAD) (Fig. 2). Mammals have a second BECN1 homolog, BECN2, that also functions in starvation-induced autophagy (He et al. 2013). BECN2 shares 56.6% sequence similarity with BECN1 and is predicted to have structure and domain architecture similar to BECN1. Besides its role in autophagy, BECN2 regulates nutrient intake and ligand-induced endolysosomal degradation of several GPCRs. In the absence of BECN2, the cannabinoid 1 receptor is overexpressed, increasing nutrient intake resulting in weight gain and insulin resistance in cells. Each BECN domain interacts with diverse regulatory proteins (Mei et al. 2016a). BECN homologs are conformationally very flexible, which likely enable diverse interactions with concomitant conformational changes in BECN that impact assembly of VPS34 complexes.

ATG14, a less well-conserved core protein of VPS34 Complex I, helps regulate localization of Complex I (Matsunaga et al. 2010). Human ATG14 is a 492-residue protein comprised of an N-terminal cysteine-rich repeat region, a CCD, an IDR, and a C-terminal Barkor/ATG14 autophagosome targeting sequence (BATS) (Matsunaga et al. 2010; Mei et al. 2014) (Fig. 2). ATG14 and BECN CCDs heterodimerize with at least tenfold tighter affinity relative to BECN1 homodimerization (Mei et al. 2016b; Su et al. 2017). Mutation of critical ATG14:BECN1 interface residues destabilize the heterodimer and down-regulate starvation-induced autophagy (Li et al. 2012; Mei et al. 2016b). The N-terminal cysteine-rich domain is essential for targeting the VPS34 complex in mammals (Matsunaga et al. 2010), while the BATS senses and preferentially binds highly curved, PI3P-rich membranes (Fan et al. 2011). UVRAG, a core component of VPS34 Complex II, is a 699-residue protein comprised of an N-terminal proline-rich sequence, a C2 domain, two central CCDs, an IDR, and a C-terminal BARA2 domain (Liang et al. 2006; Mei et al. 2014) (Fig. 2). The UVRAG CCD and BARA2 domain interact with analogous BECN1 domains.

Complex I and II have very similar architecture, with an overall V-shape, with VPS34 together with VPS15/p150 forming one arm of the V-shape (Baskaran et al. 2014; Rostislavleva et al. 2015) (Fig. 3). The VPS15/p150 kinase domain interacts with the VPS34 activating loop, regulating its activity. The other arm of the V-shape is formed by a parallel heterodimer of VPS30/BECN1 and either ATG14 in Complex I or VPS38/UVRAG in Complex II. The C-terminal domains of these proteins, e.g., the VPS30/BECN1 BARAD and VPS38/UVRAG BARA2D, are located at the tip of the arm. The base of the "V" shape is formed by the VPS15/p150 helical domain,

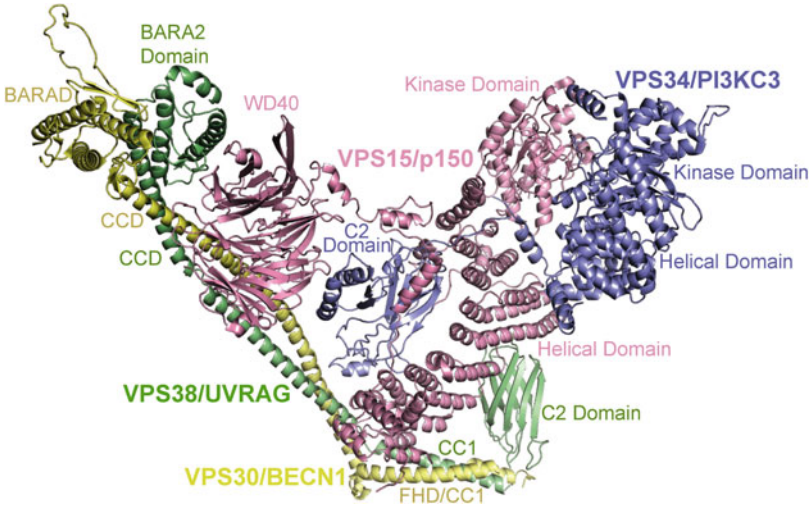

Fig. 3 Structure of VPS34 Complex II (PDB ID: 5DFZ). Each protein main-chain is traced in ribbon, colored according to Fig. 1. Domains of each protein are labeled

the VPS30/BECN1 IDR, and the N-termini of either VPS38 in Complex II or ATG14 in Complex I. The VPS34 C2 domain is buried in the center of the "V" shaped complex (Fig. 3), unlike the C2 domains of class I PI3Ks that pack between the helical and kinase domains and bind to membranes through Ca^{2+}.

In addition to interactions among protein components of VPS34 complexes, VPS34 activity is also regulated by interactions with other proteins and posttranslational modifications (PTMs).

VPS34 Regulation

VPS15/p150 binding triggers conformational changes required for VPS34 activity and starvation-induced autophagy (Rostislavleva et al. 2015). Besides direct interactions with VPS15/p150s, VPS30/BECN1, and either ATG14 or VPS38/UVRAG, in response to starvation, VPS34 activity is also regulated by the following PTMs.

VPS34 Phosphorylation

In response to starvation, the serine/threonine kinases AMPK and protein kinase D (PKD) up-regulate VPS34 catalytic activity and autophagy (Fig. 4). Glucose starvation-triggered increases in ADP and AMP levels activate AMPK, which phosphorylates VPS34 T163 and S165 (Kim et al. 2013), decreasing lipid kinase activity of nonautophagic VPS34 complexes, but increasing lipid kinase activity of autophagic

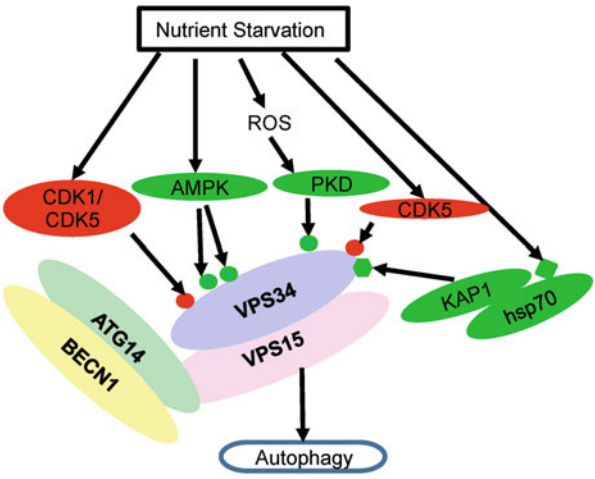

Fig. 4 VPS34 PTMs that regulate autophagy in response to starvation. The VPS34 complex is shown as in Fig. 1 and PTMs as in Fig. 2. Interacting proteins and PTMs that promote or inhibit autophagy are colored green or red, respectively

VPS34 complexes (Kim and Guan 2013). This is biologically reasonable, since VPS34 also participates in other cellular pathways and the inhibitory phosphorylation by AMPK in response to glucose starvation may down-regulate these other pathways, while simultaneously increasing the lipid kinase activity of VPS34 Complex I and II, to increase autophagy. On the other hand, in response to ROS, PKD phosphorylates the VPS34 catalytic domain T677, directly activating VPS34 and up-regulating autophagy (Eisenberg-Lerner and Kimchi 2012) (Fig. 4).

Conversely, autophagy is down-regulated in response to starvation by the cyclin-dependent kinases, CDK1 and CDK5, which are serine/threonine kinases that regulate essential cellular processes such as cell-cycle progression, development, and intracellular signaling. Starvation during mitosis triggers CDK1- and CDK5-mediated phosphorylation of VPS34 C2 domain T159 (Fig. 4), which disrupts VPS34:BECN1 association, thereby decreasing VPS34 activity (Furuya et al. 2010). CDK5 also phosphorylates the VPS34 catalytic domain T668, directly inhibiting VPS34 activity (Furuya et al. 2010) (Fig. 4). CDK-mediated down-regulation of starvation-induced autophagy during mitosis is biologically important, because increased autophagy due to normal starvation-triggered up-regulation would degrade organelles, proteins, or DNA, thereby disrupting mitosis.

VPS34 SUMOylation

Tripartite motif containing protein (TRIM)28, also called KAP1, is an E3 ligase that directs ligation of the small ubiquitin-like modifier protein (SUMO) (Ivanov et al. 2007). Amino acid deprivation promotes heat shock protein (HSP)70 acetylation. Acetylated HSP70 binds to VPS34 complexes and also recruits KAP1/TRIM28, which SUMOylates VPS34 at K820, enhancing VPS34 lipid kinase activity, thereby increasing autophagy (Yang et al. 2013) (Fig. 4).

BECN1 Regulation

BECN1-mediated autophagy is regulated in response to starvation by multiple protein interactions and PTMs.

BECN1 Interactions That Up-regulate Autophagy

Activating molecule in BECN1-regulated autophagy (AMBRA)1 binds BECN1, acting as an adaptor between the VPS34 and dynein motor complexes (Di Bartolomeo et al. 2010) (Fig. 5i). In nutrient-rich conditions, activated mTORC1 phosphorylates AMBRA1 S52 (Nazio et al. 2013) enabling binding to dynein light chain 1 (DLC1) of the dynein motor complex, thereby anchoring AMBRA1 to cytoskeletal microtubules and sequestering BECN1 and the VPS34 complex (Di Bartolomeo et al. 2010). Upon starvation, ULK1 phosphorylates AMBRA1 causing dissociation from DLC1, and VPS34 complex transport to the endoplasmic reticulum (Fig. 5i). Subsequent PI3P production at the endoplasmic reticulum initiates autophagosome nucleation.

High mobility group box (HMGB)1, a chromatin-associated nuclear protein, up-regulates autophagy by binding BECN1 (Tang et al. 2010). ROS produced upon prolonged starvation triggers HMGB1 translocation from nucleus to cytoplasm. Under oxidative conditions, an intramolecular disulfide bond forms between C23 and C45 of cytoplasmic HMGB1, enabling HMGB1 binding to BECN1, and competitive inhibition of BECN1 interaction with antiapoptotic B-cell lymphoma 2 (BCL2) proteins (Fig. 5ii). Moreover, cytoplasmic HMGB1 also promotes phosphorylation and activation of the extracellular signal-regulated kinases (ERK)1/2, which then phosphorylate BCL2 proteins, preventing them from binding BECN1 (Tang et al. 2010) (Fig. 5ii).

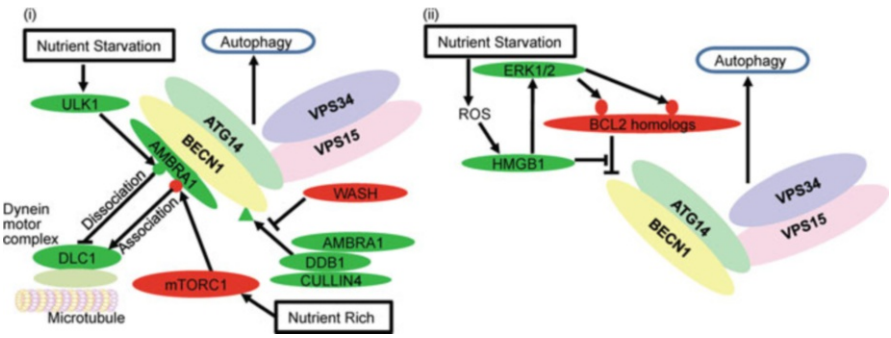

Fig. 5 Regulation of BECN1-mediated autophagy by (i) AMBRA1 (ii) HMGB1. Colors and symbols are as in Fig. 4.

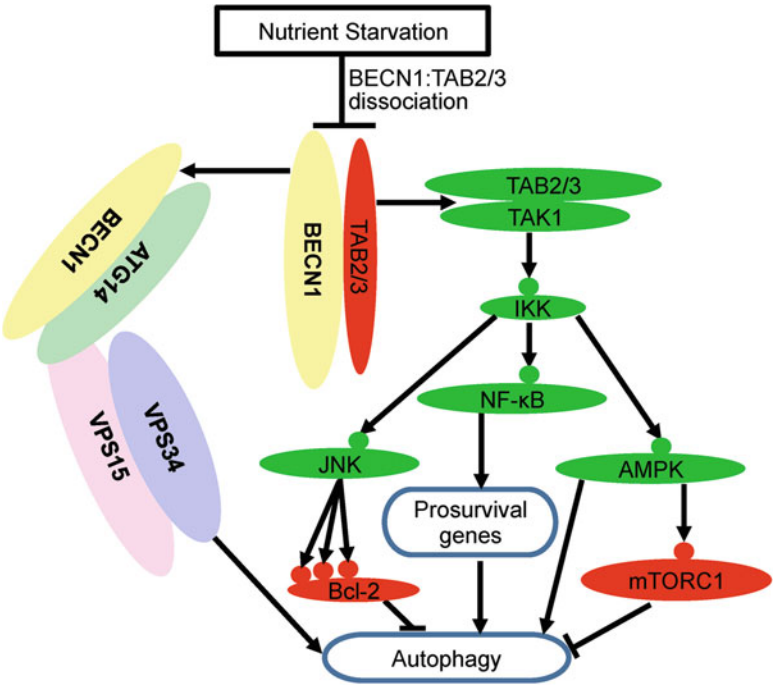

Fig. 6 Regulation of autophagy by TAB2/TAB3. Colors and symbols are as in Figs. 4 and 5

BECN1 Interactions That Down-regulate Autophagy

BCL2 proteins are characterized by the presence of poorly conserved BCL2 homology (BH) domains. Pro-apoptotic BCL2 proteins include BH3-only proteins such as BIM and BAD, as well as three-BH (BH1, BH3, and BH2) domain proteins: BAX, BAK, and BOK. Humans encode at least six, antiapoptotic, multi-BH domain (BH4, BH1, BH3, and BH2) proteins: Bcl-2, Bcl-X_L, Mcl-2, Bcl-w, A1, and Bcl-B. Many antiapoptotic BCL2 proteins bind to the BECN1 BH3D (Sinha and Levine 2008) decreasing VPS34 activity and starvation-induced autophagy (Pattingre et al. 2005). However, the mechanism(s) by which BCL2:BECN1 interactions down-regulate autophagy is unknown. Starvation induces c-Jun N-terminal protein kinase (JNK)1-mediated Bcl-2 phosphorylation at T69, S70, and S87, which disrupts interaction with BECN1, thereby stimulating starvation-induced autophagy (Wei et al. 2008a, b).

Under nutrient-rich conditions, transforming growth factor β activated kinase (TAK) 1-binding proteins, TAB2 and TAB3, bind via their CCDs to the BECN1 CCD, preventing BECN1 association with ATG14 or UVRAG, thereby down-regulating autophagy (Criollo et al. 2011) (Fig. 6). Starvation triggers dissociation of BECN1 from TAB2 and TAB3, enabling TAB2/3 binding to TAK1 via their CCDs. Consequent TAK1 activation causes TAK1-mediated phosphorylation and activation of IκB kinase

(IKK), which also up-regulates autophagy through the nuclear factor κ-light-chain-enhancer of activated B cells (NF-κB), AMPK and JNK1 (Criollo et al. 2009) (Fig. 6).

Lastly, the Wiskott-Aldrich syndrome protein and SCAR homolog (WASH) binds BECN1 and suppresses autophagy by impacting BECN1 ubiquitination as described below, (Xia et al. 2013) (Fig. 5i).

BECN1 Phosphorylation

BECN1 phosphorylation by various starvation-activated serine/threonine kinases often improves association with VPS34, increasing VPS34 lipid kinase activity and inducing autophagy. ULK1, activated by amino acid deprivation or via TORC1 inhibition, phosphorylates BECN1 S15, enhancing VPS34 activity (Russell et al. 2013). Starvation-activated AMPK phosphorylates BECN1 S90, S93, and T388, with phosphorylation at S90 and S93 substantially increased when ATG14 or UVRAG are present (Kim et al. 2013; Zhang et al. 2016). BECN1 phosphorylation at these sites decreases BECN1:BCL2 interaction and enhances interactions with ATG14 and VPS34 (Zhang et al. 2016). Similarly, mitogen activated protein kinase (MAPK)-activated protein kinases (MKs), MK2 and MK3, of the p38 MAPK family, phosphorylate BECN1 S90, inhibiting BECN1:BCL2 interaction (Wei et al. 2015). Notably, AMPK also phosphorylates BECN1 at S90 (Kim et al. 2013). Since AMPK is mainly activated by glucose deprivation, while MK2/3 are activated by amino acid starvation, they have complementary functions implemented via phosphorylation of the same residue. Lastly, the calcium/calmodulin-dependent death-associated protein kinase (DAPK)1, which can be activated by starvation (Kang and Avery 2010), phosphorylates BECN1 BH3D T119, disrupting BECN1:BCL2 binding, thereby promoting BECN1 association with VPS34 (Zalckvar et al. 2009).

Two other serine/threonine kinases, protein kinase B (PKB) or AKT, and casein kinase (CK)1γ2, phosphorylate BECN1 under nutrient-rich conditions to down-regulate autophagy. PKB/AKT phosphorylates BECN1 at S234 and S295, enhancing BECN1 interaction with the 14-3-3 protein and vimentin intermediate filaments (Wang et al. 2012), which likely reduces the BECN1:VPS34 interaction. CK1γ2 phosphorylates BECN1 at S409 facilitating BECN1 acetylation by p300 (Sun et al. 2015) (Fig. 7).

BECN1 Acetylation

Under nutrient-rich conditions, CK1γ2-mediated BECN1 phosphorylation facilitates p300-mediated BECN1 acetylation at K430 and K437 (Fig. 7). BECN1 acetylation alters VPS34 complex structure and enables association of the run domain BECN1-interacting and cysteine-rich domain-containing protein (RUBICON), a negative regulator of autophagosome maturation (Sun et al. 2015).

BECN1 Ubiquitination

BECN1 BARAD K437 undergoes K63-linked ubiquitination (i.e., covalent linkage to chains of K63-linked ubiquitin proteins) by the E3 ubiquitin ligase

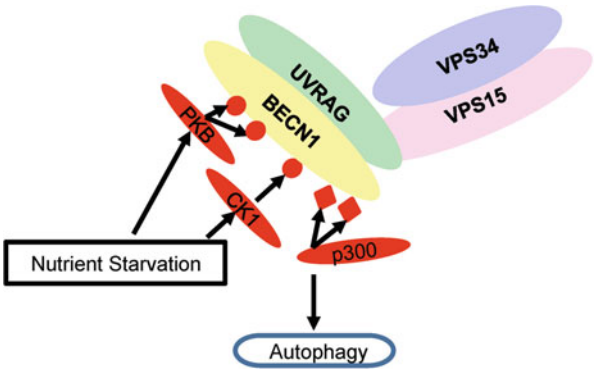

Fig. 7 PTMs that down-regulate BECN1-mediated autophagy. Colors and symbols are as in Fig. 4

complex, DNA damage-binding protein 1-CULLIN4 (DDB1-CULLIN4) complex, enabled by binding of AMBRA1 to both DDB1-CULLIN4 and BECN1 (Fig. 5i). This ubiquitination increases BECN1:VPS34 association and VPS34 lipid kinase activity and is required for starvation-induced autophagy (Antonioli et al. 2014). WASH binding to BECN1 abolishes K437 ubiquitination by the AMBRA1-DDB1-CULLIN4 complex and likely prevents excess autophagy during early embryonic development (Xia et al. 2013) (Fig. 5i).

ATG14 Regulation

ATG14 is regulated by protein interactions and PTMs.

ATG14 Interactions

Upon starvation, Syntaxin 17 (STX17), a target-soluble NSF attachment protein receptor (SNARE), along with synaptosome-associated protein 29 (SNAP29), is recruited to autophagosomes and facilitates fusion of autophagosomes with endosomes/lysosomes (Itakura et al. 2012). CCDs of each protein mediate ATG14 interaction with STX17, and with the STX17:SNAP29 binary complex, stabilizing the STX17:SNAP29 binary complex, which primes autophagosome:lysosome fusion (Diao et al. 2015).

ATG14 Phosphorylation

In nutrient-rich conditions, activated mTORC1 directly phosphorylates ATG14 S3, S223, T233, S383, and S440 (Fig. 2), decreasing VPS34 lipid kinase activity, thereby down-regulating autophagy (Yuan et al. 2013). Upon amino acid depletion, mTORC1 activity is inhibited, resulting in unphosphorylated ULK1, which is active and phosphorylates ATG14 at S29, increasing VPS34 lipid kinase activity, thereby increasing autophagy (Wold et al. 2016).

UVRAG Regulation

UVRAG function is regulated by interaction with RUBICON, as mentioned earlier, and Bax-interacting factor (BIF)1 or endophilin B1. RUBICON interacts with the VPS34 complex via UVRAG, inhibiting autophagosome maturation, thereby down-regulating starvation-induced autophagy (Matsunaga et al. 2009; Sun et al. 2011). However, the precise mechanism by which RUBICON binds to and regulates the UVRAG:BECN1 complex is unknown.

BIF1 consists of an N-terminal bin-amphiphysin-Rvs (N-BAR) domain and a C-terminal Src-homology 3 (SH3) domain. In response to starvation, BIF1 localizes to autophagosomes (Takahashi et al. 2007). The BIF1 SH3 domains bind to the UVRAG N-terminal proline-rich region, while the BIF1 N-BAR domain binds to membranes and drives membrane curvature. BIF1 BAR and SH3 domains are both required for PI3KC3 activation and autophagy.

Potential Health Benefits of Autophagy Triggered by Short-Term Starvation

Autophagy has significant health benefits as it protects against diseases like cancer, heart diseases, and neurodegenerative diseases and increases lifespan (Levine and Kroemer 2008). Indeed, several therapeutics currently being developed target autophagy proteins (Levine et al. 2015). Short-term starvation may confer similar benefits by inducing autophagy. Notably, short-term fasting, which is an established practice in many cultures, may have long-term health benefits that are yet been fully appreciated.

The Role of Autophagy in Cancer

Autophagy is either pro-tumoral or anti-tumoral depending on the stage of cancer development: initiation, promotion, progression, and metastasis. During cancer initiation, autophagy serves as a tumor suppressor pathway, for instance, by preventing ROS-induced DNA and protein damage leading to inhibition of tumorigenesis. However, in later stages of cancer, i.e., promotion, progression, and metastasis, autophagy is pro-tumoral, as insufficient oxygen and starvation in the core of the tumor triggers autophagy, enabling tumor cell survival and proliferation (Levine 2006; Mathew et al. 2007; Galluzzi et al. 2015).

The Role of Autophagy in Heart Diseases

Autophagy plays a dual role in cardiac diseases (Cao et al. 2009; Matsui et al. 2007; Rifki and Hill 2012). Inadequate blood flow to the heart due to blockage of heart arteries causes cardiac ischemia, leading to oxygen and nutrient shortage. This increases cellular ADP and AMP levels which activates AMPK, thereby triggering

autophagy and protecting myocardial cells from cell death. Conversely, restoration of blood flow to myocardial cells during reperfusion often results in ROS production, which further increases autophagy in cardiomyocytes, leading to a detrimental hypertrophic response and/or excessive self-digestion of cellular proteins and organelles leading to death.

Neuronal Autophagy Protects Against Neurodegenerative Diseases

Autophagy is important for removing misfolded and mutant proteins associated with several neurodegenerative disorders (Levine and Kroemer 2008). Mutations in proteins regulating autophagy cause accumulation of mutant huntingtin, α-synuclein, or Tau protein aggregates in neurons, causing cellular toxicity which culminates in neurodegenerative diseases such as Huntingon's, Parkinson's, and Alzheimer's, respectively (Nixon 2013; Shibata et al. 2006; Lynch-Day et al. 2012). Increased autophagy reduces these aggregated proteins in sick neuron cells (Webb et al. 2003). Short-term starvation dramatically increases autophagy in Purkinje and Cortic neuronal cells (Alirezaei et al. 2010).

Short-Term Starvation Increases Longevity

Elimination of damaged organelles and misfolded or aggregated proteins is a common feature of many lifespan-extending manipulations (Madeo et al. 2015). Short-term starvation inhibits the AKT/TORC1 pathway, thereby triggering autophagy and DNA repair pathways and increasing lifespan in several types of organisms (Madeo et al. 2015). BECN1/ATG6 are essential for autophagy induction and lifespan extension in *Caenorhabditis elegans* (Jia and Levine 2007). Under caloric restriction, decreased TOR signaling mediates lifespan extension in yeast (Powers et al. 2006). Thus, scientific evidence increasingly indicates that short-term starvation may be a readily accessible method of promoting longevity.

Therapeutic Regulation of Autophagy

Several small molecules have been shown to regulate autophagy. Rapamycin, a small molecule known to target mTORC1, up-regulates autophagy. Tamoxifen up-regulates BECN1 levels and induces autophagy. 3-Methyladenine and wortmannin target PI3KC3 and inhibit autophagy (Rubinsztein et al. 2012). Bafilomycin A1 activates mTORC1 and inhibits autophagosome fusion with lysosomes and also induces BECN1 binding to BCL2, decreasing autophagy while also promoting apoptotic cell death in pediatric patients with B-cell acute lymphoblastic leukemia (Yuan et al. 2015). Similarly, chloroquine prevents autophagy by blocking autolysosome formation and has been used to target colon cancer, malignant melanoma, hepatocellular carcinoma, low-grade glioma, and high

grade astrocytoma (Kimura et al. 2013). Small molecules like Verapamil, loperamide, and nimodipine up-regulate autophagy, enhancing clearance of soluble mutant huntingtin exon 1-encoded protein and reducing its aggregation and toxicity in neuroblastoma cells (Williams et al. 2008). Cell-permeable peptides or peptide mimetics derived from the BECN1 BH3D have been shown to selectively disrupt inhibitory interactions between BECN1 and antiapoptotic BCL2s, activating VPS34 complexes and up-regulating autophagy (Malik et al. 2011; Su et al. 2014). Another cell-permeable peptide derived from BECN1 residues 267–284 was shown to be a potent autophagy inducer that triggers autophagy to prevent replication of West Nile and Chikungunya viruses and may also target HIV-1 (Shoji-Kawata et al. 2013).

Implications of Short-Term Starvation for Human Health

The potential of short-term starvation as a therapeutic measure activating autophagy has not yet been investigated in a systematic, scientific manner in humans. However, recent scientific studies indicate significant health benefits of short-term starvation (Anton and Leeuwenburgh 2013). Caloric restriction without malnutrition extends life span and delays onset of age-related disorders in rhesus monkeys, which likely translates to human health (Mattison et al. 2017). In humans, glucose and protein-restricted diets for only 5 days each month lead to reduced body weight and body fat, lowered blood pressure, and decreased Insulin-like growth factor-1 (IGF-1) level with positive implications on aging and disease (Wei et al. 2017). Additionally, research on over-weight individuals shows that caloric restriction increases life expectancy, reduces cardiac risk factors, improves insulin-sensitivity, and prevents mitochondrial production of free radicals (Anton and Leeuwenburgh 2013).

Notably, short-term starvation by means of occasional fasting is an established ritual in various religions across the world, including Buddhism, Christianity, Hinduism, Islam, Judaism, Jainism, and Taoism. The frequency and duration of fasting varies widely, from a few hours to days, and may involve several weeks where food is consumed only at night or early morning, or selected foods are prohibited. Indeed, some cultures even fast for nonreligious reasons; for instance, in Switzerland, a day of fasting is marked as a way of remembering famines, plagues, and wars. The correlation of starvation practices, autophagy, and human health is unclear, as many interconnected cellular pathways work in conjunction, but together all evidence suggests that short-term starvation rituals may up-regulate autophagy, thereby facilitating removal of cytotoxins, improving health, and extending lifespan.

Dictionary of Terms

- **Dimer/Homodimer/Heterodimer** – Dimerization is the association of either two identical (homodimer) or different (heterodimer) polypeptides chains to form a functional protein complex.

- **Domains** – Independently folding structural units of a polypeptide chain/protein that are often the units of evolution.
- **Homolog** – Domains that share the same ancestry and three-dimensional structure and often, significant sequence similarity as well as similar function. Multidomain proteins may be homologous to other proteins over their entire length or over only specific domains.
- **Lysosome** – A cellular organelle comprising a vesicle containing hydrolytic enzymes in an acidic environment
- **Posttranslational modification (PTM)** – The covalent modification of protein side chains, or C- or N- termini, during or after polypeptide biosynthesis. PTMs facilitate cellular signaling by changing protein stability, conformation, function, and/or interactions. The most common PTMs are phosphorylation, acetylation, glycosylation, methylation, hydroxylation, and ubiquitination.
- **Serine/threonine kinase** – An enzyme that phosphorylates substrate proteins at specific amino acids, in this case at serine or threonine side-chain hydroxyls.

Summary Points

- Major starvation signals, such as reduced cellular energy, amino acid starvation, and oxidative stress, induce autophagy, which is essential for cellular recycling of nutrients.
- VPS34 complexes play an essential role in mediating autophagy.
- Starvation signals are transduced via many interacting proteins and posttranslational modifications to VPS34 complexes to regulate autophagy.
- Starvation-induced autophagy has potential health benefits such as in combating neurodegenerative diseases, cancer, heart diseases, and in lifespan extension.
- Thus, short-term starvation or caloric restriction rituals established in several religions and cultures may have beneficial effects on health and longevity.

Abstract

Macroautophagy is a cellular degradation pathway that deliver cytoplasmic components such as damaged organelles, misfolded proteins, and pathogens to the lysosomes for degradation. Autophagy is associated with the survival of the cell under stress conditions and infections. Nutrient deprivation is one of the main inducers of autophagy, which recycles cytoplasmic components to provide building blocks required for cell survival and maintains cellular homeostasis. Due to its cytoprotective effects, autophagic responses are necessary in resisting diseases and ensuring health. Understanding the regulation of autophagic responses in mammalian cells is required to improve human health through innovations in treatment strategies. This chapter focuses on recent findings about autophagy mechanisms and their role in the body's response to starvation as well as the current knowledge of autophagy-related malnutrition disorders.

Keywords

Autophagy · Starvation · Stress · mTOR · AMPK · LC3 · ULK1 · ATG · Metabolic disease · Lysosome

List of Abbreviations

3HB	3-beta-hydroxybutyrate
AcAc	Acetoacetate
ATG	Autophagy-related proteins
CD	Crohn's disease
CMA	Chaperone-mediated autophagy
HBV	Hepatitis B virus
HCC	Hepatocellular carcinoma
HCV	Hepatitis C virus
IBMPFD	Inclusion body myopathy with early-onset Paget disease and frontotemporal dementia
LC3	Microtubule-associated protein 1A/1B-Light chain 3
PE	Phosphatidylethanolamine
PI3K	Phosphatidylinositol 3-kinase
SLE	Systemic lupus erythematosus
Th2	Helper T cell 2
Ub	Ubiquitin
VLDL	Very-low density lipoprotein

Introduction

Autophagy is the primary cellular response of cells to starvation. In mammalian cells, survival responses are mainly dependent on hormonal and neuronal deregulations from stress signals. Mammalian cells respond to starvation by activating lipolysis and proteolysis, which are regulated by autophagic activation pathways upon nutrient deprivation (Hosokawa et al. 2009; Petibone et al. 2017). Activation of

lipolysis is required to provide fatty acids through the breakdown of triacylglycerols as an energy source for different tissues and organs during nutrient deprivation (Cockburn and Coore 1995; Angelini et al. 2016). Moreover, glycerol, which is a side product of lipolysis, can be utilized in the liver to be used as a glucose source under starvation conditions. When cells are exposed to long-term nutrient deprivation and energy loss, an excess amount of lipolysis results in the production of ketone bodies, which are the end product of free fatty acid oxidation reaction and can be used as an energy source in muscle and neurons. Since not all cells have the ability to use ketone bodies as an energy source, the cells that cannot utilize these small molecules activate proteolysis as a response to starvation (Luo et al. 2017; Lee et al. 2017). Proteolysis can be activated in two different ways, depending on the tissue type and stress duration. The first is the ubiquitin-mediated proteolysis system, which selectively degrades the nonfunctional or misfolded proteins which are linked to ubiquitin markers. Ubiquitin-mediated proteolysis is mostly active in skeletal muscle cells. The second pathway is the lysosomal pathway, which is activated upon long-term starvation and is responsible for the nonselective degradation of proteins through enzymatic activity in lysosomes.

Mammalian Autophagy

Autophagy is a well conserved lysosomal catabolic pathway that is required for the recycling of cellular compartments and proteins. However, this chapter is focused on macroautophagy, which is the predominant form in mammals. There are two additional types of autophagy: microautophagy and chaperone-mediated autophagy (CMA). Microautophagy occurs via the direct engulfment of cytoplasmic cargo by lysosomes by which it is degraded by enzymatic activity. CMA is a selective type of autophagy which occurs by chaperone-mediated selection and direct translocation of proteins into lysosomes without any need for the formation of double membrane structures. Macroautophagy (hereafter referred to as autophagy) is mostly activated upon stress signals in mammals; however, it also occurs under normal conditions in order to maintain cellular homeostasis by providing the turnover of long-lived, damaged, nonfunctional proteins in the cell (Erbil et al. 2016; Mathiassen et al. 2017). Upon stress, autophagy starts with the initiation and elongation of the little membrane structures in the cytosol. These double membrane structures engulf the cargo and form the autophagosomes. Lysosomes are then fused with the autophagosomes in order to form autolysosomes, by which the cargo is degraded by lysosomal enzymes and byproducts are released back to the cytosol to be utilized as an energy supply in the cell.

Molecular Signaling Pathways in Starvation-Induced Autophagy

Identification of the autophagy-related (ATG) proteins leads to an improvement of the clarification of the molecular signaling pathways of autophagy. Recently, 36 ATG proteins have been discovered in the core machinery of mammalian autophagy.

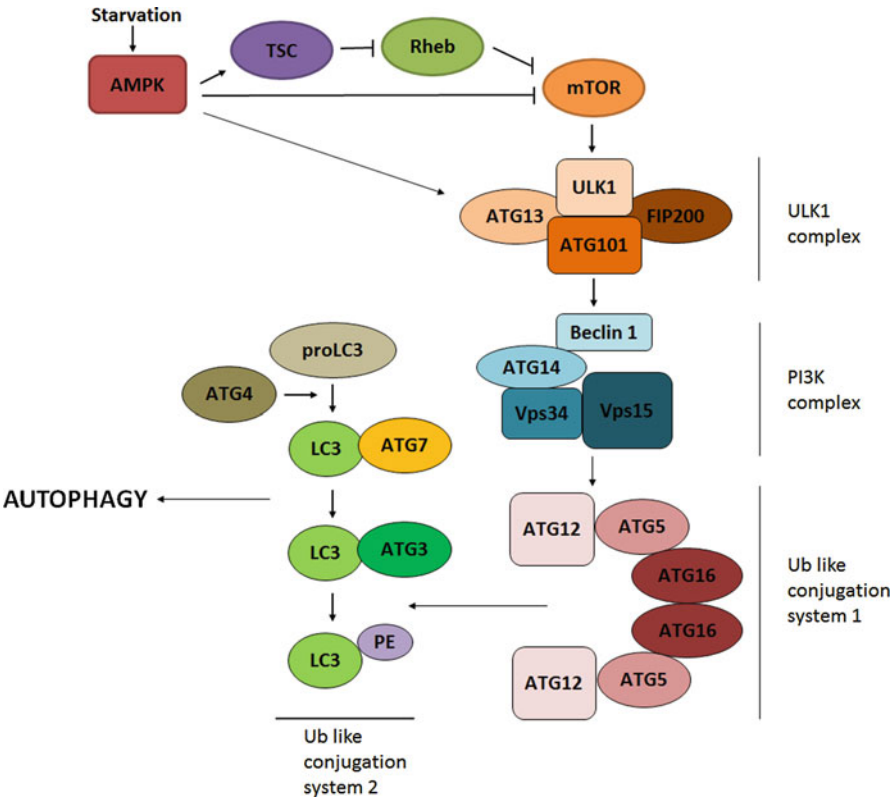

Fig. 1 **Signaling regulation of starvation-induced autophagy**. In mammals, starvation-induced autophagy starts with the activation of AMPK and TSC followed by the inhibition of Rheb and mTOR through phosphorylation events. When nutrients are limited, the phosphorylation of ULK1 by mTOR is inhibited due to mTOR inactivation. Upon dephosphorylation, ULK1 can interact with the other complex elements which mediate the formation of PAS leading to the initiation of autophagosome structures. Further nucleation steps require a PI3K complex which is formed by VPS34 and VPS15 and their regulatory subunits Beclin 1 and ATG14. Membrane elongation and closure requires two different Ub-like conjugation systems. Ub-like conjugation systems 1 and 2 together lead to PE conjugation of LC3 that is essential for the elongation of the membrane structures. Moreover, membrane-bound LC3 is required for the recognition of the cargo through adaptor proteins as well as the lysosome fusion to the autophagosomes. The resulting structure is named as autolysosomes and the cargo is degraded by enzymatic activity inside these structures. Key: PAS, phagophore assembly site; TSC, tuberous sclerosis complex; VPS34 and 15, vacuolar protein sorting 34 and 15; Ub, ubiquitin; PE, phophatidylethanolamine; LC3, microtubule-associated protein 1 light chain 3

These proteins are involved in different functional complexes in autophagycascade. The main four complexes are demonstrated in Fig. 1: ULK1 and phosphatidylinositol 3 kinase (PI3K) complexes, Ubiquitin (Ub)-like conjugation systems 1 and 2. Table 1 summarizes their key roles in the activation of autophagy as the cellular response to starvation in mammals.

Table 1 Key protein complexes acting in starvation-induced autophagy in mammalian cells. ULK1 complex, PI3K complex, Ub-like conjugation system 1, and Ub-like conjugation system 2 are the key protein complexes that act in starvation-induced autophagy. ULK1 complex consists of ULK1, ATG13, FIP200, and ATG101; PI3K complex consists of Beclin1, ATG14, Vps34, and Vps15; Ub-like conjugation system 1 consists of ATG5, ATG12, and ATG16; Ub-like conjugation system 2 consists of ATG3, ATG4, ATG7, and LC3 proteins. Key: PI3K, phosphatidylinositol 3 kinase; ATG3, 4, 5, 7, 12, 13, 14, 16, and 101, autophagy-related proteins 3, 4, 5, 7, 12, 13, 14, 16, and 101; VPS34 and 15, vacuolar protein sorting 34 and 15; Ub, ubiquitin; LC3, microtubule-associated protein 1 light chain 3

Complex	Complex elements	Function
ULK1 complex	ULK1 ATG13 FIP200 ATG101	This complex is negatively regulated by mTOR. Upon autophagy induction by starvation signals received by mTOR, ULK1 is activated by self-phosphorylation and translocates into the early autophagic structures. In addition to its self-phosphorylation, ULK1 phosphorylates ATG13 and FIP200 due to complex activation
PI3K complex	Beclin 1 ATG14 Vps34 Vps15	This complex is negatively regulated by Bcl-2 Beclin 1 interaction. Upon autophagy induction by starvation signals, Bcl-2 disassociates from Beclin 1 and forms the complex with other elements on the ER membrane. This complex is effective in the later autophagic events, as the inhibition of this complex result in the impairment of autophagosome and lysosome fusion
Ub-like conjugation system 1	ATG5 ATG12 ATG16	This complex is necessary for LC3 and phophatidylethanolamine (PE) conjugation which is essential for the elongation of the membrane structures
Ub-like conjugation system 2	ATG3 ATG4 ATG7 LC3	Deconjugation of LC3 form ATG4 is important for the LC3-PE formation and the closure of the autophagosome membrane. Since LC3-PE is localized both in the inner and the outer membranes of the autophagosome, its formation by Ub-like conjugation system 2 is important for the adaptor protein binding, such as p62, for selective autophagy

AMPK is the main energy sensor of the cell, and it plays a crucial role in the induction of starvation-induced autophagy in mammalian cells (Garcia and Shaw 2017). When a nutrient level is limited, AMPK activation leads to mTOR inhibition through TSC activation and Rheb inhibition. Therefore, AMPK indirectly activates the ULK1 complex which is in the downstream of mTOR and kept inactivated through phosphorylation events. Recent studies have showed that in addition to mTOR, AMPK can also phosphorylate ULK1 directly to lead to its activation upon starvation signals. Following phosphorylation, ULK1 interacts with the other complex elements, FIP200, ATG101, and ATG13, to form the ULK1 complex and phosphorylates them to activate the complex (Petherick 2015). The active ULK1 complex translocates to the ER membrane and activates the PI3K complex which consists of Beclin 1, ATG14, and vacuolar protein sorting 34 and 15 (VPS34 and 15). The PI3K complex recruits Ub-like conjugate system 1, formed by ATG12-5-16 proteins, which plays a role in the elongation and closure of the isolation membrane (Zhong et al. 2017). Moreover, Ub-like conjugate system 1 is also required for the

activation of Ub like conjugate system 2, which is necessary for phosphatidylethanolamine (PE) conjugation to LC3 (microtubule-associated protein 1A/1B-light chain 3) protein. The cytosolic form of LC3 is called pro-LC3. Due to the induction of autophagy, pro-LC3 is cleaved by ATG4, and then the cleaved form of LC3 is conjugated with PE by the activities of E1-like enzyme ATG7 and E2-like enzyme ATG3. PE-conjugated LC3 is membrane-bound, and it is present both in the inner and outer sides of the autophagosome (Nath et al. 2014). Therefore, it not only plays a role in membrane elongation and closure but also serves as the recognition site for adaptor proteins such as p62 (Klionsky et al. 2010).

Autophagy at Organ and Tissue Level and Affected Human Diseases from Their Impairment

Dysregulation of autophagy has been implicated in a range of diseases. Starvation-induced autophagy impairments mostly cause liver, pancreas, and muscular tissue disorders (summarized in Fig. 2).

Liver

Basal autophagy is required to maintain liver homeostasis through the clearance of protein aggregates and damaged mitochondria in order to prevent hepatocyte swelling (Wang et al. 2015). Liver autophagy is mainly controlled by hormones. While insulin, aminoacids, and glucose inhibit liver autophagy, glucagon activates the process. Activation of autophagy contributes to lipophagy through fatty acid β-oxidation, ketone body production, and glucogenesis in the liver. Moreover, liver autophagy is involved in the control of very-low-density lipoprotein (VLDL) and plasma glucose concentrations upon nutrient deprivation (Sparks et al. 2013). Since liver and liver autophagy has an extremely important role in homeostasis, the impairment of autophagy in this organ causes vital disorders such as alcoholic liver disease, fatty liver disease, hepatocellular carcinoma (HCC), liver fibrosis, and viral infection in the liver (Niu et al. 2016).

Alcohol consumption activates autophagy in the liver through the AMPK pathway in hepatocytes (Wang et al. 2016). Autophagy activation leads to the removal of lipid droplets and damaged mitochondria, thus preventing cell death. However, if alcohol consumption becomes chronic, excess amounts of ethanol inhibit hepatocellular autophagy by blocking both AMPK activation and vesicular transport that is required for autophagosome formation (Cho et al. 2017). As a result, the accumulation of aggregated proteins and damaged mitochondria leads to cell death. Additionally, lipid droplets that cannot be removed through lipophagy causes steatosis and fatty liver disease.

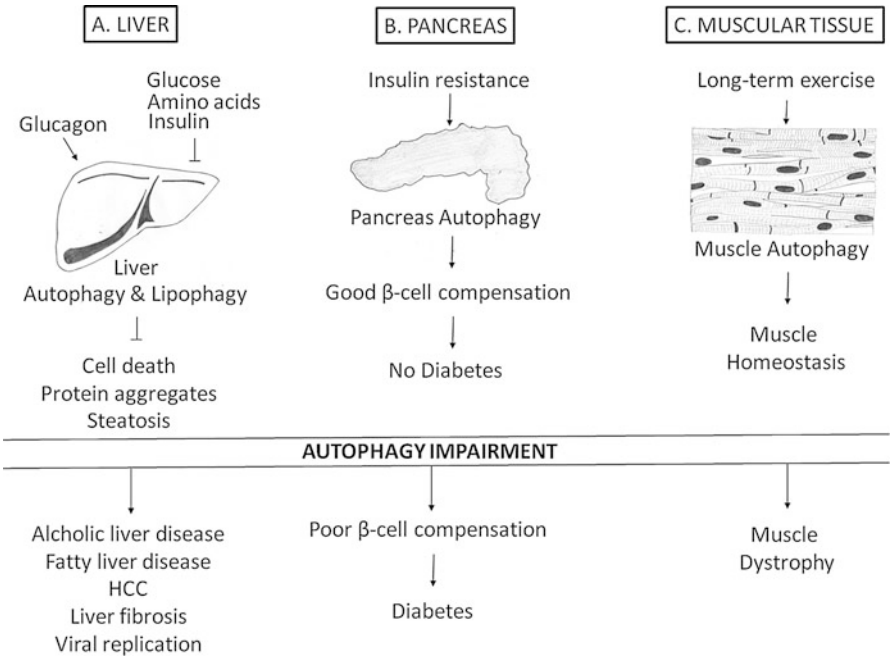

Fig. 2 The role of autophagy in liver, pancreas, and muscular tissue disorders. (**a**) Liver autophagy is inhibited by glucose, insulin, and amino acids under normal conditions. It is induced as the cytoprotective mechanism and increased glucagon level which lead to the inhibition of cell death, steatosis, and the accumulation of protein aggregates. Impaired liver autophagy may result in alcoholic and fatty liver disease, HCC, liver fibrosis, or viral replication in the liver. (**b**) Pancreatic autophagy is activated against insulin resistance to prevent poor β-cell compensation and diabetes. Since autophagy-defective cells cannot compensate the β-cells, diabetes occurs as a result of insulin resistance. (**c**) Muscle autophagy is activated after long-term exercise and maintain muscle cell homeostasis. Autophagy impairment in the muscular tissue result in macular dystrophy. Key: HCC, hepatocellular carcinoma

Hepatitis B and C viruses (HBV and HCV, respectively) require autophagy for their replication in hepatocytes. The viral proteins activate the PI3K complex and trigger autophagosome formation for their benefits (Vescovo et al. 2016). Therefore, regulation of autophagy in the liver is vital for viral infections that may end up with HCC.

Pancreas

Pancreatic β-cells are responsible for the storage and release of insulin (Morita et al. 2017). Pancreas autophagy has a significant role in maintaining β-cell homeostasis by keeping their mass and function properly. Impairment of autophagy results in dysfunctional β-cell and type-2 diabetes which is characterized by insulin resistance.

In vivo studies in ATG7 -/- mice have revealed that autophagy-defective β-cells lose their mass and insulin content, which causes suppressive insulin release (Rivera et al. 2014). Moreover, since autophagy is necessary for the clearance of damaged mitochondria, impaired autophagy in pancreatic β-cells leads to the rise of insulin resistance and impaired glucose tolerance (Xu et al. 2016).

Muscular Tissue

Similar to other organs, in muscle cells, autophagy is vital for organelle and protein aggregate clearance. However, excess amount of autophagy activation cause muscle weight loss. Impaired autophagy was also found as a main reason of malfunctional and dystrophic muscles after long-term exercise or starvation (Fiacco et al. 2016).

Autophagy is one of the major pathways of muscle homeostasis. It preserve myofiber integrity and prevents muscle damage. Autophagy impairment has been reported in several muscle diseases such as inclusion body myopathy with early-onset Paget disease and frontotemporal dementia (IBMPFD) (Bayraktar et al. 2016), Pompe Disease (Lim et al. 2017), and Danon Disease (Nascimbeni et al. 2017) (please see "Dictionary of Terms" section). In ATG7 null muscle cells obtained from ATG7-/- mice, distension of sarcoplasmic reticulum and random nonfunctional membrane structure accumulations were demonstrated (Mizushima and Komatsu 2011). All these effects may be the reason for muscular dystrophies which directly result in patient death due to myofibre necrosis in respiratory and cardiac systems.

Other Human Diseases Affected by Mutations in Starvation-Induced Autophagy Genes

Emerging molecular techniques and accumulated data about autophagy pathways allow researchers to carry out specific analyzes. Therefore, the involvement of autophagy, particularly on the molecular level, in human diseases is an attractive topic for clinical research. These diseases include asthma, systemic lupus erythematosus (SLE), Crohn's disease (CD), several types of cancers, and obesity (The diseases found to be directly related to the starvation-induced autophagy gene mutations are listed in Table 2.).

Asthma

Asthma is a common respiratory tract inflammation disease that causes high rates of death all over the world. Using a mice model, *in vivo* studies have showed that autophagy has a role in the clearance of pathogens in canonical ways, as well as its effect on helper T cell 2 (Th2) activation due to infection. Moreover, polymorphisms in ATG5 gene result in asthma symptoms in mice models (Martin et al. 2012; Pham et al. 2016).

Table 2 Known human diseases affected by mutations in starvation-induced autophagy genes. Impairments of starvation-induced autophagy resulted from ATG5 polymorphism, ATG16L T300A mutation, Beclin1 monoallelic deletion, mutations in PI3K and TSC1, or loss of ATG7 are the known causes of human diseases such as asthma, systemic lupus erythematosus, several types of cancer, and obesity. Key: ATG5, 7, and 16L, autophagy-related proteins 5, 7 and 16 like 1; T300A, threonine300 mutation to alanine; PI3K, phosphatidylinositol 3 kinase; TSC1, tuberous sclerosis complex 1

Mutation	Associated human disease
ATG5 polymorphism	Asthma (Martin et al. 2012), systemic lupus erythematosus (Zhou et al. 2011)
ATG16L T300A mutation	Crohn's disease (Massey and Parkes 2007)
Beclin 1 monoallelic deletion	Breast, ovarian, colorectal, and prostate cancers (Liang et al. 1999)
Gain of function mutations in PI3K	Cancer (Cully et al. 2006)
TSC1 mutation	Benign hamartomatous growths in multiple organs (Schwartz et al. 2007)
Loss of ATG7	Obesity (Yang et al. 2010)

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is an autoimmune disease that is described by the self-reaction of the immune system to healthy tissues and organs (Gavand et al. 2017). The pathogenesis of the disease is not clear yet; however, 50% of patients are affected genetically. In the Chinese population, rare variants ATG5 were shown to be linked to SLE. In other words, one of the reasons for SLE disease is ATG5 polymorphism (Zhou et al. 2011). Therefore, autophagy proteins could be a potential therapeutic target for SLE treatment.

Crohn's Disease

Crohn's disease (CD) is an inflammatory bowel disease characterized by multiple gastrointestinal pathology from mouth to anus (Stappenbeck et al. 2011). However, it is not classified as an autoimmune disease; it is an immune system disorder. Although genetic and environmental factors, infections, and defective autophagy are reported in CD, the causal etiologic factors are still unknown. Analyzing 735 CD patients' genotypes in comparison to healthy controls showed that the T300A mutation of ATG16 protein is responsible for Crohn's disease (Massey and Parkes 2007). However, it is not the only reason for CD.

Cancer

Genetic link between cancer and autophagy has been shown in various cancer types, including human breast, prostate, colorectal, and ovarian cancer (Sumis et al. 2016). Most of the studies have showed that Beclin 1 gene is monoallelically

deleted in most of the cancer types (Liang et al. 1999). Also, PI3K mutations cause tumor formation and TSC1 mutation leads to benign hamartomatous growths in multiple organs (Cully et al. 2006; Schwartz et al. 2007). As an evident to anticancer effect of autophagy, several studies have reported that the overexpression of ATG genes in cancer cells lead to tumor suppression (Wesselborg and Stork 2015). Although, autophagy is indeed a tumor suppressor pathway, the mechanisms and molecules playing part behind it remain largely unclear.

Obesity

Obesity is the medical condition, in which the body's fat rate is too much that negatively affects the body health (Yilmaz 2017). It is an excess amount of energy flow which disrupts the energy sensing and the utilizing mechanisms of the body. The role of autophagy in obesity was first studied in mice hepatocytes (Yang et al. 2010). In the study, obese mice hepatocytes represent low levels of ATG7 expression, while the restoration of ATG7 resulted in elevated insulin levels (Zhang et al. 2009). However, it is known that environmental conditions trigger tendency to obesity, which seems to lead autophagy impairments.

Policies and Protocols

Measuring autophagic activity at cellular level is crucial to identify therapeutic targets for diseases affected by autophagy impairments. In order to detect autophagy activation or inhibition, several molecular techniques are developed based on immunoblotting, immunofluorescence, or isotope release as described in Table 3.

Detection of autophagosomes and autolysosomes by electron microscopy can be used as a conventional autophagy procedure. By using immunoblotting technique, the conversion of cytosolic nonlipidated LC3-I into membrane-bound lipidated form of LC3-II is commonly used for analyzing autophagy induction. However, LC3 is not the direct target of autophagy, as it is degraded in autolysosomes after long-term autophagy. Therefore, LC3 turnover assay is carried out using autophagy inhibitors in order to estimate the level of LC3 protein degradation. Similarly, the GFP-tagged LC3 protein is overexpressed in mammalian cells and the amount of generated free GFP protein can be measured for autophagic activity estimation.

By using immunofluorescence, counting the average number of GFP-LC3 punctate structures on the autophagosome membranes or endogenous LC3 protein are other well-known autophagy techniques. RFP-GFP LC3 protein construct can be used to distinguish the number of autophagosomes and autolysosomes, since GFP signal is quenched by the acidic environment of autolysosomes.

Lastly, long-lived protein degradation can be measured by tracing the radioactive isotope released from the cells indicating active autophagy state.

Table 3 Protocols for detecting autophagy in mammalian cells. Immunoblotting, immunofluorescence, and isotope release are the three main protocols for detecting autophagy in mammalian cells. LC3 conversion, LC3 turnover, and GFP-LC3 cleavage tests can be carried out and the amount of p62 in the cell can be detected by using immunoblotting procedures. Number of LC3 puncta/cell, RFP-GFP LC3 color change, and the amount of p62 in the cell can be measured by using immunofluorescence techniques; while lysosome-dependent long-lived protein degradation tests can be carried out by using isotope release protocols. Key: LC3, microtubule-associated protein 1 light chain 3; GFP, green fluorescent protein; RFP, red fluorescent protein

Immunoblotting	Immunofluorescence	Isotope release
1. LC3 conversion 2. LC3 turnover 3. Amount of p62 in the cell 4. GFP-LC3 cleavage	1. Number of LC3 puncta/cell 2. Amount of p62 in the cell 3. RFP-GFP LC3 color change	1. Lysosome-dependent long-lived protein degradation

Dictionary of Terms

- **Cellular stress** – Anything that creates a challenge or a constraint to cell health. Cellular stress can be intrinsic, such as DNA damage, misfolded protein accumulation, and damaged organelles; or extrinsic, such as starvation, toxins, pathogens, toxins, heat, etc.
- **Danon disease** – An X-linked glucagon storage disorder that is characterized by weakened skeletal and cardiac muscle combined with mental retardation.
- **Glucagon** – The hormone that is produced and secreted by pancreatic α-cells. Its role is opposite to insulin, as it increases the glucose levels in the blood.
- **Glucogenesis** – The production of glucose by the breakdown of glycogen that is stored in the liver.
- **Homeostasis** – Disposition of a physiological system to preserve its internal stability and to keep vital functions active
- **IBMPFD** – Inclusion body myopathy with early-onset Paget disease and frontotemporal dementia, which is a rare multisystem disease characterized by the weakness of muscles and bones in combination to intellectual disability.
- **Insulin** – The hormone that is produced in pancreatic β-cells and secreted into blood stream where it meets with glucose and enables it to enter the cells where needed. If glucose level is higher than needed in the blood, pancreatic β-cells produce and secrete more insulin in order to store the excess amount of glucose. Therefore, insulin is the key hormone that keeps blood sugar level stable.
- **Insulin resistance** – The pathological condition in which the cells do not recognize insulin and the blood sugar cannot be utilized by the cells. As a result of insulin resistance, the blood sugar level gets higher than the normal.
- **Ketone bodies** – The water-soluble molecules that are produced in the liver, as the end product of fatty acid oxidation due to energy limitation in the body. There are two main types of ketone bodies: acetoacetate and 3-beta-hydroxybutyrate

and the spontaneous breakdown product of them is acetone which can be counted as the third type of ketone bodies that are present in the blood.

- **Lipolysis** – Breakdown of lipid molecules by the hydrolysis of triglycerides to free fatty acids and glycerol.
- **Pompe disease** – A genetically inherited glucose storage disorder that result in the accumulation of glycogen in muscle cells disabling them to function normally.
- **Proteolysis** – Breakdown of proteins into aminoacids or smaller aminoacids by protease enzyme activity.

Summary Points

- This chapter focuses on the recent findings about autophagy mechanism and its role in the body response to the starvation as well as the current knowledge of autophagy-related malnutrition disorders.
- Autophagy is a cellular degradation pathway that deliver cytoplasmic components such as damaged organelles, misfolded proteins, and pathogens to the lysosomes.
- Autophagy is associated to the survival of the cell under stress conditions and infections. The role of autophagy in cell survival is summarized in Fig. 3.

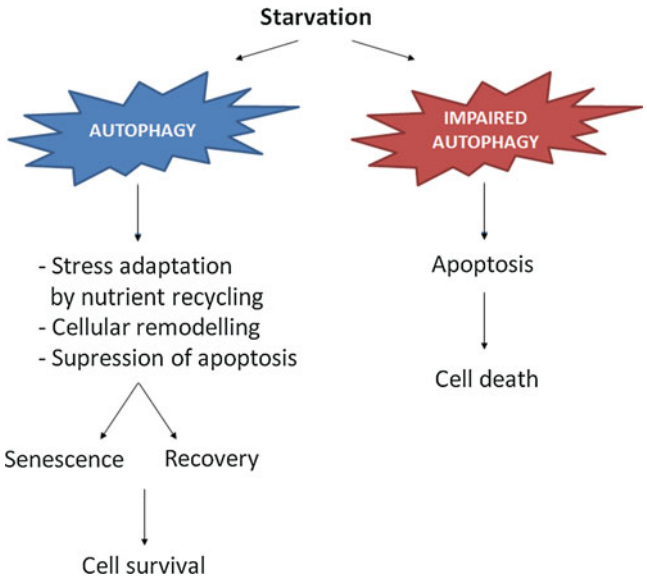

Fig. 3 The role of autophagy in cell survival. (*Left*) Autophagy acts as a survival mechanism of the cell supporting the cellular adaptation under stress conditions by nutrient recycling and cellular remodeling; (*Right*) impaired autophagy result in the rapid cell death since apoptotic pathway cannot be inhibited

- Nutrient deprivation is one of the main inducers of autophagy that recycle cytoplasmic components to provide building blocks required for cell survival and maintain cellular homeostasis
- Autophagic responses are necessary for resisting diseases and maintaining health.
- Understanding the regulation of autophagic responses in mammalian cells are required for improving human health by innovations in treatment strategies.

to degrade cargo in a selective manner. Mitochondria can be degraded through mitochondria-specific autophagy, which is termed mitophagy, and several important factors have been identified in yeast and mammals. Atg32, a mitochondrial membrane protein, functions as a receptor during mitophagy under starvation in yeast. Post-translational modification of Atg32 induces mitochondrial degradation. In mammals, several different factors for mitophagy have been reported from different research groups. In this review, we summarize the molecular mechanisms of mitophagy in yeast and mammals with respect to Atg32 in yeast and its functional homolog in mammals.

Keywords

Autophagy · Mitophagy · Mitochondria · *Saccharomyces cerevisiae* · Nitrogen starvation · Atg32 · Casein kinase · MAP kinase · Hypoxia · Tor kinase

List of Abbreviations

AIM	ATG8 interacting motif
ALS	Amyotrophic lateral sclerosis
ATG	Autophagy-related
BCL2L13	Bcl2-like13
BNIP3	BCL2/adenovirus E1B 19-kDa-interacting protein 3
BNIP3 like	BNIP3L
CALCOCO2/NDP52	Calcium binding and coiled-coil domain 2
CK2	Casein kinase 2
Drp1	Dynamin-related protein 1
ERK	Extracellular signal-regulated kinase
FUNDC1	FUN14 domain-containing protein 1
IMM	Inner mitochondrial membrane
LIR	LC3-interacting region
MAPK	Mitogen-associated protein kinase
MEK	MAPK/ERK kinase
MFF	Mitochondrial fission factor
MFN	Mitofusin
MiD	Mitochondrial dynamics protein
MKK	MAP kinase kinase
MLK	Mixed-linage protein kinase
mtROS	Mitochondrial ROS
NBR1	Neighbor of BRCA1 gene 1
OMM	Outer mitochondrial membrane
OPA1	Optic atrophy 1
OPAG	Primary open angle glaucoma
OPTN	Optineurin
PAS	Pre-autophagosomal structure
PI3K	Phosphatidylinositol 3-kinase
PI3P	Phosphatidylinositol 3-phosphate
PINK1	PTEN-induced putative kinase 1

RAF	Rapidly accelerated fibrosarcoma
ROS	Reactive oxygen species
TAX1BP1	TAX1 binding protein 1
TOR	Target of rapamycin

Introduction

In eukaryotic cells, there are two major pathways for protein degradation called autophagy and the ubiquitin–proteasome system. Generally, autophagy is a non-selective bulk degradation pathway, whereas the ubiquitin–proteasome system is selective (Hershko et al. 2000; Coux et al. 1996). This non-selective autophagy is generally termed macroautophagy, which functions not only at the basal level of protein turnover but also in considerable degradation of cytoplasmic components under starvation. Macroautophagy contributes to maintaining cellular amino acid pools for basal protein synthesis for cellular survival (Takeshige et al. 1992; Nakatogawa et al. 2009). However, recently, some types of autophagy were found to degrade specific substrates selectively. Protein aggregates, organelles, and invading bacteria are degraded by autophagy selectively (Johansen and Lamark 2011; Komatsu et al. 2007). Additionally, mitochondria are also known to be degraded by selective autophagy, which is termed mitophagy (Lemasters 2005) and is conserved from yeast to mammals.

Mitochondria are double membrane-bound organelles and play a pivotal role in cellular metabolism, including ATP synthesis, calcium buffering, regulation of apoptosis, β-oxidation of fatty acids, and thermogenesis (Mcbride et al. 2006; Brookes et al. 2004; Wallace 2005; Wanders et al. 2010; Gambert and Ricquier 2007). Therefore, quality control of mitochondria is important for maintaining cellular activity. Mitochondrial activity is maintained by mitochondrial interaction through their fusion and fission (Nakada et al. 2001). When inactive portions or damaged portions of mitochondria emerge, they can be complimented by fusion with a healthy mitochondrial portion. Additionally, when the mitochondrion is severely damaged, the damaged portion of the mitochondrion is excluded from the healthy mitochondrial network by fission and is then degraded by mitophagy (Twig et al. 2008). Accordingly, mitophagy might prevent accumulation of damaged mitochondria within the cells and prevent cellular damage by reactive oxygen species (ROS) produced from damaged mitochondria. Mitochondrial ROS are potentiated in mitophagy-defective yeast cells and cause mitochondrial DNA deletion and growth defects (Kurihara et al. 2012).

In budding yeast, Atg32 is the master regulator for mitophagy (Kanki et al. 2009; Okamoto et al. 2009). Atg32 is an outer mitochondrial membrane (OMM) protein and binds with cytosolic Atg11. Atg11 is an adaptor protein for selective autophagy that allows selective degradation of mitochondria (Kanki et al. 2009; Okamoto et al. 2009).

In contrast to yeast, several types of mitophagic pathways have been reported in mammalian cells. One of the well-studied pathways is PTEN-induced putative

kinase 1 (PINK1)-Parkin-mediated mitophagy. PINK1 and Parkin are causative genes of familial Parkinson's disease. Recent studies have shown that PINK1 and Parkin accumulate on damaged mitochondria and induce its degradation (Narendra et al. 2008). Another type of mitophagy is mitochondrial receptor-mediated mitophagy. Several mitophagy receptors have been identified, including BCL2/adenovirus E1B 19-kDa-interacting protein 3 (BNIP3) (Zhu et al. 2013; Thomas et al. 2011), BNIP3L/NIX (Schweers et al. 2007; Sandoval et al. 2008), FUN14 domain-containing protein 1 (FUNDC1) (Liu et al. 2012), and Bcl2-like 13 (BCL2L13) (Murakawa et al. 2015). Unfortunately, these receptors were evaluated by mutually different methods. Therefore, the priority and importance of these proteins in several situations and tissues remain unclear. In this review, we summarize the molecular mechanisms, signal transduction, and physiological relevance of mitophagy in yeast and mammals.

Molecular Mechanisms and Signaling of Autophagy

Autophagy is a subcellular degradation pathway and is drastically induced by starvation. Upon starvation, a membranous structure termed the isolation membrane/phagophore first emerges at the initiation site of autophagosome formation and then elongates and engulfs the cargo. Eventually, a double membrane-bound structure (termed an autophagosome) containing the cargo is formed and then fuses with vacuoles/lysosomes. Many proteins required for autophagy have been identified. Autophagy proceeds through the functions of autophagy-related proteins termed ATG proteins. More than 40 proteins belonging to this family have been identified (Itakura and Mizushima 2010; Koyama-Honda et al. 2013). ATG proteins can be divided into several functional groups, including the ATG1/ULK1 complex (ATG1/ULK1/2, ATG13, ATG17/FIP200, ATG101) (Hosokawa et al. 2009; Jung et al. 2009), ATG9 vesicle, the class III phosphatidylinositol 3-kinase (PI3K) complex (VPS34, VPS15/p150, ATG14, ATG6/Beclin1), phosphatidylinositol 3-phosphate (PI3P)-binding proteins and their interaction partner proteins (ATG18/WIPIs, ATG2, DFCP1), and two ubiquitin-like conjugation systems (ATG12, ATG7, ATG10, ATG5 and ATG8, ATG7, ATG3). These core ATG proteins are conserved from yeast to mammals and required for almost all autophagic pathways (listed in Table 1).

In the process of autophagosome formation (Fig. 1), the ATG1/ULK1 complex and ATG9 are initially recruited to the site for initiation of autophagosome formation, termed the pre-autophagosomal structure (PAS). The PAS is adjacent to vacuoles in yeast or a site close to the endoplasmic reticulum in mammals (Nakatogawa et al. 2009; Hamasaki et al. 2013). ATG9 localizes on the vesicle, shuttling between the Golgi apparatus, endosomes, and the initiation site for autophagosome formation (Young et al. 2006; Orsi et al. 2012). After ATG1/ULK1 complex and ATG9 vesicle recruitment to the initiation site, the PI3K complex localizes at the site and forms PI3P. PI3P-binding proteins localize at the site through binding to PI3P and contribute to elongation of the isolation

Table 1 Autophagy-related proteins in yeast and mammals

Yeast	Mammal	Function
Atg1/ULK1 complex		
Atg1	ULK1/2	Serine/threonine proteinkinase
Atg13	Atg13	Component of Atg1/ULK1 complex
Atg17	FIP200	Component of Atg1/ULK1 complex
	Atg101	Component of Atg1/ULK1 complex
Phophatidylinositol 3-kinase complex		
Atg14	Atg14L	Component of Class III PI3K complex
Atg6/ Vps30	Beclin1	Component of Class III PI3K complex
Vps34	Vps34	Catalytic subunit of Class III PI3K complex
Vps15	Vps15	Component of Class III PI3K complex
Phosphatidylinositol 3 phosphate binding proteins and Atg9 vesicle cycling		
Atg18	WIPI1/2/3/4	WD40 repeat protein, PI3P binding protein
Atg9	Atg9A, Atg9B	Transmembrane protein
Atg2	Atg2A, Atg2B	Atg9 vesicle cycling
Ubiquitin-like conjugation system		
Atg8	LC3A/B/C, GABARAP, GABARAPL1/2/3	Conjugated to phosphatidylethanolamine
Atg12	Atg12	Conjugated to Atg5
Atg4	Atg4A/B/C/D	Cysteine protease for C-terminal region of Atg8 family proteins
Atg7	Atg7	E1-like enzyme for Atg8 family and Atg12 conjugation system
Atg3	Atg3	E2-like enzyme for Atg8 family proteins
Atg10	Atg10	E2-like enzyme for Atg12 family proteins
Atg5	Atg5	Conjugated by Atg12
Atg16	Atg16L	Component of Atg12-Atg5-Atg16 complex

membrane (Polson et al. 2010; Proikas-Cezanne et al. 2004). Two ubiquitin-like conjugation systems then mediate closure of the isolation membrane. Finally, the autophagosome fuses with a vacuole/lysosome and the cargo is degraded by vacuolar/lysosomal proteinases. The autophagosome–lysosome fusion step is mediated through an interaction between syntaxin 17, an autophagosomal soluble *N*-ethylmaleimide-sensitive factor activating protein receptor, and the homotypic fusion and protein sorting-tethering complex (Itakura et al. 2012; Jiang et al. 2014). Starvation signals enter the initial complex of autophagy, the ATG1/ULK1 complex, via nutrient-sensing kinases. Under nutrient-rich conditions, target of rapamycin (TOR) kinase/mammalian TOR (mTOR) kinase inhibits the ATG1/ULK1 complex by phosphorylation of ULK1 and ATG13. Under starvation conditions, TOR/mTOR kinase is inactivated, resulting in dephosphorylation and activation of ULK1 and ATG13 (Fujioka et al. 2014; Hosokawa et al. 2009; Kamada et al. 2000).

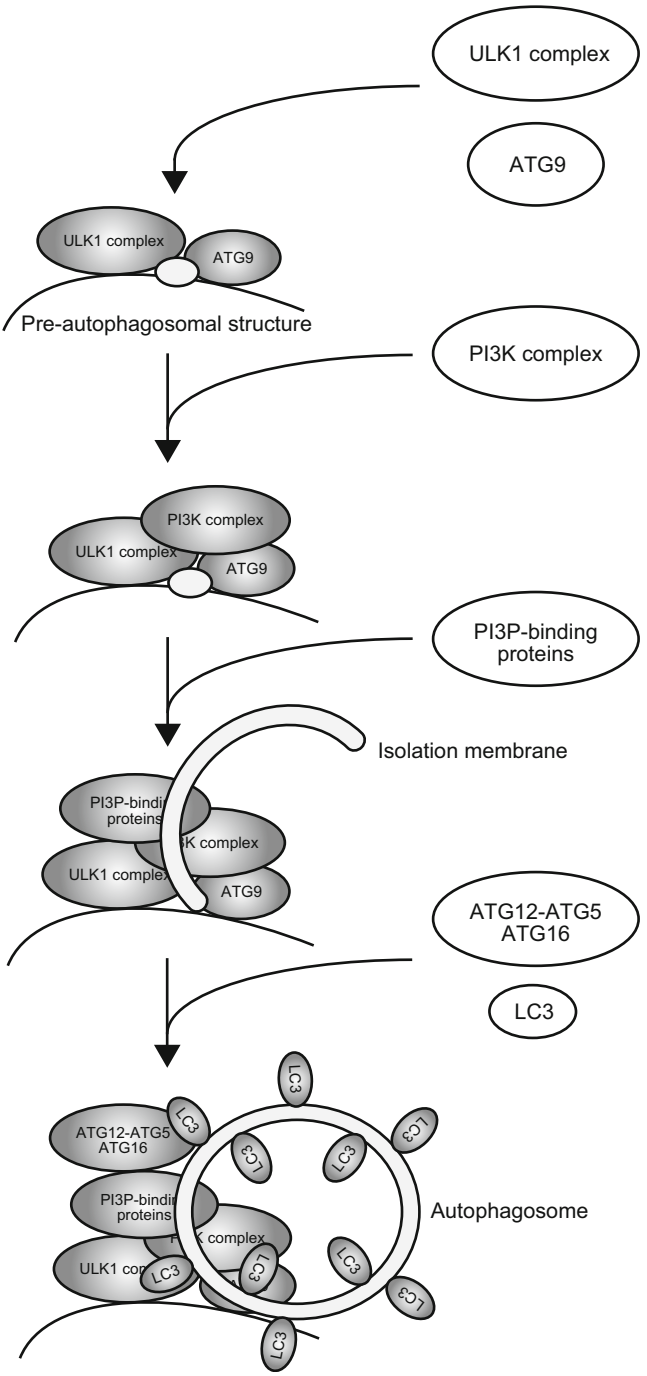

Fig. 1 (continued)

Signaling Pathways of Starvation for Inducing Mitophagy in Yeast

Nitrogen starvation is the most commonly used cellular stress to induce mitophagy in yeast. However, the cells are usually pre-cultured in medium with a non-fermentable carbon source as the sole carbon source before nitrogen starvation to enhance the level of mitophagy. Two mitogen-activated protein (MAP) kinases (Hog1 and Slt2) are involved in mitophagy. The upstream factors of Hog1 signaling, Sln1, Ssk1, and Pbs2, and the upstream factors of Slt2 signaling, Wsc1, Pkc, Bck, and Mck1/2, are also involved in induction of mitophagy (Mao et al. 2011). This suggests that the cell wall osmosensor Sln1 and the stress sensor Wsc1 recognize cellular stress by starvation and activate the Hog1 and Slt2 signaling cascade to induce mitophagy. However, downstream of Hog1 and Slt2 is not well understood.

Starvation inactivates TOR kinase. It was shown that expression levels of a key factor of mitophagy, Atg32, were suppressed by Tor kinase and its downstream histone deacetylase complex (Ume6-Sin3-Rpd3) under normal conditions. Upon starvation or rapamycin treatment, TOR kinase and the downstream complex Ume6-Sin3-Rpd3 were inactivated, and then expression of Atg32 was increased (Aihara et al. 2014). This regulation of Atg32 expression is important to efficiently induce mitophagy responding to starvation. The expressed Atg32 targets the mitochondrial outer membrane and is phosphorylated by starvation. This phosphorylation is essential for mitophagy (see below).

Atg32, a Receptor Protein for Mitophagy

Atg32, which is an outer mitochondrial membrane protein, is required for mitophagy in yeast. Atg32 has a single transmembrane domain and its N-terminus is oriented toward the cytoplasm (Fig. 2). After nitrogen starvation, two serine residues, Ser 114 and 119, on the cytoplasmic region of Atg32 are phosphorylated by casein kinase 2 (CK2) (Aoki et al. 2011; Kanki et al. 2013). Phosphorylated Atg32 then interacts with cytoplasmic Atg11, an adaptor protein for selective autophagy. Finally, Atg11 anchors mitochondria on the PAS for selective degradation. Therefore, the phosphorylation-mediated Atg32–Atg11 interaction is essential for mitochondrial recognition as cargos. However, how phosphorylation of Atg32 by CK2 is regulated under starvation is still unclear.

Atg8, an ubiquitin-like modifier, is conjugated to phosphatidylethanolamine, which is located on the isolation membrane. The interaction between Atg8 and

Fig. 1 Atg proteins in autophagosome formation. The Atg1/ULK1 complex and Atg9 vesicle are initially recruited to the site for autophagosome formation, resulting in the pre-autophagosomal structure (*PAS*). Subsequently, the phosphatidylinositol 3-kinase (*PI3K*) complex localizes at the site and forms phosphatidylinositol 3-phosphate (PI3P). PI3P-binding proteins localize at the site through PI3P-binding. Finally, two ubiquitin-like conjugation systems mediate closure of the isolation membrane, resulting in autophagosomes

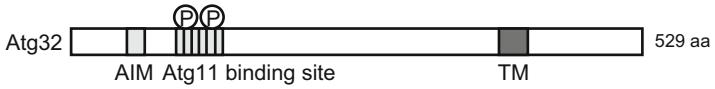

Fig. 2 Functional domains of Atg32 for mitophagy. Atg32, an outer mitochondrial membrane protein, consists of a C-terminal single transmembrane domain and N-terminal cytosolic region. The N-terminal region has two functional domains of the Atg8-family-interacting motif (*AIM*) and Atg11-binding site. Under starvation conditions, phosphorylation at Ser 114 and 119 by casein kinase 2 is required for binding with Atg11

receptor proteins for selective autophagy through the Atg8-interacting motif (AIM)/LC3-interacting region (LIR) is important for selective autophagy. The consensus sequence of AIM (W/Y-X-X-L/I/V) can be found in almost all receptor proteins for selective autophagy from yeast to mammals. Atg32 also possesses an AIM in its cytoplasmic region and interacts with Atg8 (Okamoto et al. 2009). In this case, however, an AIM is not essential for mitophagy because an Atg32 mutant lacking AIM, which cannot interact with Atg8, only has a partial effect on mitophagy (Kondo-Okamoto et al. 2012). Therefore, the Atg32–Atg8 interaction may facilitate engulfment of mitochondria by autophagosomes via tethering mitochondria to the isolation membrane.

Mitophagy in Mammals

Mitochondrial Receptor Proteins for Mitophagy in Mammalian Cells

In mammalian cells, some functional counterparts of Atg32 in yeast, receptor proteins for mitophagy, have been reported by several groups. All of the receptor proteins, FUNDC1, BNIP3, BNIP3L/Nix, and BCL2L13, are outer mitochondrial membrane proteins and have AIM/LIR in their cytoplasmic region (Fig. 3). LC3 is a mammalian homolog of Atg8 and is localized on the isolation membrane. Mitophagy receptor proteins interact with LC3 via LIR and facilitate engulfment of mitochondria by autophagosomes. Similar to Atg32 in yeast, the function of these mitophagy receptors are thought to be regulated by their phosphorylation. These receptor proteins for mitophagy in mammalian cells are summarized below.

FUNDC1

FUNDC1 has three transmembrane domains and exposes its N-terminal region containing LIR to the cytoplasm. Under normal cell culture conditions, Ser 13 and Tyr 18 on FUNDC1 are phosphorylated by CK2 and Src kinase, which inhibit the interaction between FUNDC1 and LC3 (Liu et al. 2012; Chen et al. 2014). Upon mitophagic conditions, such as hypoxia or depolarization of the inner mitochondrial membrane (IMM), dephosphorylation of Ser 13 on FUNDC1 is induced by the phosphoglycerate mutase family member 5 phosphatase. This leads to activation of

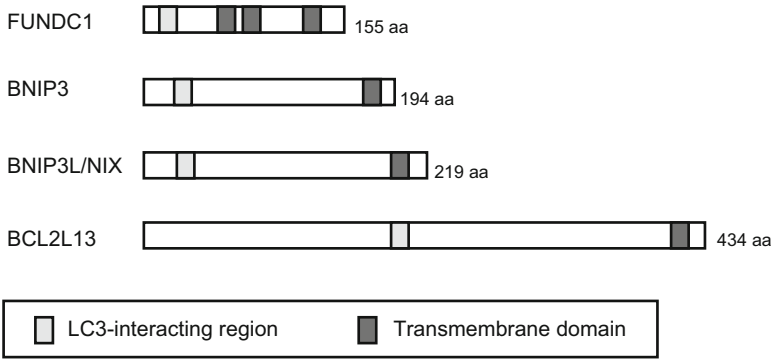

Fig. 3 Mitophagy receptor proteins in mammalian cells. FUNDC1, BNIP3, BNIP3L/NIX, and BCL2L13 are localized at the outer mitochondrial membrane through C-terminal transmembrane domains, and N-terminal regions are oriented toward the cytoplasm. The LC3-interacting region (*LIR*) is located at the N-terminal region of these receptors

an interaction with LC3 proceeding mitophagy. Additionally, Ser 17 on FUNDC1 is phosphorylated by ULK1, and this phosphorylation enhances FUNDC1 interaction with LC3 (Wu et al. 2014).

BNIP3 and BNIP3L

BNIP3 and its homolog BNIP3L/NIX are BH3-only proteins and members of the pro-apoptotic BCL2 family. They are localized on the OMM via their C-terminal transmembrane domains, and their N-terminal regions are exposed to the cytoplasm. Under hypoxic conditions, expression of BNIP3 and BNIP3L/NIX is increased at the transcriptional level by stabilization of hypoxia-inducible factor 1. BNIP3 and BNIP3L/NIX can induce loss of the mitochondrial membrane potential, permeability of the OMM, and cell death through their homodimerization (Kubli et al. 2007; Chen et al. 2010). In addition to cell death, these proteins can also induce macroautophagy and mitophagy. The N-terminal regions of BNIP3 and BNIP3L/NIX contain LIR and can interact with LC3 upon mitophagy. In the case of BNIP3, Ser 17 and 24 adjacent to the LIR are phosphorylated by an unidentified kinase. Phosphorylation of BNIP3 on Ser 17 is required for its interaction with LC3, whereas phosphorylation at Ser 24 only enhances the affinity (Zhu et al. 2013). BNIP3L/NIX-dependent mitophagy is particularly important for elimination of mitochondria during maturation of erythroid cells (Sandoval et al. 2008). In this case, BNIP3L/NIX induces loss of the mitochondrial membrane potential and autophagic elimination of mitochondria. BNIP3 and BNIP3L/NIX are also involved in regulation of bulk autophagy as upstream signal transduction machinery. Under hypoxic conditions, BNIP3 and BNIP3L/NIX expression levels are increased. This can lead to release of Beclin1, an essential component of the autophagy-specific PI3K complex, from complexes with Bcl-XL and Bcl-2 through their competitive binding with Bcl-proteins (Bellot

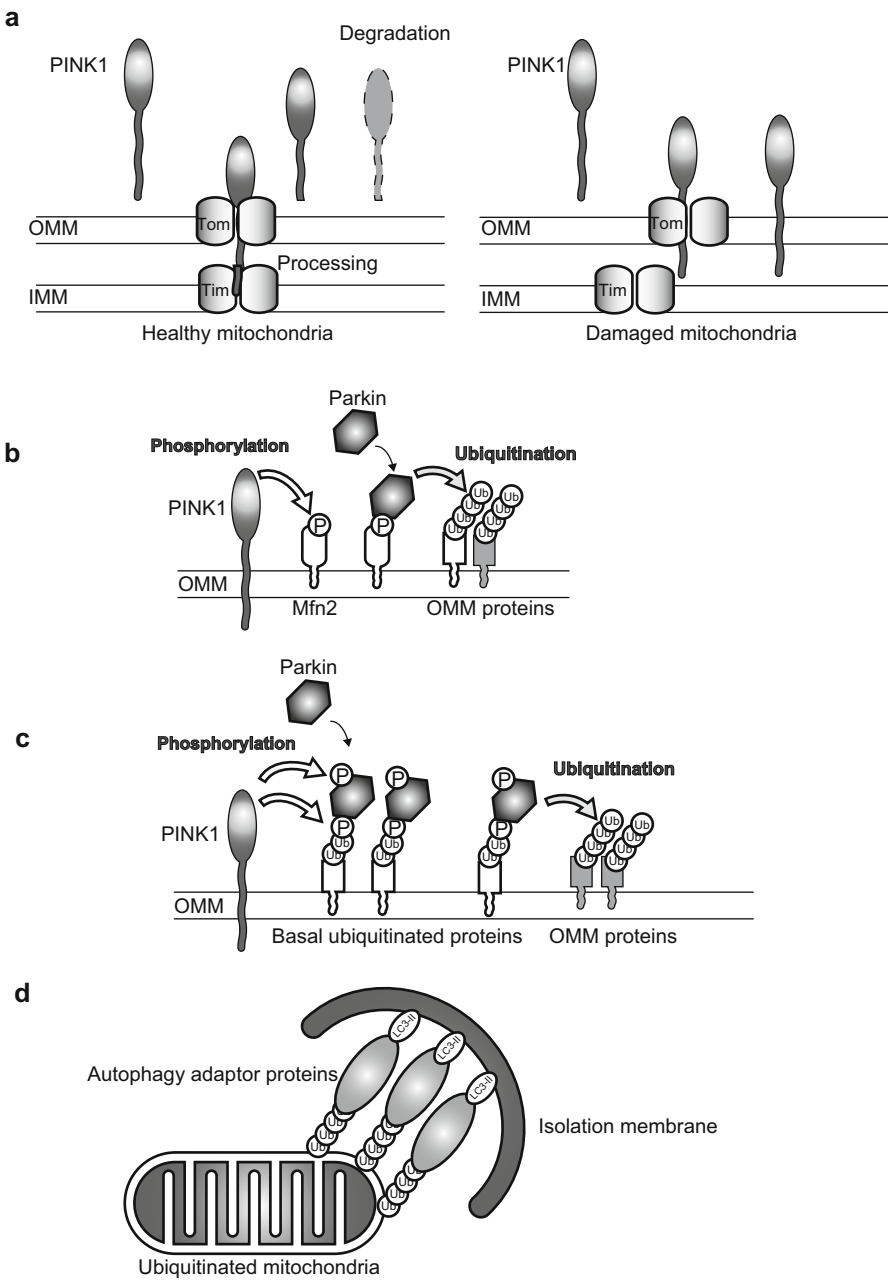

Fig. 4 PINK1-Parkin-mediated mitophagy. (**a**) PINK1 is constitutively targeted to the inner mitochondrial membrane (*IMM*). IMM targeted-PINK1 is degraded in healthy mitochondria, while it is stabilized at the outer mitochondrial membrane (*OMM*) in damaged mitochondria. (**b**) PINK1 phosphorylates mitofusin 2 (*Mfn2*) and Parkin is translocated to the OMM through binding

et al. 2009). Further, BNIP3 and BNIP3L/NIX can bind to Rheb GTPase, a factor for mTOR complex 1 (mTORC1) activation, and enhance autophagic activity by inactivation of mTORC1 activity (Li et al. 2007).

Bcl2L13

Recently, Bcl2-like 13/Bcl-Rambo (BCL2L13) was identified as one of the functional counterparts of Atg32. Similar to Atg32 and the other mitophagy receptor proteins in mammals, BCL2L13 also localizes at the OMM via the C-terminal transmembrane domain and its N-terminal region is exposed to the cytoplasm. The LIR is found in the N-terminal region, and it can interact with LC3 upon mitophagic conditions. Mutation at S272A adjacent to the LIR in BCL2L13 causes a decrease in the binding affinity to LC3. Therefore, the binding between BCL2L13 and LC3 is likely regulated by phosphorylation at Ser 272, resembling the other adaptor proteins for mitophagy (Murakawa et al. 2015).

Autophagy Adaptor Proteins in PINK1 and Parkin-Related Mitophagy

In the last decade, PINK1- and Parkin-mediated mitophagy has been extensively examined (Fig. 4). Serine/threonine kinase PINK1 and the E3 ubiquitin ligase Parkin are encoded by PARK6 and PARK2, respectively, and they are linked to familial Parkinson's disease. PINK1 is constitutively targeted to the IMM via a mitochondrial targeting sequence at its N-terminal region. IMM-targeted PINK1 is rapidly degraded by the combination of presenilin-associated rhomboid-like protein and the proteasome (Jin et al. 2010; Matsuda et al. 2010). Therefore, mitochondrial PINK1 is maintained at a low level in healthy mitochondria (Fig. 4a). However, upon loss of the mitochondrial membrane potential, PINK1 cannot translocate IMM and is accumulated on the OMM (Fig. 4a). OMM-localized PINK1 recruits Parkin from the cytoplasm to mitochondria through its kinase activity dependent pathways. The molecular mechanism for PINK1 recruiting Parkin is not well understood. One possible mechanism is that PINK1 phosphorylates mitofusin 2 (Mfn2) and phosphorylated Mfn2 interacts with Parkin on the OMM (Chen and Dorn 2013) (Fig. 4b). Another possible mechanism is that PINK1 phosphorylates the ubiquitin-like domain of Parkin and ubiquitin. This phosphorylation contributes to recruitment of

Fig. 4 (continued) with phosphorylated Mfn2. (**c**) PINK1 phosphorylates ubiquitin (*Ub*) on the OMM and Parkin is recruited to the OMM through binding with phosphorylated Ub. PINK1 activates ubiquitin ligase activity of Parkin through its phosphorylation and induces further ubiquitination of OMM proteins. (**d**) Autophagy adaptor proteins link ubiquitinated mitochondria to the isolation membrane through binding between autophagy adaptor proteins and LC3-II

Parkin to the OMM (Kane et al. 2014; Koyano et al. 2014) (Fig. 4c). Once Parkin is recruited on the OMM, Parkin ubiquitinates mitochondrial proteins (Fig. 4b, c). Autophagy adaptor proteins, including p62, neighbor of BRCA1 gene 1 (NBR1), optineurin (OPTN), calcium-binding and coiled-coil domain 2 (CALCOCO2/NDP52), and TAX1 binding protein 1 (TAX1BP1), have a ubiquitin-binding domain and LIR and can interact with ubiqutinated proteins and the isolation membrane (Fig. 4d). Therefore, these adaptor proteins function in selective autophagy of ubiquitinated proteins. In the case of PINK1-Parkin-mediated mitophagy, OPTN, NDP52, and TAX1BP1 function as autophagy adaptors to recognize and degrade ubiquitinated mitochondria (Lazarou et al. 2015). Notably, OPTN has several mutations that cause amyotrophic lateral sclerosis (ALS) and primary open angle glaucoma (POAG), and these mutations are involved in mitophagy flux. ALS mutation of OPTN is more effective than POAG (Maruyama et al. 2010; Rezaie et al. 2002). This suggests that in addition to Parkinson's disease, deficiency of mitophagy may contribute to the onset of ALS and POAG.

Regulation of Mitochondrial Morphology in Response to Starvation

Mitochondrial morphology is regulated by fission and fusion (Bereiter-Hahn and Voth 1994). Mitochondrial fission and fusion are maintained by dynamin-like GTPases, including dynamin-related protein 1 (Drp1) (Otera et al. 2013), Mfn1, Mfn2, and optic atrophy 1 (OPA1) (Cipolat et al. 2004; Santel and Fuller 2001). In the case of mitochondrial fission, cytoplasmic Drp1 localizes on the OMM through its modification-dependent recruitment. Drp1 binds to OMM-anchored receptor proteins, including mitochondrial fission factor (Mff) and mitochondrial dynamics proteins of 49 and 51 kDa (MiD49 and MiD51). During mitochondrial fission, the GTP-binding form of Drp1 oligomerizes and wraps around mitochondria at the fission site and then constricts their membrane through GTP hydrolysis (Otera et al. 2013). Therefore, recruitment of Drp1 on the OMM dependent on Mff, MiD49, or MiD51 and GTPase activity is essential for mitochondrial fission. Recruitment of Drp1 to the OMM is also regulated through post-translational phosphorylation at several different sites. Under starvation conditions, protein kinase A is activated by increased levels of cyclic AMP and phosphorylates Drp1 at Ser 637. This results in inhibition of recruitment of Drp1 to the OMM. Phosphorylation at Ser 637 is negatively regulated by calcineurin, calcium, and calmodulin-dependent phosphatase (Gomes et al. 2011). Mitochondrial fusion is activated under conditions of stress, including serum and amino acid deprivation (Tondera et al. 2009). Therefore, mitochondria are elongated upon starvation. The physiological relevance of morphological regulation of mitochondria is protection from unexpected elimination through non-selective macroautophagy upon starvation. Elongated mitochondria are thought to be too large to be engulfed by autophagosomes and mitochondrial fission events prior to enwrapping might be required for mitophagy. However, elongated mitochondria can be degraded by mitophagy in Drp1-deficient cells. Interestingly, in

the course of mitophagy, the mitochondrial portion that is destined for degradation in tubular mitochondria is first recognized by the isolation membrane, and then this portion is budded and separated concomitant with autophagosome formation (Yamashita et al. 2016). This suggests that mitochondria-specific autophagy is not induced at the early stage of starvation, whereas non-selective autophagy is induced, and protection of mitochondria is only from non-selective autophagy.

Furthermore, starvation-induced mitochondrial elongation potentiates mitochondrial ATP synthesis by possessing more cristae, and increasing dimerization and activation of ATP synthase on the IMM. Cells that are deficient in mitochondrial elongation upon starvation consume cytoplasmic ATP to maintain the mitochondrial membrane potential, resulting in cell death (Gomes et al. 2011). These findings suggest that regulation of mitochondria in response to starvation plays an important role in cellular survival.

Signaling Pathway for Starvation-Induced Mitophagy in Mammals

As mentioned above, at the early stage of starvation, mitochondria are enlarged through inhibition of fission and induction of fusion, and as a result, autophagic degradation of mitochondria is inhibited (Gomes et al. 2011). However, mitochondria can be degraded by autophagy under long-term starvation (Hirota et al. 2015). In this case, similar to yeast, two MAP kinase cascades, the extracellular signal-regulated kinase (ERK) 1/2 and p38 pathways, are required for mitophagy. Upstream kinases, rapidly accelerated fibrosarcoma (RAF) and MAPK/ERK kinase (MEK) 1/2 for ERK1/2, mixed-linage protein kinase (MLK) 3 and MAP kinase kinase (MKK) 3/6 for p38, are also involved in starvation-induced mitophagy (Hirota et al. 2015). With regard to the p38 signaling pathway, Hog1, a yeast homolog of p38, is also required for mitophagy. This suggests that the p38 MAP kinase cascade in starvation-induced mitophagy is conserved from yeast to mammals (Mao et al. 2011; Kanki et al. 2013). Furthermore, BNIP3L is required for starvation-induced mitophagy, whereas Parkin is dispensable (Hirota et al. 2015).

Physiological Relevance of Mitophagy

The majority of cellular ATP is produced by oxidative phosphorylation complexes of the IMM. In this process, the mitochondrial membrane potential is formed through the electron transport chain and used as the driving force of ATP synthase in the IMM. Although most of the electrons pass through the oxidative phosphorylation complexes, some electrons occasionally leak out from them constitutively. These electrons eventually cause formation of ROS (mitochondrial ROS, mtROS), and thus mitochondria are constitutively exposed to mtROS and eventually disordered. To protect cells from excess ROS, damaged mitochondria, which produce further mtROS, must be eliminated. Mitophagy-deficient Atg32 or Atg11 knockout yeast

strains cause abnormalities of mitochondrial DNA and show petite colony formation by culturing in stressful conditions, such as starvation (Kurihara et al. 2012). In this case, the ROS scavenger N-acetylcysteine can suppress the phenotype, suggesting that excess mtROS emerges in mitophagy-deficient cells. Therefore, mitophagy adequately eliminates damaged mitochondria to minimize mtROS production in wild-type cells (Kurihara et al. 2012). In mammalian cells, loss of the mitochondrial membrane potential causes PINK1-Parkin-mediated mitophagy, suggesting that damaged mitochondria-specific autophagy is implicated in Parkinson's disease (Narendra et al. 2008). However, further in vivo examination is required to clarify the pathophysiological role of mitophagy.

Perspectives

Mitophagy plays an important role in maintaining mitochondrial quality and quantity. The molecular mechanisms of mitophagy have been extensively examined in yeast and are currently relatively well understood. However, with regard to the regulation of Atg32 activity, how phosphorylation of Atg32 by CK2, a constitutive active kinase, is regulated remains unclear. To clarify regulation of starvation-induced mitophagy in yeast, spatiotemporal analysis for phosphorylation of Atg32 may be required. In mammalian cells, several types of mitophagic processes have been reported in different types of cells and under different mitophagy-inducing conditions. This impairs our understanding of mitophagy in mammalian cells. Additionally, the physiological role of mitophagy in mammals is largely unclear because of experimental limitations of analysis for mitophagy *in vivo*. To determine the physiological and pathophysiological role of mitophagy in mammals, a versatile strategy for detection of mitophagy in animal tissues must be developed.

Policies and Protocols

Policies for Studying Mitophagy: Proposal of the Molecular Basis for Treatment of Mitochondria-Related Diseases

In this chapter, we have described the molecular mechanisms and physiological roles of mitophagy under starvation in yeast and mammalian cells. Mitochondria have energy-producing machinery termed oxidative phosphorylation, and most of the energy used within a cell is produced in mitochondria. However, this pathway is a "double-edged sword," producing reactive oxygen species (mtROS) simultaneously with energy production. Therefore, mitochondria are also known as a harmful component for the host cell. Accordingly, if dysfunction of mitochondria increases within the cell, it causes many types of human diseases, including neurodegenerative diseases and aging-related diseases.

Mitophagy is the only degradation system that can degrade whole mitochondria and can contribute to mitochondrial quality control by eliminating dysfunctional

mitochondria. Therefore, the policy for studying mitophagy should determine the molecular basis of mitochondrial degradation and molecular targets in mitophagy for treatment of mitochondrial dysfunction-related diseases.

Dictionary of Terms

- **Reactive oxygen species** – Reactive oxygen species are reactive molecules derived from molecular oxygen. They are mainly produced as byproducts from mitochondrial electron transport chain complexes and can potentially harm other proteins in cells.
- **Organelle** – Organelles are membranous compartments in eukaryotic cells, including the nucleus, endoplasmic reticulum, Golgi apparatus, lysosomes, peroxisomes, and mitochondria. Each organelle has specific activity for numerous cellular events.
- **Mitochondria** – Mitochondria are double membrane-bound organelles that are present in all cells of the body, except for red blood cells. Mitochondria have many important metabolic functions, including energy production, calcium buffering, regulation of apoptosis, beta-oxidation of fatty acids, and thermogenesis.
- **Mitochondrial disease** – Mitochondrial diseases result from failure of the mitochondria. When mitochondria fail, the level of mitochondria-generated energy is decreased, resulting in cellular damage, followed by cell death. When disordered mitochondria emerge throughout the body, whole organ systems become dysfunctional.
- **Mitochondrial DNA** – Mitochondrial DNA, termed mtDNA, is an approximately 16-kbp circular DNA that is located in the mitochondrial matrix. mtDNA encodes 13 proteins of oxidative phosphorylation complexes, 2 ribosomal RNAs, and 22 transfer RNAs.
- **Oxidative phosphorylation** – Oxidative phosphorylation is a reaction for energy production at the IMM. During oxidative phosphorylation, electrons are transported through four complexes and eventually transferred to oxygen. The pathway forms discontinuous proton concentrations across the IMM, termed the mitochondrial membrane potential. The mitochondrial membrane potential is used as the driving force for the ATP synthase complex, which is the fifth complex of this pathway.

Summary Points

- Mitochondria are multifunctional organelles and important for cell survival.
- Mitochondria can generate most of the energy in cells.
- Mitochondria are constitutively exposed to reactive oxygen species that are derived from their electron transport chain.
- Damaged mitochondria are harmful to host cells.

- Mitophagy is a type of autophagy that can selectively degrade mitochondria and contributes to eliminating damaged mitochondria from cells.
- Mitophagy is induced under starvation in yeast and mammalian cells.
- Most mitophagy receptor proteins are regulated through their phosphorylation upon stress, including starvation.
- Mitophagy may contribute to the onset of human diseases, including Parkinson's disease.
- Molecular analysis of mitophagy has the potential for determining molecular targets for treatment of mitochondrial dysfunction-related diseases.

List of Abbreviations

ACoAT	Acetoacetyl CoA thiolase
CAT	Catalase
GDH	Glutamate dehydrogenase
GK	Glycerol kinase
GOT	Aspartate aminotransferase
GPT	Alanine aminotransferase
GPX	Glutathione peroxidase
GR	Glutathione reductase
HK	Hexokinase
HOAD	β-hydroxyacyl CoA dehydrogenase
LDH	Lactate dehydrogenase
PK	Piruvate kinase
ROS	Reactive oxygen species
SOD	Superoxide dismutase
β-OHBDH	β-hydroxybutyrate dehydrogenase

Introduction

All animals need the input of energy from the environment to stay alive. As a survival mechanism they have developed adaptive processes that allow them to continue living for a certain time when energy input does not occur. It is appropriate to name these periods of external limitation of food resources as starvation and not as fasting (McCue 2010).

Periods of food deprivation are frequent in many species of fish in their natural environment. Climate changes, seasonal variations, competition for food, breeding migrations are common processes that involve starvation in fish. To survive these periods with lack of food intake, fish have developed a series of adaptive physiological processes. These processes allow fish to endure starvation periods of several months and are closely related to biotic and abiotic factors. Thus, carnivorous species are better adapted to face periods of food restriction than herbivores and detritivores species which tend to eat continuously. Furthermore, the consequences of starvation are more pronounced in larvae and juvenile stages than in adult fish, probably due to a higher amount of energy reserves in the latter (Gadomski and Petersen 1988). Environmental variations such as temperature may also have an impact on these adaptive mechanisms.

During starvation, adaptive physiological processes affect organs such as liver, brain, skeletal muscle, and digestive and produce changes in the intermediary metabolism of carbohydrates, lipids, and proteins to maintain the homeostasis (McCue 2010; Rossi et al. 2015; Barreto-Curiel et al. 2017).

Short-term starvation promotes rapid mobilization of available reserves. In the first week of starvation, the glycogenolytic pathway increase in liver. Gluconeogenic processes, from the seventh day and onwards, tends to increase glycemia. At the same time, an increase in the ketogenic capacity of the liver occurs in order to produce alternative energetic substrates for its potential use in organs such as the brain. Glycogen depletion is followed by lipid and protein catabolism, as well as a loss of body weight. In addition, many anabolic pathways are diminished, such as the synthesis of glycogen, protein, lipids, and nucleic acid precursors (Rossi et al. 2015).

In the fish brain, after 1 week of starvation, there is a depression of the glycolytic pathway and a greater use of ketone bodies as energetic substrates (Vigliano et al. 2002; Polakof et al. 2012). In addition, it is necessary to emphasize the gluconeogenic capacity of the brain in fish, since in other animals this occurs only in the liver and renal cortex (Lehninger et al. 1993; Polakof et al. 2012).

Muscle metabolism is characterized by a rapid consumption of glycogen, lipid, and protein reserves during starvation (Machado et al. 1988). Lack of food results in a decrease in the synthesis and secretion of enzymes in the digestive system (Gannam 2008; Shan et al. 2016). Recent studies have shown an alteration of the intestinal microbiota with an increase of bacteroidetes and a depletion of betaproteobacteria (Hong and Rhee 2014).

Finally, other notable change in response to fasting in fish is the alteration in oxidative state (Rossi et al. 2015).

All functional changes during fish starvation are controlled by the neuroendocrine system. Neuroactive and hormonal substances (cholecystokinin, neuropeptide Y, galanin and orexin, leptin insulin, glucagon, somatostatin, growth hormone, thyroid hormones, catecholamines, cortisol, corticosterone, and cortisone) have been shown to have important regulatory functions in physiological processes during starvation in fish (Bar 2014; Bond 1996).

This book chapter focuses on metabolic changes, alterations in the oxidative state, and changes in digestive enzymatic activities in response to starvation in fish with the main focus on the trout *Oncorhynchus mykiss* and the sturgeon *Acipenser naccarii*.

Trout is an actinopterigian fish belonging to the Salmonidae family. This family includes 3 subfamilies, 11 genera, and 176 species (Nelson et al. 2004). It is original of the rivers of the west of North America, although introduced in rivers almost all over the world. It lives in clear and relatively cold waters and has a longevity from 4 to 6 years. Sexual maturity is reached when they exceed 10 cm in length, in the second or third year of life. Predatory feeding is mainly composed of zooplankton, aquatic macroinvertebrates, and small fish. The size generally does not exceed 40–50 cm in length and 5 kg in weight.

Sturgeons are bony fishes, actinopterigios of the family Acipenseridos that includes two subfamilies. The genus Acipenser includes 21 species. Sturgeons have been revealed as fish with remarkable peculiarities in many aspects of their biology, in

particular in their physiology and metabolism, with respect to other fish groups. To a large extent, these peculiarities have been attributed to their remarkable phylogenetic antiquity (they are called authentic "living fossils") estimated to having existed for 250 million years. Its habitat is associated with the great fluvial systems of the northern hemisphere, being abundant in the Black Sea, Caspian, and in seas and rivers of North America and Europe. *Acipenser naccarii* is a migrating species that reproduces in fresh water, using the sea for its growth. Sexual maturity reaches the age of 6–8 years. The adult specimens reach a weight greater than 100 kg and up to more than 2 m in length, being the larger females, although there is no evident sexual dimorphism (Domezain Fau 2003). It mainly feeds on benthic invertebrates, although they also consume remains of animals, plants, and seeds (Soriguer et al. 1999). This would explain that nutritional studies in this species have revealed a greater predisposition of the digestive and metabolic machinery for the use of carbohydrates than exists in a strictly carnivorous fish such as rainbow trout (*Onchorynchus mykiss*) (Furne et al. 2008). Likewise, Sanz et al. (1997) have found a better use of feed in this sturgeon species in which the protein/energy ratio is lower than that of a strict carnivore.

Metabolic Modification During Starvation

To maintain the vital processes and survival during periods of starvation, fish reduce their energy expenditures, which in a high percentage are derived from protein synthesis and mobilize their endogenous reserves to obtain the energy.

The utilization of energy reserves during starvation periods appears to differ according to the species of fish. Moreover, intraspecific adjustments to these conditions will depend on different factors, such as age or nutritional state (Navarro and Gutiérrez 1995). The metabolic responses of fish to starvation are also influenced by the feeding habits of the species.

Liver Metabolism During Starvation

Most studies report that glycemia never falls below the basal levels established for most fish species (65–70 mg 100 ml^{-1}) (Echevarría et al. 1997; Rios et al. 2006; Pérez-Jiménez et al. 2007). Plasma glucose levels in sturgeon notably decreased after 2 days of starvation, while in the trout plasmatic glucose showed a more gradual response over time (Furne et al. 2012) (Fig. 1). Plasma glucose levels decline in starved fish (Gillis and Ballantyne 1996; Soengas et al. 1996; Figueiredo-Garutti et al. 2002; Pérez-Jiménez et al. 2007, 2008; Rossi et al. 2015).

The maintenance of plasma glucose levels during food deprivation is attributed to three processes: glycogen mobilization, decreased glucose consumption, and gluconeogenesis.

In both sturgeon and trout, a mobilization of liver glycogen has been observed during the first few days of starvation. Although hepatic glycogen is consumed to cover energy demands in both species, this response has been reported to occur earlier in sturgeon. A

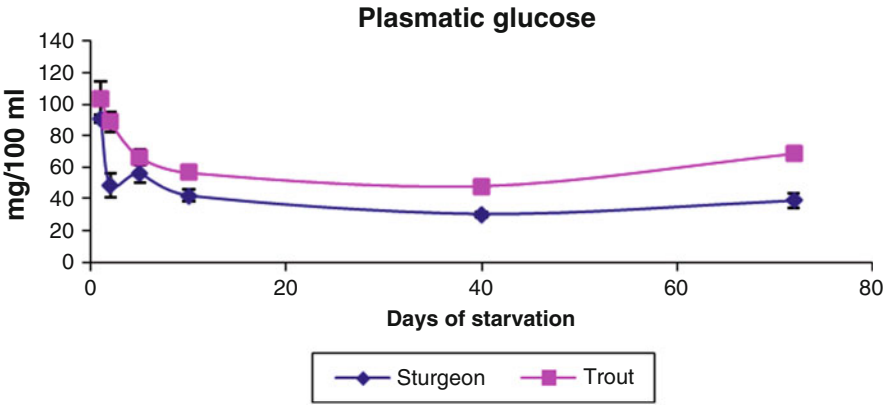

Fig. 1 Plasmatic glucose levels during starvation in sturgeon and trout. Values are mean ± SEM ($n = 5$; number of fish sampled per sampled points) (Data are taken from Furne et al. 2012)

large reduction of liver glycogen has been reported in many starved fish species, at least during the initial stages of starvation (Navarro and Gutiérrez 1995; Metón et al. 2003; Rios et al. 2006; Pérez-Jiménez et al. 2007; Menezes et al. 2015), but in most fish species, glycogen deposits were not completely exhausted, suggesting that a strategy is operating to preserve liver reserves (Collins and Anderson 1997; Rios et al. 2006; Pérez-Jiménez et al. 2007; Pérez-Jiménez 2008).

The reduced activity of hepatic enzymes from the glycolytic and the pentose phosphate pathways, and enhanced or sustained hepatic gluconeogenesis from amino acids and glycerol, are other strategies operating in fish to maintain glycemia during starvation (Polakof et al. 2012).

The decrease of blood glucose in sturgeon in the first few days of food deprivation is accomplished by a peak in the activities of the glycolytic enzymes such as HK and PK (Figs. 2 and 3). Although glycogenolysis occurs in the sturgeon, glucose demands and a minor content of hepatic glycogen would explain the decrease of glycemia. On the other hand, in the trout, a higher gluconeogenic activity in the liver from noncarbohydrate substrates such as amino acids and lactate was found (increased of GPT and LDH activities). Induction of gluconeogenic processes and a decrease of glycolytic enzymes activity (HK and PK) in the trout liver during the starvation would explain the more gradual decline of glycemia in this specie (Furne et al. 2012).

Triglycerides are the main form of energy storage in fish. During starvation, fatty acids derived from triglyceride hydrolysis are preferentially used through β-oxidation as fuels for most fish tissues. Triglycerides may be deposited as perivisceral fat, in liver or in muscle. Liver is the main site for lipid storage in sturgeon, while salmonids like the trout accumulate perivisceral fat. Despite the storage site, a marked reduction in fat storage occurs in starved fish (Grigorakis and Alexis 2005; Rios et al. 2006; Furne et al. 2008; Pérez-Jiménez 2008; Barreto-Curiel et al. 2017) (Fig. 4). Regarding the enzymes involved in fatty acid catabolism, it has been

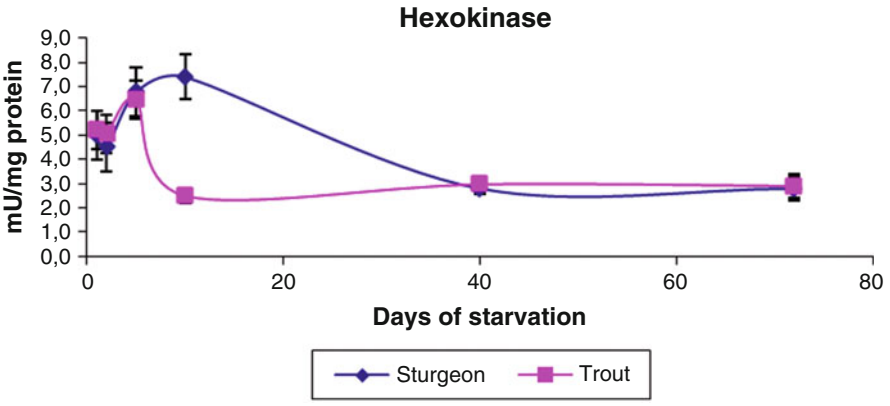

Fig. 2 Hepatic hexokinase activity during starvation in sturgeon and trout. Values are mean ± SEM ($n = 5$; number of fish sampled per sampled points) (Data are taken from Furne et al. 2012)

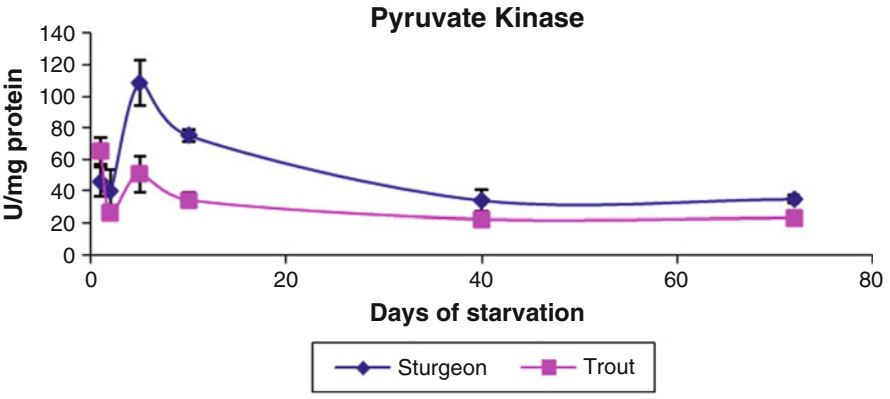

Fig. 3 Hepatic pyruvate kinase activity in the liver during starvation in sturgeon and trout. Values are mean ± SEM ($n = 5$; number of fish sampled per sampled points) (Data are taken from Furne et al. 2012)

reported an increase in hepatic HOAD activity in starved sturgeon but not in trout, which agrees with a higher lipid content storage in the liver in the sturgeon (Fig. 5).

It has been suggested by some authors that ketone bodies do not play an important role as an energy source during starvation in fish (Zammit and Newsholme 1979; Black and Love 1986). However, many studies have already demonstrated β-OHBDHB activity in several teleost species. Furthermore, an increase in plasma levels of ketone bodies and in the activity of enzymes involved in ketone body synthesis has been reported in fish deprived of food (Soengas et al. 1996; Furne et al. 2008). In the sturgeon, the maintenance of triglyceride catabolism, which produces acetyl-coA, encourages the use of this metabolite for the synthesis of ketone bodies in the liver. This fact was supported by high β-OHBDH and ACoAT activities in

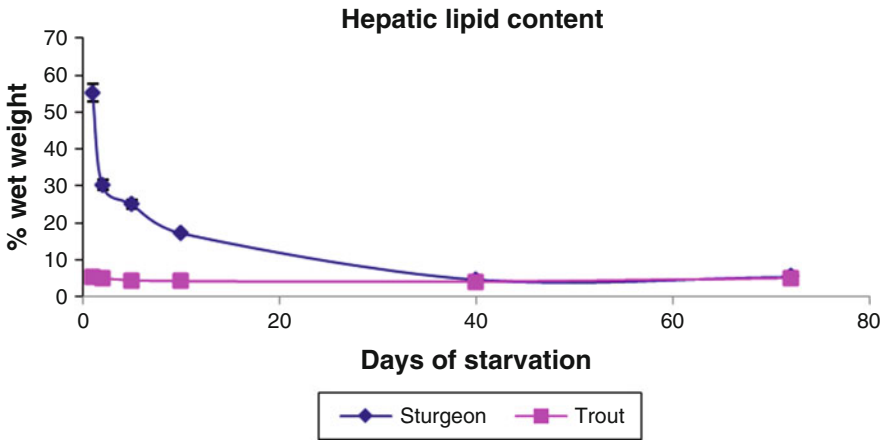

Fig. 4 Lipid content levels in liver during starvation in sturgeon and trout. Values are mean ± SEM ($n = 5$; number of fish sampled per sampled points) (Data are taken from Furne et al. 2012)

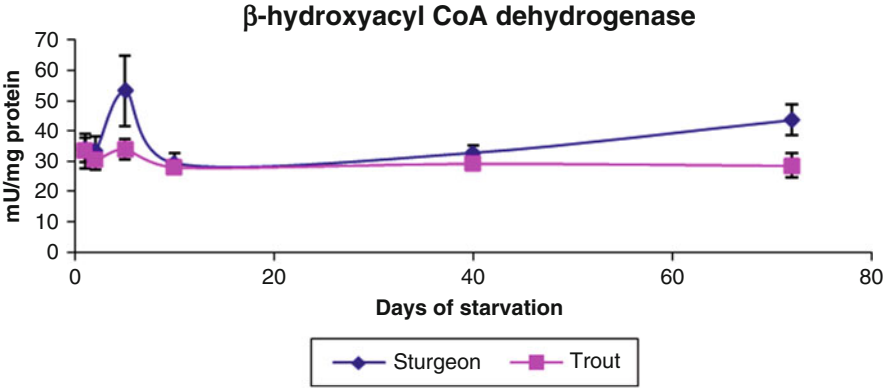

Fig. 5 Hepatic β-hydroxyacyl CoA dehydrogenase activity during starvation in sturgeon and trout. Values are mean ± SEM ($n = 5$; number of fish sampled per sampled points) (Data are taken from Furne et al. 2012)

sturgeon. However, the trout synthesizes ketone bodies in the liver (increased of ACoAT) as a response to the excess of acetyl CoA produced by Krebs cycle from catabolic activity during starvation (Furne et al. 2012).

Muscle Metabolism During Starvation

Muscle is one of the tissues that is considerably affected by starvation in fish (Johansen and Overturf 2006). As muscle glycogen is a short-term reserve, during periods of starvation, lipid stores and muscle protein breakdown provide the bulk of energy.

In a few days of starvation, a mobilization of carbohydrate stores in white muscle was detected as an energy resource in both sturgeon and trout (Furne et al. 2012). Mobilization of carbohydrates during starvation has been reported in Atlantic cod by Black and Love (1986), whereas other species showed no variations in muscle glycogen reserves (Gutierrez et al. 1991; Blasco et al. 1992; Barcellos et al. 2010).

Sturgeon and trout mobilize lipids and proteins from the muscle during starvation. In both species, an increase in lipid catabolism enzymes (HOAD and GK) has been reported and the fish keep protein catabolism enzymes active (GPT, GOT and GDH). In contrast to the sturgeon which showed a decrease in enzymes involved in gluconeogenesis during starvation periods, the trout keeps the gluconeogenic pathways active using lactate as a substrate. Because protein is the main muscle component, they are the main energy source in muscle under prolonged starvation.

Starvation and Antioxidant Defenses

Oxidative stress arises from an imbalance between antioxidant defenses and oxidative processes. The high quantity of ROS present in situations of oxidative stress can provoke tissue damage, affecting biomolecules, which in the case of lipids could be quantified by peroxide formation (Halliwell and Gutteridge 2015).

Food deprivation leads to depletion of antioxidant stores and increased levels of ROS in organs of living organisms. Starvation has been reported to have pro-oxidant effects in mammals as ROS generation is not adequately neutralized by antioxidant systems (Robinson et al. 1997; Domenicali et al. 2001). It is known that a lack of available food can affect the antioxidant defenses in fish but, as opposed to studies on mammals, few publications are available on the consequences of starvation with regard to antioxidant mechanisms in fish. Most available studies on the impact of starvation on antioxidant defenses of fish are focused on liver, since it is the main organ for metabolic control and has a key role in ROS generation.

Oxidative Stress in Red Blood Cells and Liver During Starvation

Sturgeon and trout under prolonged starvation showed an increase in the lipid peroxidation levels in liver and in red blood cells. Studies in fish unanimously show that starvation augments lipid peroxidation. However, with respect to the activity of antioxidant enzymes, studies disagree, particularly depending on the tissue examined. In liver and red blood cells in sturgeon and trout, there was an early decline at 10 days starvation in both species. This decline, triggered by the restriction of enzyme synthesis substrates, was probably responsible of the rise of the lipid peroxidation levels seen (Furne et al. 2009). The enzymes SOD, CAT, GPX, and GR constitute the main enzymatic mechanism of antioxidant defense. The rise in the lipid peroxidation levels, together with a fall in the activity of the main antioxidant enzymes, appears to indicate the incapacity of the liver to meet the stress

situation provoked by prolonged starvation, leading ultimately to the oxidation of biomolecules.

Hepatic GR activity decreased in rainbow trout subjected to 3 weeks of starvation (Blom et al. 2000). Atlantic cod (*Gadus morhua*) showed an increased activity of antioxidant enzymes in liver, while in muscle those enzymes did not vary after 12 weeks of starvation (Guderley et al. 2003). Lipid peroxidation increased due to food deprivation in gilthead seabream (*Sparus aurata*). A decrease of CAT activity was found while SOD, GR, and GPX activities increased. Moreover, it has been detected new isoforms of the SOD enzyme (Pascual et al. 2003). An increase in activity in SOD, CAT, and GPX, and a decreased in GR activity in the liver of Common dentex (Dentex dentex) submitted to 5 weeks of starvation was reported by Morales et al. (2004). Zhang et al. (2008), in lang yellow croaker (*Pseudosciaena croceae*), showed an increase in hepatic SOD and GPX activities during starvation. Several studies have also evaluated the transcriptional responses to starvation of major antioxidant enzyme genes in the liver of some fish species. In rockbream (*Oplegnatus fasciatus*) significant alterations were apparent, whereas mRNA levels of SOD, CAT, GPX, and GST in the liver increased in fish subjected to short-term starvation (Nam et al. 2005). In rainbow trout (*Oncorhynchus mykiss*) starved for 3 weeks, expression levels of GST and GPX were reduced (Salem et al. 2007). Also in the zebrafish (*Danio rerio*), genes involved in neutralizing ROS, such as SOD, GPX, and several other selenium-binding proteins, were downregulated in livers of fish starved for 21 days (Drew et al. 2008). These results indicate that prolonged starvation decreases the capacity of fish liver to ameliorate oxidative stress.

Oxidative Stress in Heart During Starvation

Studies analyzing the antioxidant defenses of the heart in starved fish are scarce and the results contradictory. In Adriatic sturgeon and rainbow trout, a starvation period of 10 weeks did not induce lipid oxidative damage in the heart. The activity of antioxidant enzymes in the heart of starved sturgeon remained unchanged, whereas cardiac CAT and SOD activities were enhanced by starvation in rainbow trout (Furne et al. 2009). These observations might indicate that the heart, being a crucial organ for life, would be in some way protected from stressful circumstances such as starvation. However, in common dentex, 5 weeks of starvation depressed cardiac activities of SOD, GPX, and GR. Although CAT activity increased during these circumstances, it was not sufficient to avoid an increase in lipid peroxidation (Pérez-Jiménez 2008).

Oxidative Stress in White Muscle During Starvation

In white muscle, specific activity of the antioxidant enzymes did not differ between fed and starved cod (Guderley et al. 2003). Also in common dentex, the specific activity of antioxidant enzymes, as well as the levels of lipid peroxidation, remained

unchanged by starvation (Pérez-Jiménez 2008). An increased activity of antioxidant enzymes and no variation in lipid peroxidation in white muscle was found in Adriatic sturgeon and rainbow trout starved for 10 weeks (Furne et al. 2009). Probably, cellular disruption during macromolecular mobilization may increase the sensitivity to damage by ROS, explaining why maintenance of antioxidant defenses would be useful during starvation.

Starvation and Digestive Physiology

The lack of food is a situation undergone and tolerated by many fish species in the natural environment. The metabolic strategy used to supply energy to the organism depends on several factors such as species, physiological state of the fish, and environmental conditions. Thus, some fish use protein as the main energy source, maintaining the hepatic glycogen reserve by means of glyconeogenesis, while other fish use lipids ahead the glycogen reserve. In addition, not all body tissues contribute to such reserves in the same way; some fish have a large energy reserve in the mesenteries of the digestive tract, while other fish have storage in the liver and still others in muscle.

Because the gastrointestinal tract and its associated organs can account for up to 40% of an animal's metabolic rate (Cant et al. 1996), one would have the a priori expectation for the digestive tract toatrophy during periods of food deprivation and flourish during food abundance (Theilacker 1978; Bogé et al. 1981; McLeese and Moon 1989; Diamond and Hammond 1992; Wang et al. 2006). Indeed, fish enduring food deprivation have been observed to decrease their gut length (Rios et al. 2004), intestinal fold and microvilli length (Gas and Noailliac-Depeyre 1976; German et al. 2010), and digestive enzyme activities (Krogdahl and Bakke-McKellep 2005; Chan et al. 2008; Furne et al. 2008; Abolfathi et al. 2012).

In the trout, the digestive somatic index declined during starvation, which could indicate a quicker mobilization of energy reserves from the digestive tract with respect to the overall body mass. Similar findings have been reported by other authors in rainbow trout (Storebakken et al. 1998). Metabolic and digestive results suggest that the trout mobilizes preferentially energy from the perivisceral tissues, while sturgeon mobilizes energy from muscle and liver tissues.

Regarding digestive enzymes, sturgeon and trout showed a decrease in protease, amylase, and lipase activities after 10 weeks of starvation. Sturgeon and trout have shown different eating habits. Trout has higher protease activity than sturgeon and sturgeon has higher amylase activity. Furthermore, sturgeon has greater digestive capacity for carbohydrates than trout (Furne et al. 2005). With respect to starvation, amylase activity in both species decreased more than 50% at 10 days of food deprivation. However, the protease activity did not change until 3 weeks of starvation. The literature shows that alkaline phosphatase, an enzyme located in the microvilli of the intestinal epithelium, gradually diminishes in starved carp, and after 13 month of starvation this activity cannot be detected (Gas and Noailliac-Depeyre 1976). A decline in trypsin activity during prolonged starvation in Atlantic

salmon was reported by Bélanger et al. (2002). On the other hand, a very different effect was noted after a brief starvation, with an increase in digestive enzymatic activities in Nile tilapia (Mommsen et al. 2003). Krogdahl and Bakke-McKellep (2005) detected a decrease in the total activity of enzymes in the intestinal microvellosities in Atlantic salmon after 40 days of starvation and a rapid recuperation after 7 days of re-feeding. A proteolysis of the intestinal mucosa, a progressive degeneration of exocrine pancreatic cells, and a decrease of zymogen activity during 48 h of starvation were observed in tench by Ostaszewska et al. (2006). Studies realized with catfish submitted to 150 days of starvation showed that the fish reduced the surface area of their intestines by 70% and reduced the microvilli surface area by 52% (German et al. 2010).

Fluctuations in food availability are natural in most aquatic systems, and fish show an impressive capacity to withstand prolonged periods of food limitation, particularly in comparison with mammals. Despite the many ways in which food limitation affects the metabolic capacities of fish, perhaps even more striking is their capacity to rebound from these difficulties. In fact, after starvation, fish enter a period of compensatory growth during which they rapidly accumulate reserves and reinstate their metabolic capacities. This compensatory growth occurs despite the previous atrophy of the digestive system. The malleability of the piscine digestive system and its capacity to rise to renew feeding opportunities is impressive. There are several areas in which information about oxidative defense mechanisms is scant, so new investigations concerning the control of oxidative defense mechanisms during renewed tissue growth after starvation should help elucidate how and why fish are so adapted to survive prolonged periods of food limitation.

This book chapter describes the mechanisms that allow fish to enhance prolonged starvation periods. The ability to face prolonged starvation is higher in fish than for example in humans, and the following two facts might contribute to the explanation of this phenomenon. First, fish are ectotherms (animals that do not regulate the body temperature) and maintaining vital processes requires lower energy levels in comparison to endotherms like humans (endotherms require high expenditures of metabolic energy in order to keep a constant body temperature). Second, fish do not need to keep balance since they live in aquatic environment, whereas humans require the performance of the antigravity muscles. Consequently, during food deprivation events, the energy balance in fish is less negative than in humans. The mechanisms of mobilization of energetic reserves occur at a lower rate in fish such that energy reserves last longer and allow prolonged starvation periods.

Policies and Protocols

The animals to which this study refers were sturgeons (*Acipenser naccarii*) and trout (*Oncorhynchus mykiss*) of 1+ year of age. The maintenance and feeding conditions were those of the fish farm. The fish were starved during a total period of 72 days. Five fish for each species were sampled on days 1, 2, 5, 10, 40, and 72 of food deprivation. All the procedures were conducted according to the guidelines of the

Council Directive 609/86/EEC (European Communities 1986) on the use of animals for experimental and scientific purposes. Animals were anesthetized with clove oil. Blood samples were taken from the caudal vessels using heparinized syringes and transferred to heparinized tubes, to be kept on ice until centrifugation. Following blood collection, the heart, liver, and a white-muscle portion, from anterior dorsal region, were quickly removed. Tissue samples were frozen in liquid nitrogen and stored in the laboratory at −80 °C until analyze.

Dictionary of Terms

- **Glycogenolysis** – Process by which glycogen, the primary carbohydrate stored in the liver and muscle cells of animals, is broken down into glucose to provide immediate energy and to maintain blood glucose levels during fasting.
- **Gluconeogenesis** – Metabolic pathway that results in the generation of glucose from non-carbohydrate substrates such as lactate, glycerol, and amino acids
- **Glycemia** – Level of glucose in blood.
- **Ketone bodies** – Three related compounds (acetoacetic acid, acetone, and beta-hydroxybutyric acid) produced during the metabolism of fats, they are used as a source of energy instead of glucose during a period of fasting.
- **Reactive oxygen species (ROS)** – A type of unstable molecule that contains oxygen and that easily reacts with other molecules in a cell.

Summary Points

- The decrease in blood glucose in trout during the first days of starvation is more gradual than in sturgeon. One of the reasons could be a greater gluconeogenic capacity of the liver of the trout in comparison to the sturgeon liver and increased glycogen storage capacity in trout liver.
- Although it seems to be that ketone bodies do not play an important role as an energy source during starvation in fish, the synthesis of ketone bodies in the liver of the sturgeon comes from the catabolism of hepatic triglycerides, whereas trout liver comes from the Krebs cycle.
- In a few days of starvation, a mobilization of carbohydrate, lipid, and protein in the muscle was detected as an energy resource in both sturgeon and trout.
- Sturgeon and trout under prolonged starvation show an increase in the lipid peroxidation and a decrease in antioxidant enzymes in liver and in red blood cells. Conversely, the oxidative state of the sturgeon and trout heart and muscle is less disturbed by the starvation than the liver.
- The trout mobilizes preferentially energy from the perivisceral tissues, while sturgeon mobilizes energy from muscle and liver tissues.
- The starvation motivates a decrease of the amylase activity earlier than that of the protease in both species.

Activity-Based Anorexia and Food Schedule Induction

Contents

Abstract

The term activity-based anorexia refers to the animal model of anorexia nervosa in humans, by which laboratory rats lose weight rapidly and progressively when submitted to a food access regime of 1 h a day and free access to an activity wheel the remainder of the time. This combination of diet and exercise eventually leads the animals into a process of self-starvation that can end up in their death, a reason by which activity-based anorexia is considered analogous of anorexia nervosa in humans, a disease that combines self-imposed food restriction with an excessive increase in physical activity. The best-studied example of schedule-induced behavior is the excessive ingestion of water in animals that are food deprived and for whom the food episodes occur intermittently. Schedule-induced

polydipsia is characterized by the consumption of water around the feeding episodes, similarly to what is seen with activity in the phenomenon of activity-based anorexia. The study presented supports the relationship between both phenomena, so that the initial development of excessive drinking facilitates the subsequent development of wheel running. It is suggested that the imposition of very strict feeding episodes could play an important role during the initial stages of the development of anorexia, facilitating the development of hyperactivity that could end up interfering with food ingestion. Prevention for the development of anorexia should focus on a more efficient control of food regimes rather than limiting physical exercise. The adequate scheduling of feeding episodes should reduce hyperactivity, as it follows from its conception as induced behavior.

Activity-Based Anorexia

The Disorder

In 1988, Epling and Pierce defined the term activity-based anorexia (ABA) in reference to the animal model of anorexia nervosa in humans, a serious psychiatric disorder included in the International Classification of Diseases (ICD-10), published in its tenth edition in 1992 by the World Health Organization (WHO). This manual describes anorexia nervosa as an eating disorder characterized by the existence of a great weight loss induced or maintained by the patient him/herself, which must include the indispensable diagnostic criterion of the said loss of body weight being originated by the patient him/herself through excessive body exercise. In 2016, the WHO published the 11th revision of the International Statistical Classification of Diseases and Related Health Problems (ICD-11), which will not be approved until May 2018. However, the ICD-11 has the same descriptive criteria for the anorexia nervosa disorder, characterized by a significantly low body weight accompanied by a persistent pattern of behaviors that prevent recovery of normal weight, including

restricted eating along with behaviors aimed at increasing energy expenditure, such as excessive exercise.

The American Psychiatric Association published in 2013 its fifth version of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5), which included anorexia nervosa under the feeding and eating disorders section, defining it as a restriction of energy intake that leads to a significantly low body weight in relation to age, sex, developmental stage, and physical health. The restrictive type of anorexia nervosa is described as the loss of weight due to dieting, fasting, and/or excessive exercise.

The Animal Model

Although it is true that animal models used in scientific research may never fully cover the human psychological complexity, they are necessary to study characteristic aspects of clinical disorders, which could otherwise not be addressed in humans for ethical reasons.

In the case of anorexia nervosa, although there are different proposals for animal models (Siegfried et al. 2003; Treasure and Owen 1997), it is worth highlighting the analogous model called ABA, cited at the beginning of this section. This model reproduces the most objective signs of the anorexia nervosa psychiatric illness, such as weight loss, restrictive diet, and excessive exercise (see Gutiérrez 2011).

The beginnings of this research line refer back to Richter (known as "the father of the biological clock" (Boakes 2007) for his pioneering research on biological rhythms in the 1920s), who, while studying the organisms' spontaneous activity in response to various external stimuli, such as food restriction, found that the experimental subjects, in this case rats subjected to a food diet, increased their physical activity considerably and concluded that once the activity rhythms have been established, these tend to persist even after of the elimination of the stimulus that provoked them (Richter 1922).

Hall et al. (1953) and Hall and Hanford (1954) systematically replicated an experiment where when rats were subjected to a food restriction schedule of 23 h a day, their level of activity increased rapidly in a negative way depending on the number of days lapsed under the deprivation regimen. This data contrasted markedly with the relatively constant level of activity found for a control group that had been subjected to the same activity conditions but under an ad libitum feeding schedule.

Routtenberg and Kuznesof (1967) called this combination of diet and exercise self-starvation due to the decline of the experimental subjects who, when subjected to a regime of access to food for only 1 h a day and with access to an activity wheel during the remaining 23 h, could not maintain their own body weights, presenting very high levels of activity without apparent compensation in their food intake.

Cheney and Epling (1968; cited in Pierce and Cheney 2004) replicated the procedure described in the previous paragraphs, drawn by how rats exercised in the activity wheel more and more, losing substantial amounts of body weight, to the

extent that if they were not removed from this experimental situation, they ended up dying from starvation.

Paré and Houser (1973) and Paré (1975) proposed this experimental technique as a new paradigm in order to investigate gastrointestinal pathology, calling it "activity-stress paradigm." These researchers, using experimental rats aged between 60 and 110 days, housed in activity cages and fed only for 1 h a day for 21 days, reported very high mortality rates before the end of the experiment, caused by extensive lesions in glandular portions of the stomach, in comparison with control rats that were also fed for only 1 h a day but housed in standard cages without access to an activity wheel. The experimental rats that died were more active than the experimental rats that survived and ate less than the surviving rats and the control rats. These researchers emphasized that the main cause of the rapid development of the gastrointestinal disease was the level of activity exerted by the experimental rats, instead of the food deprivation to which all the rats were subjected, both the experimental ones and those in the control group.

Epling et al. (1983) proposed that the ABA phenomenon in rodents was a plausible analogue model of human anorexia nervosa, pointing out that the majority of cases of anorexia nervosa, which they estimated to be up to 75%, were actually examples of anorexia due to activity, a psychiatric illness that combines food self-starvation with an excessive increase in physical activity of the patients (Gutiérrez and Pellón 2002).

Epling et al. (1981, 1983) observed that when rats were fed only for 1 h a day, they lost a lot of body weight but were able to adjust to that diet and survive. Yet, when those same animals were exposed to the same food restriction conditions and in addition were provided with an activity wheel on which they were free to exercise on for the rest of the time they were not eating, the rats started a process that inexorably leads to death, due to their excessive level of activity on the wheel, running up to 10,000 laps a day, which is equivalent to about 10 km. Interestingly, these researchers were even more surprised to observe that the rats, although eating a little bit more when their level of exercise on the wheel began to increase, actually later declined food intake, leading to drastic consequences such as the phenomenon of self-starvation.

Explanations

The interaction between physical activity and diet becomes lethal for subjects, because strenuous exercise reduces the value of food reinforcement, thus decreasing intake and increasing the motivational value of physical activity. Therefore, this is an ideal analogous model to human anorexia nervosa. The cultural practices of diet and exercise initiate the anorexic cycle, which, once initiated, is resistant to change. It is a biological-behavioral perspective of the phenomenon, as this type of anorexia could be the result of natural selection that favors those organisms that became active in times of food shortages. Activity-based anorexia could be part of the explanatory basis of the development of anorexia nervosa (see Epling and Pierce 1988).

The above proposals could be considered as granting a reinforcing and motivational value to physical exercise. On the contrary, other authors formulate different explanatory arguments. Kanarek and Collier (1983) reasoned that the ABA phenomenon results from a failure to adapt to food restriction conditions. These researchers were able to demonstrate how rats did not develop ABA when they had more than one daily access to food (specifically, four 15-min accesses), compared to a control group with the standard access of 60 min all together. Based on these results, they proposed that the weight loss was not induced solely by the activity but rather resulted from a failure to adapt to the new regime of food availability.

Likewise, Dwyer and Boakes (1997) highlighted as an explanatory argument for the ABA phenomenon that it is the history of food restriction that modulates the loss of body weight and physical activity on the wheel. To support this hypothesis, they preexposed experimental rats for 2 weeks to a food restriction schedule with 60 min of access every 24 h, before being placed in boxes with available activity wheels. The rats in the control group did not receive this preexposure phase, resulting in that the subjects of the experimental group ran more than the control group rats and that the weight reduction or weight loss was lower in the preexposed rats. This experimental result conforms to the theory that the history of food deprivation or restriction is what modulates the loss of body weight and the level of activity on the wheel, also strengthening the theoretical explanation of the ABA phenomenon as the subjects' failure to adapt to food regime due mainly to the development of excessive food-anticipatory activity.

A third explanatory line of the ABA phenomenon would be based on the intermittent occurrence of food episodes, capable of generating induced behaviors in the intervals between them. Following Epling and Pierce (1992), it can be suggested that the excessive running in the ABA phenomenon could be a behavior induced by the schedule of intermittent food presentation, as the activity wheel in the experimental situation is continuously available. In the next section, we will present evidence that activity can be induced by the intermittent occurrence of biologically relevant events, such as food for a relatively hungry animal, thus, yielding a better conceptualization than the traditional view of a non-induced facultative behavior (Roper 1981; Staddon and Ayres 1975).

Schedule-Induced Behavior

In 1961, J.L. Falk, investigating rats' fluid regulation and exposing these animals to intermittent reinforcement schedules with food and with a bottle of water present in the experimental situation, highlighted the enormous amount of water that rats could drink in such situation. This excessive drinking has been labelled as schedule-induced polydipsia (SIP), characterized by the fact that rats drink a little immediately after the ingestion of each pellet of food, which appears intermittently, resulting in excessive accumulation throughout the experimental session. Because animals are just deprived of food, but not of water, and they do not have to drink in order to get

the food reinforcer, SIP has been considered the prototype of a category of behavior named by Falk (1971) as an adjunctive, different from the operant and other forms of learned behavior. This type of distinction has been frequently discussed, and today the operant vs. adjunctive distinction is not so clear (Killeen and Pellón 2013).

Whatever the nature of the adjunctive (or schedule-induced) behavior, it can be defined as an increase in the frequency of a behavior not explicitly reinforced in the presence of conditions that require intermittently reinforced responses, compared to the frequency of such behavior when intermittent reinforcement is not required (Wallace and Singer 1976). There are three fundamental characteristics to consider a behavior as adjunctive: (1) It must occur at a significantly higher rate, persistently and even excessively, with respect to its baseline. (2) It must occur immediately after the reinforcer. (3) It must produce an occurrence pattern in the form of an inverted U shape, depending on the duration of the interval between reinforcements (see reviews by Pellón 1990; Wetherington 1982). Under this triple criterion, many behaviors have been identified as adjunctive: excessive drinking (Falk 1961), running on the activity wheel (Levitsky and Collier 1968), licking an air current (Mendelson and Chillag 1970), pica, or aggression and attack (Azrin et al. 1966). They have also been demonstrated in different animal species and even replicated in humans (Kachanoff et al. 1973), using food (Porter et al. 1982), games (Wallace et al. 1975), or sweets and candy in children (Granger et al. 1984) as reinforcers.

According to Staddon (1977), three behavior categories can be identified that occur during the period between reinforcers: terminal activities directed toward obtaining the prize or reward (see Skinner 1948); interim activities, which occur at a high frequency just after obtaining the reinforcer and preceding the terminal response with which they are usually incompatible; and facultative behaviors, which are not usually excessive and show an inverse relationship with the frequency of reinforcement. Both interim and terminal behaviors, in contrast with facultative ones, would be schedule-induced behaviors, being by their very nature facilitated by the parameters of the schedule, the level of deprivation of the subject, or the frequency and magnitude of the reinforcer (Pellón 1992). Timberlake and Lucas (1991), for example, considered excessive drinking as an interim behavior, while they catalogued wheel activity as a facultative one. Research such as that of Penney and Schull (1977) demonstrated, also with laboratory rats, the different functionality of excessive drinking and activity wheel as adjunctive behaviors.

Excessive Activity and Induction

In an attempt to demonstrate that the ABA procedure resembles that of the schedule-induced behaviors due to the intermittent availability of the food reinforcer, and considering the resemblance of the level of running exerted by the experimental rats to that of their licking behavior during exposure to a SIP procedure, an experimental study was designed whereby the rats were exposed successively to the procedures, firstly to SIP and secondly to ABA, in order to check the degree of facilitation in the

development of ABA compared to another group of animals that was directly exposed to the ABA procedure without preexposure to SIP.

An Experimental Test

Eight Wistar male rats were subjected to a fixed time (FT) 60-s schedule of administration of a food pellet, whereby a pellet of food was dispensed at said regular intervals without the animals needing to do anything to obtain them. The rats were maintained at 100% of their theoretical growth weight during the 30 sessions of the SIP procedure. As a result of the exposure to the intermittent reinforcement schedule, and given that they had continued access to water during the experimental sessions, the animals developed induced drinking in the intervals between reinforcers (see also Todd et al. 1997).

Once the preexposure to the adjunctive drinking-inducing schedule phase was finished, the animals were kept at 100% theoretical weight and rested for 30 days.

Immediately afterward, the ABA procedure began, for the eight rats that had been preexposed to the SIP procedure and for another eight rats that had not had such experience. In this procedure, access to food was restricted to 1 h a day, and access to an activity wheel was enabled for the remaining 23 h (for a detailed description of the procedure, see Carrera et al. 2014). All rats, at the beginning of the ABA procedure, had a 100% weight with respect to their own theoretical weight. The procedure was in operation for each rat until it reached for 2 consecutive days a loss greater than 75% of its initial weight, at which time the said animal was removed from the experiment (Boakes and Dwyer 1997).

The first rats that had to be withdrawn from the ABA procedure were four belonging to the group preexposed to the SIP procedure, and, in general, the rats that were directly exposed to ABA took longer to develop the phenomenon than the preexposed rats, thus showing a greater resistance to its development. Statistically, there were differences between groups ($p < 0.01$) in the direction of facilitation for the development of ABA by rats that had had previous experience in SIP.

The acquisition of ABA was analyzed by means of an ANOVA with a between-group factor with two levels (SIP/ABA vs. ABA groups) and a within-subject factor with six levels (corresponding to the six acquisition sessions in ABA necessary to reach the withdrawal criterion of the first rat from the activity wheel). The dependent variables were the decrease in the rats' body weight in percentage with respect to the value at the initial day of the procedure, the amount of food ingested in grams, and the level of running exercised on the activity wheel. The obtained results are shown in Fig. 1.

The upper panel of Fig. 1 shows the mean (± standard error) of the percentage of daily body-weight loss of the rats in both groups while the ABA procedure was taking place. It can be observed that the decrease in body weight, although drastic for both groups, was somewhat more marked in the SIP/ABA rats (black triangles), which reached the withdrawal criterion one session earlier than the ABA-only rats (white circles). Taking the data of the first six sessions, during which all the rats from

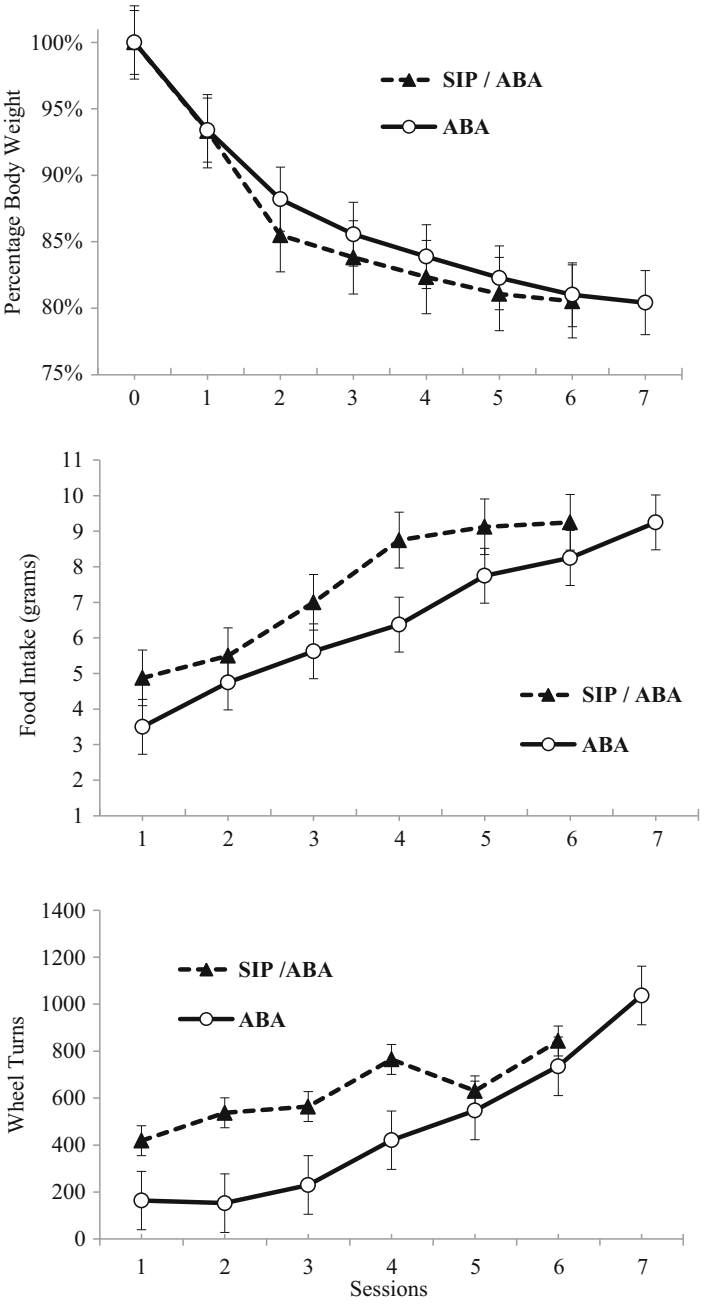

Fig. 1 Development of activity-based anorexia. Percentage of body-weight reduction, grams of food intake, and wheel turns in the two groups of rats that either went directly into activity-based anorexia (ABA) or were previously exposed to an experience of schedule-induced polydipsia (SIP/ABA). For the ABA rats, the first withdrawn animal was in session 7; for the SIP/ABA rats, the first four withdrawn animals were in session 6

both groups were on the activity wheel, the results of the ANOVA were significant for the Group factor [$F(1,84) = 5.93$, $p < 0.01$] and for the Session factor [$F(5,84) = 49.63$, $p < 0.01$], which point toward the progressive development of ABA in both groups with a greater overall weight loss for the SIP/ABA group. Post hoc tests indicated that there were significant differences ($p < 0.01$) in the first session compared to the second, third, fourth, fifth, and sixth sessions. There was no significant effect ($p > 0.05$) for the Group x Session interaction.

In the intermediate panel of Fig. 1, the mean (± standard error) of the amount of food ingested by the rats throughout the daily experimental sessions is observed. In general, a progressive increase in the grams of food ingested as the ABA procedure progressed can be observed, with always a slightly higher consumption for the SIP/ABA group. The ANOVA performed confirmed statistical significance for both the Group factor [$F(1,84) = 36.30$, $p < 0.01$] and the Session factor [$F(5,84) = 43.27$, $p < 0.01$], but not for their interaction ($p > 0.05$). The post hoc comparisons yielded significant differences ($p < 0.01$) in a lower food consumption during days 1 and 2, with respect to days 4, 5, and 6.

The lower panel in Fig. 1 shows the mean (± standard error) of the level of running exercised on the activity wheel during the sessions that the ABA (white circles) and SIP/ABA (black triangles) groups were in the experimental boxes submitted to the ABA procedure. A progressive increase in running can be observed as the experimental sessions lapsed. This level of running was generally somewhat higher for the SIP/ABA group during the first four sessions. The statistical results of the ANOVA for the first six sessions showed significant effects for the Group factor [$F(1,84) = 9.18$, $p < 0.01$] and for the Session factor [$F(5,84) = 3.46$, $p < 0.01$], but not for the interaction between them ($p > 0.05$). In the post hoc analyses, significant differences were found ($p < 0.05$) between the first and sixth sessions.

Figure 2 shows the mean (± standard error) of the distribution of wheel turns performed by the rats during the interval between meals (white circles for the ABA group and black triangles for the SIP/ABA group) during the last criterion day for each rat. The wheel turns performed during the 23 h between meals were recorded in units of 15 min in order to observe the way in which running developed. In general, running maximums can be observed after each meal, approximately when the dark period began (or was about to begin), and then in anticipation of the following meal, showing the SIP/ABA group, in general, greater activity during those periods. The ANOVA performed yielded a main effect of Bin [$F(3,176) = 35.70$, $p < 0.01$] and of Group [$F(1,176) = 12.90$, $p < 0.01$]. For the Group x Bin interaction, there was also statistical significance [$F(3,176) = 14.91$, $p < 0.01$]. The post hoc comparisons were significant ($p < 0.01$) for the activity displayed during the hours just prior to the delivery of food (12:00–17:00 h) with respect to the greater majority of the night hours spent in the activity boxes.

Some Caveats and Conclusions

Rats that were previously exposed to SIP developed ABA faster by means of running more and eating also more than the rats that were not preexposed to SIP. Therefore, to

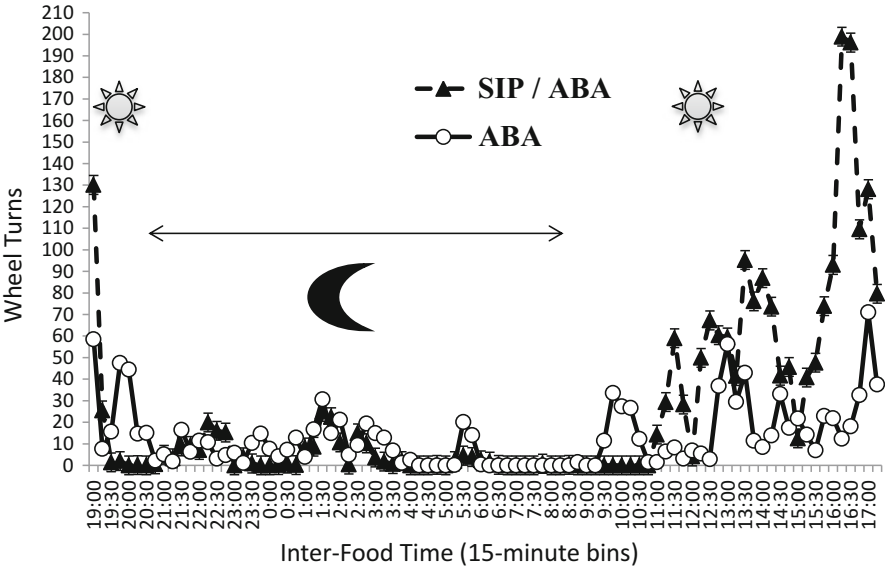

Fig. 2 Hourly distribution of wheel turns in anorexic rats. Wheel turns during the 23 h of running availability of day 6. After this session it was necessary to withdraw the first four rats from the SIP/ABA group

the extent of the results presented here, the critical variable for a higher development of ABA seems to be the running activity developed by the rats, not their failure to adapt to the food regime as both groups ate progressively more as exposure to the ABA procedure advanced and also to a greater extent in the rats that lost more weight.

Indeed, a clinical key aspect of anorexia nervosa is a voluntary reduction of food intake, a symptom that only occurs in the animal model if rats are exposed to the ABA protocol for a long extended time at the risk of dying. Because the procedure is typically stopped when animals have reached a loss of 75% in their weight, with this model we are possibly investigating the conditions that favor the initial development of anorexia rather than the development of the clinical syndrome at full.

Previous literature has shown mutual substitutability between schedule-induced activities, such as when drinking (SIP) and running compete for expression under time constraints imposed by food reinforcement schedules (Roper 1978; Segal 1969; Wetherington and Riley 1986). The running generated under the ABA procedure seems also functionally similar to induced drinking, given its facilitation by prior SIP. Furthermore, the running in ABA occurred predominantly before and after food episodes, which is characteristic of schedule-induced behaviors (Staddon 1977) and contrary to facultative behavior given that it does not seem to be independent of the induction and reinforcement provided by the schedule of food availability.

Thus, a good way to prevent initial risk of developing anorexia nervosa may involve paying attention to feeding regimes, as we know that the frequency of meals is the best determinant of level of induction (e.g., Íbias and Pellón 2011), and by

considering activity as being initiated by the intermittency of feeding, very high and very low feeding schedules will be best options to prevent the development of excessive activity that might lead to the initiation of a phenomenon that can end up in deleterious effects.

Additionally, activity is regarded as reinforcing by itself for caged laboratory rats (e.g., Belke et al. 2017), so that the combination of inducing activity by the intermittency of restricted food and reinforcer activity itself could create a circle for the excessive development of running and the development of losing weight as the defining characteristic of ABA achievement.

Alternatively, the possibility exists that prevention of activity might be a therapeutic treatment of anorexia once developed, but because health recommendations are geared toward prompting exercise and good eating practices, we are more inclined at this point to pay attention to food regimens rather than restricting access to activity, at least as a first approach to prevent development of the disease.

This viewpoint is in line with the original proposal of Epling and Pierce (1992) on the inducing capacity of events that occur intermittently at low frequency, in addition to the contribution of access to activity as a reinforcing event in addition to food, not just in substitution as suggested by Epling and Pierce.

That the marker of running comes from the occurrence of food contradicts in part the proposal of Beneke et al. (1995) who conferred a larger influence to the 24-h circadian rhythm based on light/dark periods. The initial circadian control of activity subsides to the control of the food rhythm in the case of ABA (cf. Fuentes et al. 2015).

Policies and Protocols

In this chapter we have described a study in which it is suggested that the critical role for the initial development of anorexia in an animal model of the disease is the development of excessive activity as a consequence of the intermittent occurrence of feeding episodes. The loss in weight that characterizes the development of anorexia seems to be initiated by the hyperactivity developed by the animals and not as an initial failure to adapt to the feeding regime. This excessive activity finally interferes with eating, thus leading to the deleterious circle of increasing activity and decreasing food intake. It is our recommendation to focus on the strict eating regimes that normally accompany the initial stages of the development of anorexia in humans, suggesting that by setting different meals to appropriate times within a day might be a good health recommendation for potentially attenuating the development of the disease.

Dictionary of Terms

- **Activity-based anorexia** – A laboratory model mostly used with rats that simulates the combination of food dieting and strenuous exercise that characterizes anorexia in humans.

- **Animal model** – The development with nonhuman animals in the laboratory of a model of a disease in humans that looks similar in its appearance and underlying mechanisms.
- **Anorexia nervosa** – A human disease with a high prevalence in young adolescent women (but not only in women) characterized by a dramatic loss in weight normally accompanied by concurrent food dieting and hyperactivity.
- **Schedule-induced polydipsia** – A phenomenon first shown in the laboratory by which moderately hungry rats drink excessive quantities of water when food is scheduled intermittently.
- **Schedule induction** – The occurrence of patterns of behavior only by the delivery of noncontingent relevant events, such as when food is delivered on a time basis to food-deprived rats and it induces drinking, running, grooming, etc.

Summary Points

- This chapter focuses on activity-based anorexia, an animal model of anorexia nervosa in humans.
- Anorexia is characterized by the loss in weight that results from a combination of dieting and exercise.
- It is suggested that excessive exercise is a product of strict intermittent feeding episodes.
- Excessive activity can be induced by intermittent food schedules that also induce other patterns of behavior, notably excessive drinking.
- The previous development of schedule-induced drinking facilitates later development of activity-based anorexia by means of increased wheel-running activity.
- Initial development of activity-based anorexia does not reflect a failure to adapt to food restriction.
- Excessive activity in anorexia seems to be the result of the intermittent scheduling of food episodes.
- Wheel-running activity also seems to be reinforcing for caged animals.
- The way to reduce excessive activity by means of controlling feeding episodes seems to appropriate in place of, or in addition to, simply restricting the possibility of exercising.

Abstract

The maintenance of plasma glucose is a vital necessity in all situations. Multiple adaptations permitting endogenous glucose production from the liver, kidneys, and gut take place during starvation. The mobilization of liver glycogen stores is the more rapid process to tune blood glucose from the moment where glucose

availability from food starts to lack. Increased lipolysis from the adipose depots plays a crucial role to provide energy to the whole body and especially to allow the liver to carry out gluconeogenesis from lactate and alanine, which is an endergonic process. Proteolysis from skeletal muscles then supplies carbon skeletons to build glucose from amino acids released in blood. Among the exquisite late adaptations of gluconeogenesis taking place after the exhaustion of liver glycogen stores, the progressive replacement of hepatic gluconeogenesis by renal and intestinal gluconeogenesis (from glutamine) is essential, since it permits to maintain plasma glucose and in the same time to preserve energy balance of the body. Gluconeogenesis from glutamine, indeed, is an exergonic process. The late blunting in hepatic GNG paralleling the increase in intestinal GNG in late starvation allows the liver to store glycogen again, which might be a key adaptation for survival.

Keywords

Endogenous glucose production · Liver · Kidney · Intestine · Gluconeogenesis · Glycogen · Glucose-6 phosphatase · Phosphoenolpyruvate carboxykinase · Metabolic acidosis · Insulin · Glucagon

List of Abbreviations

CREB	cAMP-response element binding protein
EGP	Endogenous glucose production
G6Pase	Glucose-6 phosphatase
G6PC	G6Pase catalytic subunit
G6PT	G6Pase transporter subunit
GNG	Gluconeogenesis
PCK1	Phosphoenolpyruvate carboxykinase-cytosolic form

Introduction

The maintenance of plasma glucose concentration around 0.9 mg/L is a vital necessity for all animal classes. Indeed, a few minutes under hypoglycemia is sufficient to rapidly promote deleterious metabolic events in some organs, such as the brain or the gut that require glucose permanently (Delaere et al. 2010). Glucose supply in blood must therefore be continuous. The main source of external glucose under physiological conditions of nutrition derives from food assimilation. However, it is well known that most animal have the capacity to endure long periods of fasting (weeks or even months), which is a condition for survival in the wildlife. Hopefully, natural selection has allowed animals to cope with the eventuality of hypoglycemia during starvation, owing to glucose-producing organs. These are the liver, kidney, and intestine, which are able to synthesize glucose from nonglucidic three carbon compounds and to release it in blood, a process called gluconeogenesis. Specifically, the liver is able to store glucose imported from blood during food assimilation under the form of a

polymeric macromolecule called glycogen. This store can be rapidly mobilized when glucose in blood is lacking, owing to a process called glycogenolysis (Mithieux 1997; Nordlie et al. 1999).

Glucose-6 Phosphatase: Key Enzyme of Endogenous Glucose Production

What makes that the liver, kidneys and intestine are able to produce glucose in blood is the presence of glucose-6 phosphatase (G6Pase). This is the only intracellular enzyme of the body capable of hydrolyzing glucose-6 phosphate that can be either released from glycogen stores in the liver or synthesized via gluconeogenesis in the 3 organs (Mithieux et al. 2004b) (Fig. 1). Both the catalytic subunit of G6Pase (called C6PC) and a glucose-6 phosphate transporter subunit (called G6PT) essential to G6Pase activity are intramembranous proteins, deeply embedded in the endoplasmic reticulum membrane.

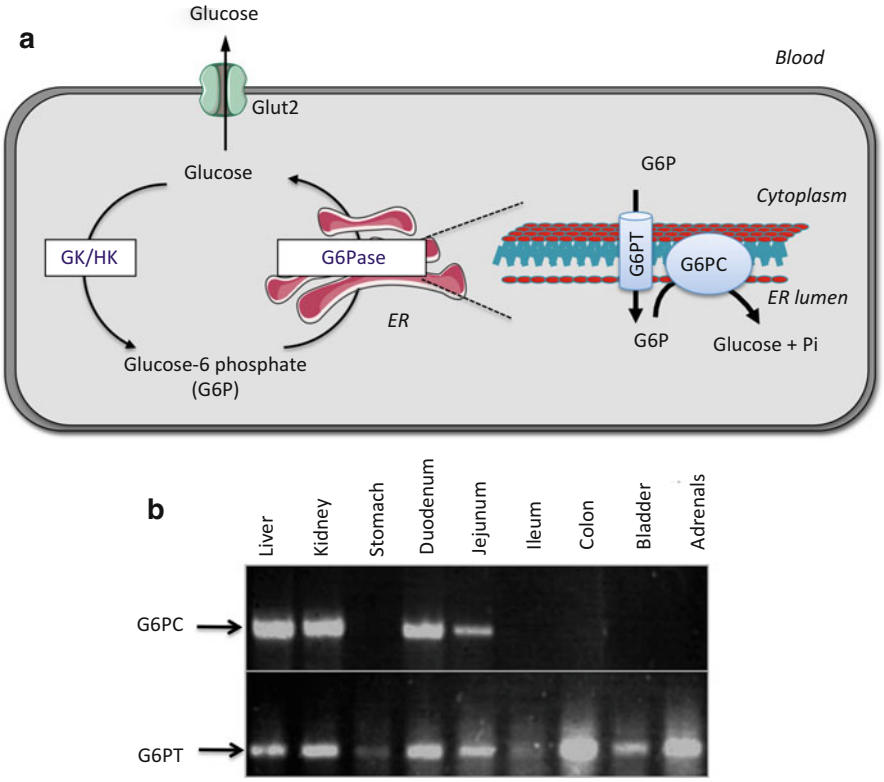

Fig. 1 Glucose-6-phosphatase is the key enzyme in endogenous glucose production. *Panel A*: Position of glucose-6-phosphatase in metabolism and structure within the membrane of the endoplasmic reticulum. *Panel B*: Expression of *g6pc* and *g6pt.* genes in various tissues, studied through the presence of their respective mRNAs

Whether or not they are in physical interaction is still to be deciphered (Soty et al. 2012). The G6PT subunit is ubiquitous, and therefore, it is G6PC expression which confers the capacity on the liver, kidney, and gut to produce glucose in blood (Fig. 1). It is noteworthy that *G6PC* gene expression and G6Pase activity are increased during starvation, when glucose release in blood is needed. This takes place in the three gluconeogenic organs (Mithieux 1997; Rajas et al. 1999).

Adaptations of Endogenous Glucose Production in Postabsorptive Period

Utilization of Hepatic Glycogen Stores

Once the postprandial period is ending, glucose production in blood becomes crucial to avoid the drop in plasma glucose, which would be the consequence of glucose utilization by all organs of the body to feed glycolysis. Endogenous glucose is first produced from the hepatic glycogen stores, possible owing to the activity of a key enzyme: glycogen phosphorylase. Glycogen phosphorylase is controlled by glucagon secreted by pancreatic α-cells in the postabsorptive and fasting states, and insulin secreted by pancreatic β-cells in response to elevations in plasma glucose. Under the action of the glucagon receptor and its second messenger cAMP, the phosphorylation of glycogen phosphorylase by the catalytic subunit of protein kinase A (PKA) activates the enzyme (Saltiel 2001). In the same time, PKA inhibits glycogen synthase, the regulatory enzyme of glycogen synthesis opposing to glycogen phosphorylase. The decrease in plasma insulin (an inhibitory hormone of glycogen phosphorylase and an activating hormone of glycogen synthase) occurring from the end of the postprandial period facilitates the activation of glycogen phosphorylase by glucagon and the release of glucose from hepatic glycogen stores (Fig. 2). Glucose-1 phosphate released from glycogen is converted in glucose-6 phosphate, which is then hydrolyzed in glucose and Pi by G6Pase. Glycogen stores are considered to contribute to endogenous glucose production (EGP) for about 10–12 h in rodents and 20 h in human subjects. After exhaustion of hepatic glycogen, gluconeogenesis must relay glycogenolysis to maintain plasma glucose. It must be recalled that glycogen storage is a specificity of the liver among gluconeogenic organs, since the kidney and the small intestine are unable to carry out glycogen synthesis under physiological conditions.

Posttranslational Activation of Gluconeogenesis

It is noteworthy that the enzymatic activity of two regulatory enzymes of gluconeogenesis, namely G6Pase and fructose-1,6-bisphosphatase, is activated by mechanisms dependent on glucagon and cAMP (Ichai et al. 2001; Rider et al. 2004; Soty et al. 2016). It could be further specified that G6PT, rather than G6PC, is the target of the activation of G6Pase activity by PKA (Soty et al. 2016) and that the mechanism

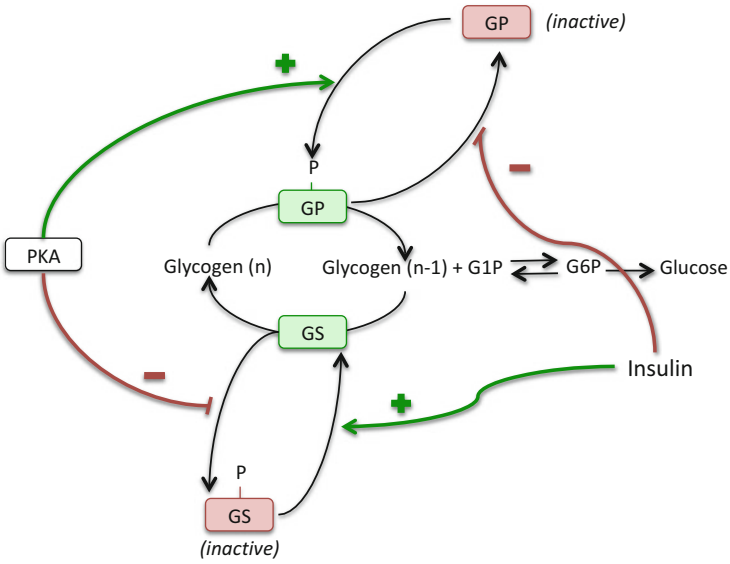

Fig. 2 Control of glycogen synthesis and glycogenolysis by glucagon and insulin. Regulation by phosphorylation of glycogen synthase (*GS*) and glycogen phosphorylase (*GP*) by PKA and insulin

of activation requires biochemical conditions compatible with membrane fluidity (Ichai et al. 2001) (Fig. 3). It is noteworthy that G6Pase activity is also controlled (inhibited) during the fasted to fed transition (Minassian et al. 1995, 1999), via a mechanism involving both hyperglycemia and insulin (Guignot and Mithieux 1999). Under the action of insulin, its target phosphatidylinositol-3 kinase is translocated at the endoplasmic reticulum membrane and suppresses G6Pase activity, via competitive inhibition by its product phosphatidylinositol-(3,4,5) triphosphate (Fig. 3) (Mithieux et al. 1998; Daniele et al. 1999). The drop in plasma insulin and glucose accompanying fasting thus promotes reversal of this inhibition. It must be mentioned that additional regulations of G6Pase activity involve free fatty acids and fatty acyl-CoA species (Mithieux et al. 1993; Mithieux and Zitoun 1996) and α-ketoglutarate in the presence of Mg^{++} (Mithieux et al. 1990; Minassian et al. 1994). Interestingly, the decrease in liver α-ketoglutarate concentration at the beginning of fasting might play a role in the stimulation of hepatic glucose production (Minassian et al. 1994).

Besides, fructose-1,6 bisphosphatase is indirectly activated in response to the drop in fructose-2,6 biphosphate, its key allosteric activator. The latter, indeed, is hydrolyzed by fructose-2,6 bisphosphatase-phosphofructokinase 2, a bifunctional enzyme hydrolyzing or synthetizing fructose-2,6 bisphosphate from fructose-6 phosphate, which phosphatase activity is activated by PKA (Rider et al. 2004) (Fig. 4). Interestingly, the PKA-dependent drop in fructose-2,6-bisphosphate promotes the inhibition of phosphofructokinase 1, the glycolytic enzyme opposing to fructose-1,6-bisphosphatase, thus favoring the substrate flux in the sense of gluconeogenesis (Fig. 4).

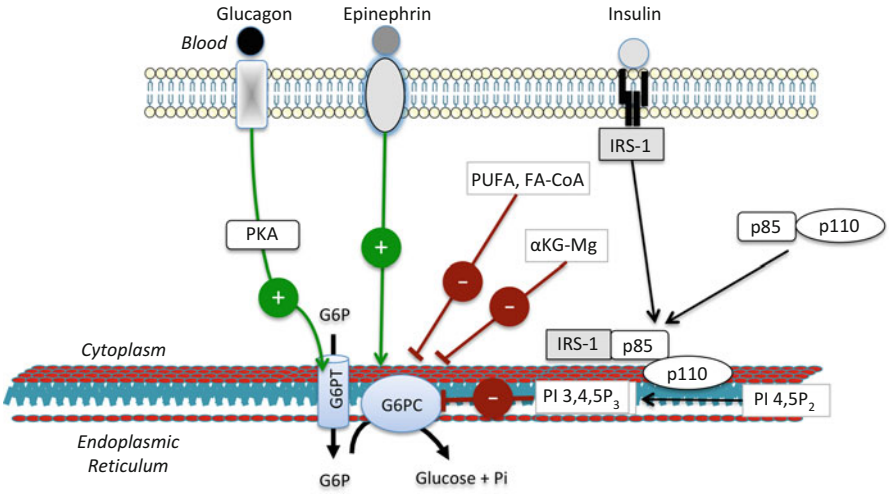

Fig. 3 Regulation of glucose-6-phosphatase activity by hormones and nutrient-derived metabolites. Biochemical regulations of G6Pase activity by glucagon/PKA, epinephrin, polyunsaturated fatty acids (*PUFA*), fatty-acyl-CoAs (*FA-CoA*), alpha-ketoglutarate-magnesium chelates (*aKG-Mg*), and insulin/phosphatidylinositol-3 kinase (p85 refers to the regulatory subunit and p110 to the catalytic subunit). It has been specified that PKA-dependent phosphorylation is targeted on G6PT and not G6PC

Two other important enzymes in gluconeogenesis are pyruvate carboxylase converting pyruvate in oxaloacetate and phosphoenolpyruvate carboxykinase-cytosolic form (PCK1) converting oxaloacetate in phosphoenolpyruvate. No short-term regulation has been demonstrated up to know for PCK1. It is noteworthy that pyruvate carboxylase activity is stimulated by acetyl-CoA, a product of free fatty acid oxidation, which is a process activated by glucagon (McGarry and Foster 1980; Puigserver and Spiegelman 2003). Therefore, pyruvate carboxylase is activated during fasting, once adipose tissue lipolysis has taken place and free fatty acids are elevated in the plasma (Hue 1987) (Fig. 5).

Long-Term Adaptations of Gluconeogenesis During Fasting

Induction of Gluconeogenesis Gene Expression

If fasting continues after the prior postabsorptive period, the induction of gluconeogenesis genes expression takes place to sustain EGP. Glucagon and its second messenger cAMP are key regulators of gluconeogenesis genes expression, together with glucocorticoids, the secretion of which is increased during starvation. This increases the amount of enzymes able to produce glucose in blood. This control relates to *G6pc* gene expression at a transcriptional level, especially involving a crucial transcription factor, named CREB for cAMP-response element binding

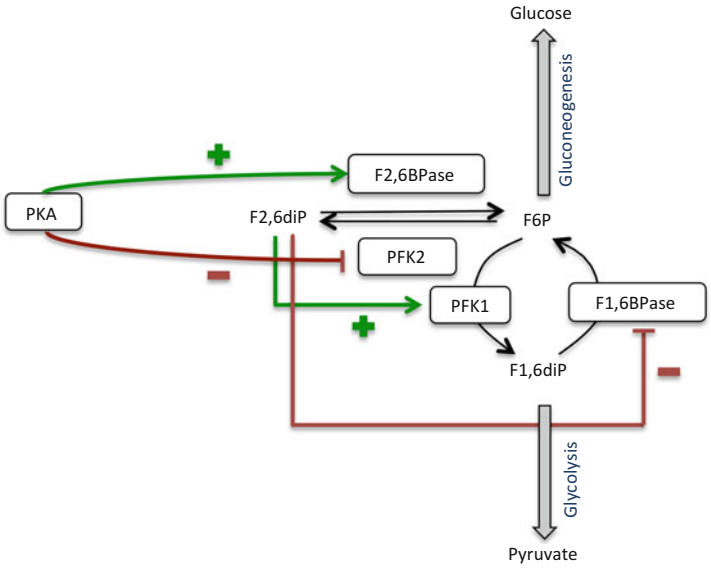

Fig. 4 Control of fructose-1,6-bisphosphatase and phosphofructokinase activities by protein kinase A. Regulation of fructose-1,6 bisphosphatase (*F1,6BPase*) and phosphofructokinase-1 (*PFK1*) by fructose-2,6 diphosphate (*F2,6diP*). The synthesis/degradation of F2,6 diP is controlled by PKA-phosphorylation via the regulation of the bifunctional enzyme (activation of fructose-2,6 bisphosphatase (*F-2,6BPase*), inhibition of phosphofructokinase-2 (*PFK2*)

protein. This factor is phosphorylated by PKA under the influence of cAMP, which increases its binding to the *G6pc* gene regulatory sequences (promoter) and the production of *G6pc* mRNA (and then protein product). Transcriptional regulation by glucagon and glucocorticoids requires functional interaction of phosphorylated CREB with several other transcription factors (Gautier-Stein et al. 2005), including the glucocorticoid receptor (Vander Kooi et al. 2005) (Fig. 6). Interestingly, CREB plays a crucial role in the liver and in the two other gluconeogenic organs as well (Gautier-Stein et al. 2006; Mutel et al. 2011). It must be mentioned that comparable regulations involving cAMP, PKA, and glucocorticoids take place for PCK1, another crucial regulatory enzyme of gluconeogenesis, in the liver and intestine (Hue 1987; Mutel et al. 2011). However, it must be specified that a process dependent on metabolic acidosis accounts for the induction of PCK1 gene expression in the kidney as fasting prolongs (Alleyne and Scullard 1969; Mutel et al. 2011).

Altered Repartition of Endogenous Glucose Production Among Gluconeogenic Organs

At the beginning of postabsorptive period, a time where liver glycogen stores are present and are being mobilized, the liver accounts for at least 80% of EGP in rats (Fig. 7). Renal GNG in this situation accounts for about 15–20% and intestinal GNG

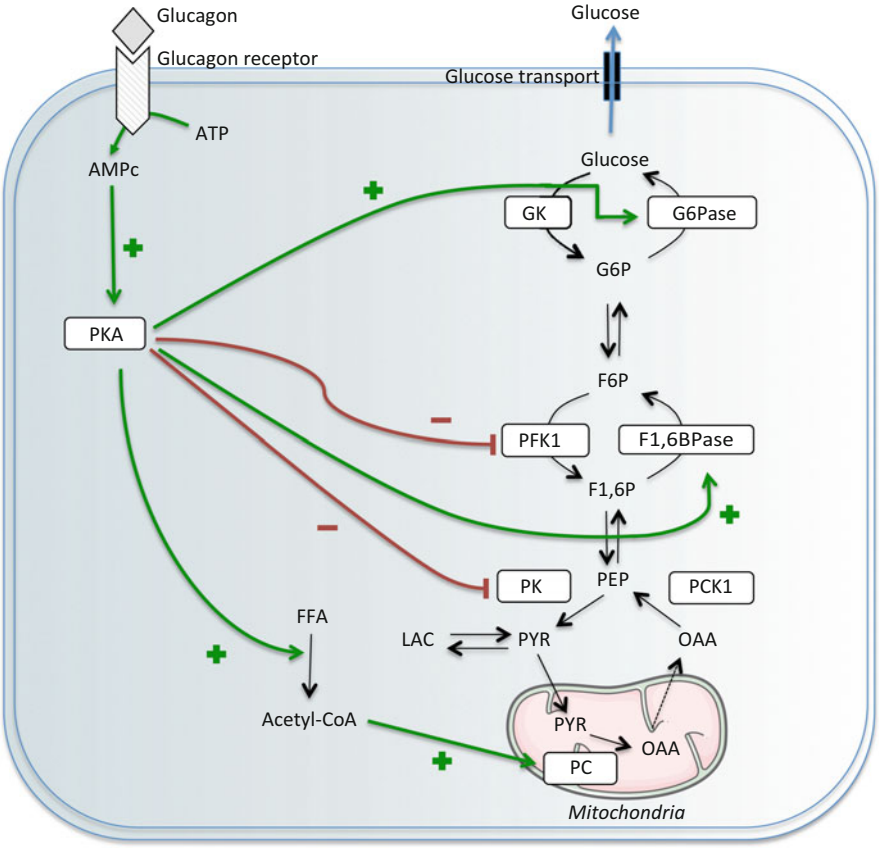

Fig. 5 Regulation by glucagon and protein kinase A of key steps of glycolysis and gluconeogenesis. Glucagon and PKA control multiple steps of glycolysis/GNG. Protein kinase A inhibits pyruvate kinase (*PK*) directly by phosphorylation, which inhibits glycolysis and redirects phosphoenolpyruvate (*PEP*) in GNG. In the same time, PKA activates pyruvate carboxylase (*PC*) indirectly via acetyl-CoA produced from free fatty acids (*FFA*). This increases the amount of oxaloacetate (*OAA*), the substrate of PCK1, and contributes to the stimulation of GNG

is weak, estimated between 5% and 10% of EGP (Croset et al. 2001; Mithieux et al. 2006; Pillot et al. 2009). It must be mentioned that intestinal GNG can be induced under the influence of some macronutrients, such as in animals fed foods enriched in proteins (Mithieux et al. 2005; Duraffourd et al. 2012) or in soluble fibers (De Vadder et al. 2014; De Vadder et al. 2016). However, this is out of the scope of the adaptations to starvation described herein. The repartition is dramatically different at 24 h of fasting, a time at which glycogenolysis has ended because of glycogen store exhaustion. In this case, intestinal and renal GNG increase their participation to EGP to account for about 20–25% and 50–55% of EGP, respectively, in fasting rats (Croset et al. 2001; Pillot et al. 2009) (Fig. 7). It is noteworthy that comparable results were obtained for renal GNG in humans in the postabsorptive state and after

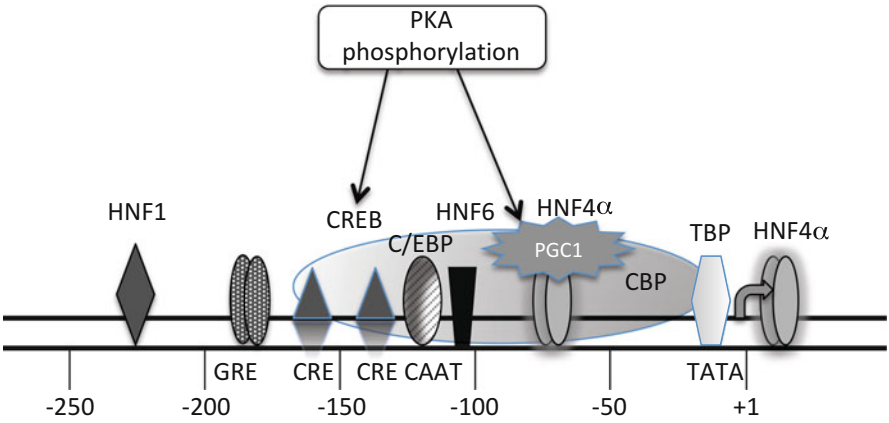

Fig. 6 Regulation by protein kinase A and glucocorticoids of gene transcription of glucose-6 phosphatase catalytic subunit. The phosphorylation of CREB by PKA activates its binding to two CREB response elements (*CRE*) of the *G6pc* promoter and in parallel to the promoter of *Pgc1* (peroxisome proliferator-activated receptor gamma coactivator 1-alpha). Glucocorticoids promote the binding of the glucocorticoid receptor (*GR*) to the GR element of the *G6pc* promoter. Several tissue-specific transcription factors: C/EBP (CAAT-enhancer binding protein), HNF1, HNF4α, and HNF6 (hepatic nuclear factors) also contribute to the stabilization of the cofactors PGC1 and CBP (CREB binding protein), which results in the induction of the transcriptional activity of *G6pc*

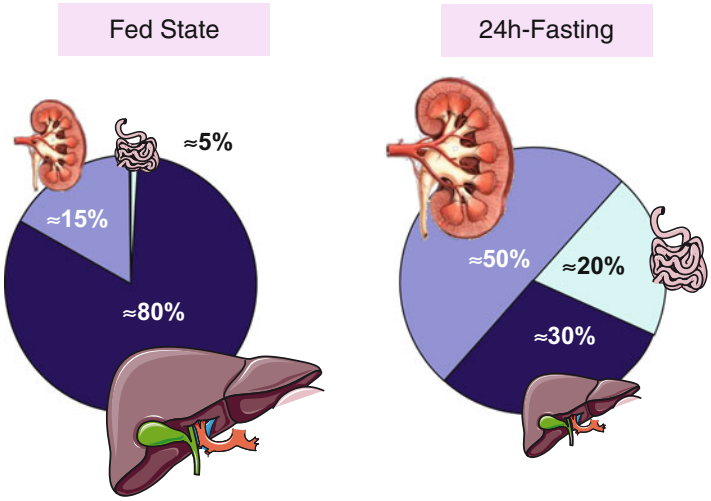

Fig. 7 Repartition of glucose production among gluconeogenic organs in the fed post-absorptive state and in 24 h-fasting state. *Left panel*: the rats were studied at the beginning of the postabsorptive period (food removal 6 h before). *Right panel*: relates to the situation at 24 h of fasting. The results shown here are compiled from Croset et al. (2001), Mithieux et al. (2006), and Pillot et al. (2009)

prolonged fasting, respectively (Owen et al. 1969; Gerich et al. 2001). It is likely that a combination of posttranslational regulations of gluconeogenic enzyme activities and inductions of gluconeogenic gene expression concur to these changes in EGP.

Late Adaptations During Starvation

Surprisingly, if fasting lasts more than two days in rats, after a prior phase of liver glycogen exhaustion up to 48 h of fasting, a rebound in glycogen stores to about 15% of the fed state level takes place at 72 h and 96 h of fasting (Minassian et al. 1994). This is the likely result of the combination of at least three processes taking place after 48 h of fasting. (1) There is a further increase in intestinal GNG between 48 h and 72 h of fasting, a time where IGN may account to about 1/3 of EGP (Mithieux et al. 2004a). (2) There is an intriguing drop in hepatic *G6pc* gene expression, promoting a decrease in G6Pase activity at 72 h of fasting (Minassian et al. 1994; Minassian et al. 1996). In contrast, G6Pase activity further increases in kidney and plateaus in gut after 48 h of fasting (Fig. 8). (3) There is a reset of hepatic α-ketoglutarate at a fed level, i.e., a concentration at which this metabolite is able to inhibit G6Pase activity (Minassian et al. 1994). In agreement with the inhibition of G6Pase activity, an increase in hepatic glucose-6-phosphate occurs at 72 h of fasting, thus favoring the synthesis of glycogen, since glucose-6-phosphate is a key allosteric activator of glycogen synthase (Villar-Palasi and Guinovart 1997). That *G6pc* gene expression resumes fed level at 72 h of fasting could appear surprising, since the gene is controlled by the glucagon/insulin ratio and no change in this ratio occurs between 48 h and 72 h of fasting (Minassian et al. 1996). Interestingly, it has been shown that IGN, via the nervous detection of glucose released in the portal vein, is able to activate a gut-brain-liver neural circuit promoting hepatic insulin sensitivity and inhibiting hepatic glucose production (Pillot et al. 2009; De Vadder et al. 2016). Therefore, intestinal GNG might have a role in this process, being further increased at 72 h of fasting compared with 48 h (Mithieux et al. 2004a).

Benefits for Survival Provided by Induction of Renal and Intestinal Gluconeogenesis During Starvation

Glucose homeostasis being a vital phenomenon (see introduction), it is obvious that the recruitment of renal and intestinal GNG is beneficial during food deprivation. However, there are also multiple other benefits in energy homeostasis provided by the induction of renal and intestinal GNG during food deprivation.

First, glutamine is a major substrate for both renal and intestinal GNG (Croset et al. 2001; Gerich et al. 2001). On the contrary, the liver is unable to metabolize glutamine since, due to its kinetic properties, liver glutaminase cannot use glutamine at physiological concentration (Hartmann and Plauth 1989). Therefore, renal and intestinal GNG allow the body to engage glutamine carbons in gluconeogenesis, a process that the liver is unable to do. One must keep in mind that glutamine released

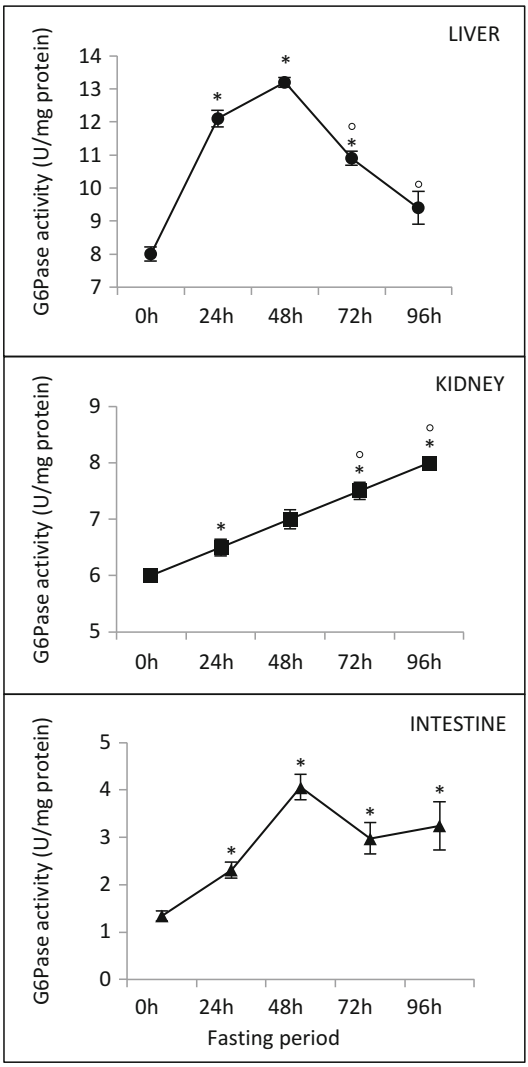

Fig. 8 Time course of hepatic, renal, and intestinal glucose-6-phosphatase activity in starvation. The results are expressed as unit of enzymatic activity/g of tissue. The data shown are compiled from Minassian and Mithieux (1994), Minassian et al. (1994), and Mithieux et al. (2004a). *, different from time 0; °, different from time 48 h

in blood in response to the activation of muscular proteolysis represents a crucial gluconeogenic reservoir during starvation.

Second, in the intestine, glutamate (produced from glutamine by glutaminase) is metabolized by glutamate-pyruvate carboxylase, a two-substrate enzyme utilizing pyruvate as a second substrate and releasing alanine from pyruvate (Windmueller and Spaeth 1974; Watford 1994). Pyruvate is also utilized by lactate dehydrogenase to produce lactate. Alanine and lactate, released in the portal vein, are then captured by the liver, in which they constitute the main gluconeogenic substrates. Therefore, a consequence of the use of glutamine by intestinal GNG is the feeding of hepatic GNG (Croset et al. 2001).

Third, it is a widely accepted dogma that gluconeogenesis, as anabolic process, is endergonic and consumes energy. This is indeed true for hepatic GNG from lactate and alanine. However, glutamine, a five-carbon compound, is partly oxidized in the Krebs cycle and provides energy before three remaining carbons are incorporated into the glucose skeleton. As a consequence, glucose production from glutamine by renal and intestinal GNG is exergonic and produces four ATP per mole of glucose synthesized (Mithieux et al. 2004b). Therefore, a major advantage of the switch from hepatic to intestinal and renal GNG during starvation is that it permits to fulfill the need of glucose homeostasis and in the same time this preserves the energetic balance of the kidney and intestine. It is noteworthy that in the liver and intestine, a comparable benefit may be ascribed to gluconeogenesis from glycerol (+4 ATP per mole of glucose produced). Gluconeogenesis from glycerol becomes substantial following the activation of adipose tissue lipolysis accompanying fasting (Croset et al. 2001; Mithieux et al. 2004b).

At last, the presence of glycogen stores in starvation is likely very useful in the situations requiring an urging availability in blood glucose. This relates for example to situations requiring to run, e.g., to escape a predator, to catch a pray, or to fight, which are under the influence of stress hormones (glucagon, catecholamines). Therefore, the novel repartition of gluconeogenesis permitting the rebound of liver glycogen stores (see above) may be essential for survival in the wild life.

Conclusion

There are multiple metabolic adaptations taking place in animals permitting to cope with food deprivation. The maintenance of plasma glucose constant is certainly a vital necessity within a time scale in the minute range. Increased lipolysis from the adipose depots plays a crucial role to provide energy to the whole body and especially to permit liver gluconeogenesis. The mobilization of liver glycogen stores is the more rapid process to tune blood glucose from the moment where glucose availability from food starts to lack. Among the exquisite adaptations of gluconeogenesis taking place after the exhaustion of liver glycogen stores, the replacement of hepatic GNG by renal and intestinal GNG seems essential, permitting to maintain plasma glucose and in the same time to preserve energy balance of the body. The late mirror evolution of hepatic and intestinal GNG in late starvation, allowing the liver to store glycogen again, is likely a key adaptation for survival.

Dictionary of Terms

- **Gluconeogenesis** – A process of synthesis of glucose from nonglucidic compounds, e.g. amino acids.
- **Glycogen** – A macromolecule that is a polymer of glucose and serves as storage of glucose.

Summary Points

- The maintenance of plasma glucose is a function of vital necessity during starvation.
- Endogenous glucose production allows the body to maintain plasma glucose during food deprivation.
- Glucose-6-phosphatase is the key enzyme of endogenous glucose production, since it is capable of hydrolyzing glucose-6-phosphate.
- Glucose-6-phosphatase is expressed in the liver, kidney, and intestine exclusively, and confers on these organs only the capacity to release glucose in blood.
- Hepatic glycogen stores are first mobilized to cope with short deprivation of food glucose.
- Gluconeogenesis from the liver, kidney, and intestine is then induced to maintain plasma glucose during lasting food deprivation.
- Glucagon and its intracellular relay protein kinase A play a key role in the activation of gluconeogenesis, via biochemical regulations of several gluconeogenic enzymes and inductions of gene expression at a transcriptional level.
- The progressive replacement of liver gluconeogenesis from alanine and lactate (an endergonic process) by renal and intestinal gluconeogenesis from glutamine (an exergonic process) during starvation is beneficial for energy balance.
- The late storage of glycogen in the liver, combining a suppression of hepatic glucose production and sustained intestinal gluconeogenesis, is a notable adaptation of interest for survival.

Stress Response of Nutrient-Starved Cardiovascular Cells

111

Lakshmi Pulakat and Madhavi P. Gavini

Contents

Abstract

Both starvation and over-nutrition are conditions that exert nutrient stress on cardiovascular cells. Undernutrition results in reduced availability of micro- and macronutrients to all organ systems. However, studies have shown that overweight and obese individuals also have micronutrient deficiencies that contribute to the pathogenesis of cardiovascular disease. In utero nutrient deficiency negatively affects birth weight, total cholesterol, glucose tolerance, triglycerides, risk of coronary heart disease, and obesity. These effects are intergenerational. Some of the key signaling pathways responsible for these effects are discussed in this chapter. mTORC1 functions as a nutrient sensor; both overactivation of mTORC1

via over-nutrition and chronic suppression of mTORC1 causes cardiovascular stress and CVD. mTORC1 overactivation is well-addressed clinically via the development of inhibitors such as rapamycin. However, chronic suppression via inhibitors leads to suppressed expression of cardiac prosurvival proteins including MCL-1. Activation of the anti-inflammatory arm of the RAS (AT2R) via peptide agonist NP-6A4 restores MCL-1 and protects cardiomyocytes from nutrient stress.

Keywords

Cardiovascular disease · *mTOR* · Rapamycin · MCL-1 · IRS · AKT/PKB · Angiotensin II · AT1R · AT2R · NP-6A4 · ARB

List of Abbreviations

ACS	Acute coronary syndrome
AdipoR1	Adiponectin receptor 1
AMP	Adenosine monophosphate
Ang II	Angiotensin II
AKT/PKB	Protein kinase B
asTORi	Active-site mTOR inhibitor
AT1R/AT2R	Angiotensin II type 1 receptor/ type 2 receptor
ARB	Angiotensin II type 1 receptor blocker
BMI	Body mass index
CI	Cell index
CGP42112A	AT2R peptide agonist
CHF	Congestive heart failure
CRP	C-reactive protein
CVD	Cardiovascular disease
Deptor	DEP-domain-containing mTOR interacting protein
GAP	GTPase activating protein
GDP	Guanosine diphosphate
GFP	Green fluorescent protein
GTP	Guanosine triphosphate
GPCR	G-protein coupled receptor
hCAVSMC	Human coronary artery vascular smooth muscle cells
HL-1	A mouse atrial cardiomyocyte cell line
IL-1alpha	Interleukin 1 alpha
IL-6	Interleukin 6
IRS1/2	Insulin receptor substrate 1/substrate 2
IRS	Insulin receptor substrate
LAMP-1	Lysosomal-associated membrane protein 1
MACE	Major adverse cardiac events
MCL-1	Myeloid cell leukemia 1
miR-26/miR-29	microRNA 26/29
mLST8	Sec13 protein 8 (also known as GbL)
mSIN1	Mammalian stress-activated protein kinase interacting protein

mTORC1 and mTORC2	Mechanistic target of rapamycin complexes 1 and 2
MMP2/9	Matrix metalloproteinase 2/9
NP-6A4	AT2R agonist developed by Novopyxis Inc.
NRK	Normal rat kidney cells
PD123319	AT2R antagonist
PLC	Phospholipase C
PRAS40	Prolinerich AKT substrate 40 kDa
Protor-1	Protein observed with Rictor-1
PTEN	Phosphatase and tensin homolog
PP2A	Protein phosphatase 2A (PP2A)
PP242	A drug that inhibits mTOR
PI3K	Phosphatidyl inositol 3 kinase
RAG GTPases	Sixth subfamily of Ras-related GTPases (consisting of RAGA, RAGB, RAGC, and RAGD) where Ras is a superfamily of small molecular weight GTPases
Raptor	Regulatory-associated protein of mTOR
Rictor	Rapamycin-insensitive companion of mTOR
Rheb	Ras homolog enriched in brain
S6 K1	Ribosomal protein S6 kinase beta-1 also known as p70s6 kinase
TSC	Tuberous sclerosis complex consisting of TSC1 or hamartin and TSC2 or tuberin
TIMP1	Tissue inhibitor of metalloproteinases
TNFα	Tumor necrosis factor-alpha
RAS	Renin angiotensin system
Ras-Raf-MEK-ERK1/2	Ras-mediated growth promoting signaling pathway
Src	Proto-oncogene tyrosine-protein kinase Src
4E–BP	Eukaryotic translation initiation factor 4E–binding protein

Introduction

Despite significant advances in diagnosis and treatment options, cardiovascular disease (CVD) is still the leading cause of death globally (Benjamin et al. 2017). Several factors contribute to the high mortality and increasing prevalence of CVD including increased rates of diabetes, obesity, poor diet, and physical inactivity. As a result, the majority of research efforts are focused on overnutrition and lack of physical activity, as they are the leading contributing factors to CVD. Overnutrition causes obesity and exerts nutrient stress on cardiovascular cells via a pathological increase in a constellation of nutrients such as glucose, cholesterol, and amino acids. These conditions lead to hemodynamic overload, hypertension, insulin resistance, Type 2 diabetes, atherosclerotic plaque formation, narrowing of arteries, and ischemic conditions that result in reduced availability of oxygen and nutrients to cardiovascular cells. These effects are intergenerational and lead to elevated CVD rates (Patti 2013).

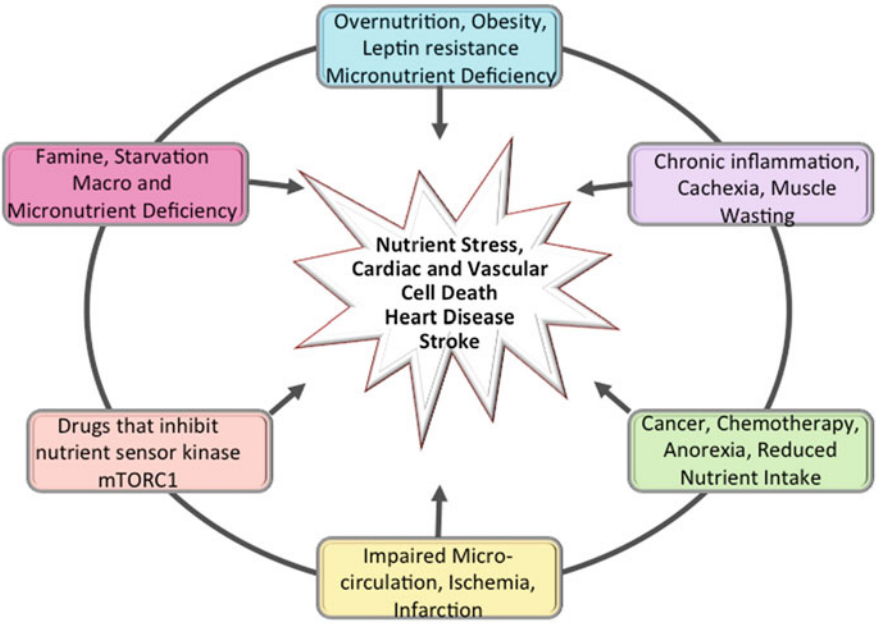

Fig. 1 Conditions that contribute to nutrient stress of cardiovascular cells. Famine, starvation, and micronutrient deficiency caused by drugs (mTORC1 inhibitors, chemotherapeutic agents), obesity, impaired microcirculation, and ischemia induce nutrient stress of cardiovascular cells

Like obesity, starvation and chronic undernutrition can also cause cardiovascular stress and subsequent CVD (Gottdiener et al. 1978; Fisler 1992). Additionally, starvation increases the intergenerational risk factors for developing CVD (Desai et al. 2015). Cachexia also exerts severe nutrient stress on cardiovascular cells. Thus, nutrient stress on cardiovascular cells comes from different underlying conditions (Fig. 1.). The focus of this review is on the mechanisms that contribute to nutrient stress of cardiovascular cells, their effects on cardiovascular cell survival and function, and current approaches to mitigate such stress.

Effect of Famine on CVD

Since it is not possible to study chronic undernutrition in humans via clinical trials, the majority of our knowledge on starvation comes from historical instances of famine exposure in various populations. Despite some limitations in famine research, there are strong population-wide correlations to mortality, fertility, weight gain during pregnancy, birth weight, and subsequent risk of cardiovascular disease (Painter et al. 2006, Lumey et al. 2011).

In studies on prenatal famine exposure in the Dutch famine, gestation stage during famine exposure impacted outcomes (Painter et al. 2006). For example,

Table 1 Effect of in utero exposure to famine on cardiovascular diseases and their predictors. *Pink labeled columns* denote female-specific effects

Characteristic	Early Gestation	Mid-Gestation	Late Gestation
Obesity	More Prevalent	Normal	Normal
Elevated Cholesterol	Elevated	Elevated	Elevated
Elevated Triglycerides	Elevated	Elevated	Elevated
Glucose Tolerance	Reduced (–21%)	More Reduced (–53%)	Reduced (–21%)
Birth Weight	Low	Low	Normal
Coronary Artery Disease (CAD)	High (8.8% vs 3.2%)	Normal	Normal

Lumey et al. stated that while children of mothers who were exposed to famine during their third trimester had normal birth weights, those exposed earlier in pregnancy (during their first or second trimesters) had firstborn offspring with lower birth weights compared to unexposed controls (Stein and Lumey 2000). Importantly, famine exposure effects proved to be intergenerational since mothers born after third-trimester famine exposure had babies with lower birth weights. In addition to low birth weight, the cardiovascular effects of in utero famine exposure are seen primarily in those exposed to famine in early gestation (Lumey et al. 2011). Those individuals had a higher prevalence of coronary heart disease compared to nonexposed individuals (8.8% v 3.2%; odds ratio adjusted for sex 3.0, 95% confidence interval (CI) 1.1 to 8.1) (Table 1) (Roseboom et al. 2000).

A significant risk factor for CVD is type 2 diabetes. Diabetes risk was also affected by famine exposure in utero (Lumey et al. 2011). Glucose tolerance was shown to be impaired in those who were prenatally exposed to famine. This effect was more profound in those exposed to famine mid-gestation with a disposition (−53% [−126 to −3]) compared with controls. Impaired glucose tolerance is an early symptom of type 2 diabetes, which is an independent risk factor for CVD (Table 1).

Elevated triglycerides and total cholesterol, which are other risk factors for CVD, also increased in populations exposed to famine in utero (Stein et al. 2009; Lumey et al. 2011). Studies by Lumey et al. showed that famine exposure at any time in gestation was associated with an increase in the level of total cholesterol and triglycerides in women. While the increase in triglycerides was independent of mid-thigh circumference, it was attenuated by controls for waist circumference and BMI. However, increases in total cholesterol were independent of BMI as well as waist and mid-thigh circumference. Interestingly, obesity was also increased in women exposed to famine during early gestation in the Dutch famine (Ravelli et al. 1999). This effect was also seen in studies that examined populations from other famines including those born during the famine years of the Chinese Great Leap Forward (Luo et al. 2006; Yang et al. 2008). Results from these population studies

show that famine exposure resulted in increases in many of the same independent risk factors for CVD such as obesity. These observations also provide insights into famine survival and subsequent development of CVD. The mechanisms behind this seeming paradox are explained in the section below.

Both starvation and overnutrition are conditions that exert nutrient stress on cardiovascular cells. Undernutrition results in reduced availability of micro- and macronutrients to all organ systems in the affected individual. Micronutrient deficiency is an important underlying reason for cardiovascular pathology in response to starvation (Benjamin et al. 2017). However, obesity results in impaired microcirculation, which can restrict nutrient flow and availability to key organs (de Jongh et al. 2004). Although increased dietary consumption (carbohydrate, sugar, protein, lipids) is linked to overnutrition and obesity, studies have shown that overweight and obese individuals still have micronutrient deficiencies (Via 2012). Michael Via highlights that obese individuals often have significant deficiencies in vitamin D, chromium, biotin, and thiamine (Via 2012) and their absence contributes to the progression of type 2 diabetes. Supplementation with the micronutrients results in positive clinical trial outcomes. This was corroborated in a recent study by Saponaro et al., which used data from 261 heart failure patients and demonstrated that they were deficient in vitamin D (Saponaro et al. 2017). This has been corroborated by several meta-analyses of epidemiological studies (Grandi et al. 2010; Pilz et al. 2016, Wei et al. 2016; Saponaro et al. 2017).

Other important micronutrient deficiencies include reduced vitamin A and iron (Syrkis and Machtey 1973; Zhao et al. 2015; Wei et al. 2016). A recent study on school-age children in Chongqing, China, has highlighted the association of vitamin A insufficiency with obesity (Wei et al. 2016). Iron deficiency (hypoferremia) is also associated with obesity. A recent quantitative meta-analysis was performed using 26 cross-sectional and case-control studies comprising 13,393 overweight and obese individuals and 26,621 normal weight participants. Results from that study demonstrate that overweight and obese individuals have hypoferremia (Zhao et al. 2015). Additionally, it is suggested that hypoferremia is associated with myocardial infarction (Syrkis and Machtey 1973). These analyses show that micronutrient deficiencies that arise as a result of either obesity or undernutrition can induce similar nutrient stress on the cardiovascular system (Fig.2). In the next section, the maladaptive cardiovascular signaling due to nutrient stress as a way of elucidating the molecular mechanisms responsible for cardiac dysfunction is discussed.

Nutrient Stress Associated Maladaptive Cardiovascular Signaling

The mTORC1 and the critical need to achieve a fine balance of mTOR signaling in cardiovascular cells: The mechanistic target of rapamycin (mTOR) serves as a regulator of an evolutionarily conserved mechanism that is critical for the survival of cardiovascular cells (Mazelin et al. 2016). mTORC1 functions as a nutrient sensor. During the initial stage of starvation and conditions of calorie restriction without malnutrition, mTORC1 activity is suppressed (Wullschleger et al. 2006). mTOR is a hub for the signaling activated by amino acids, glucose, insulin, and

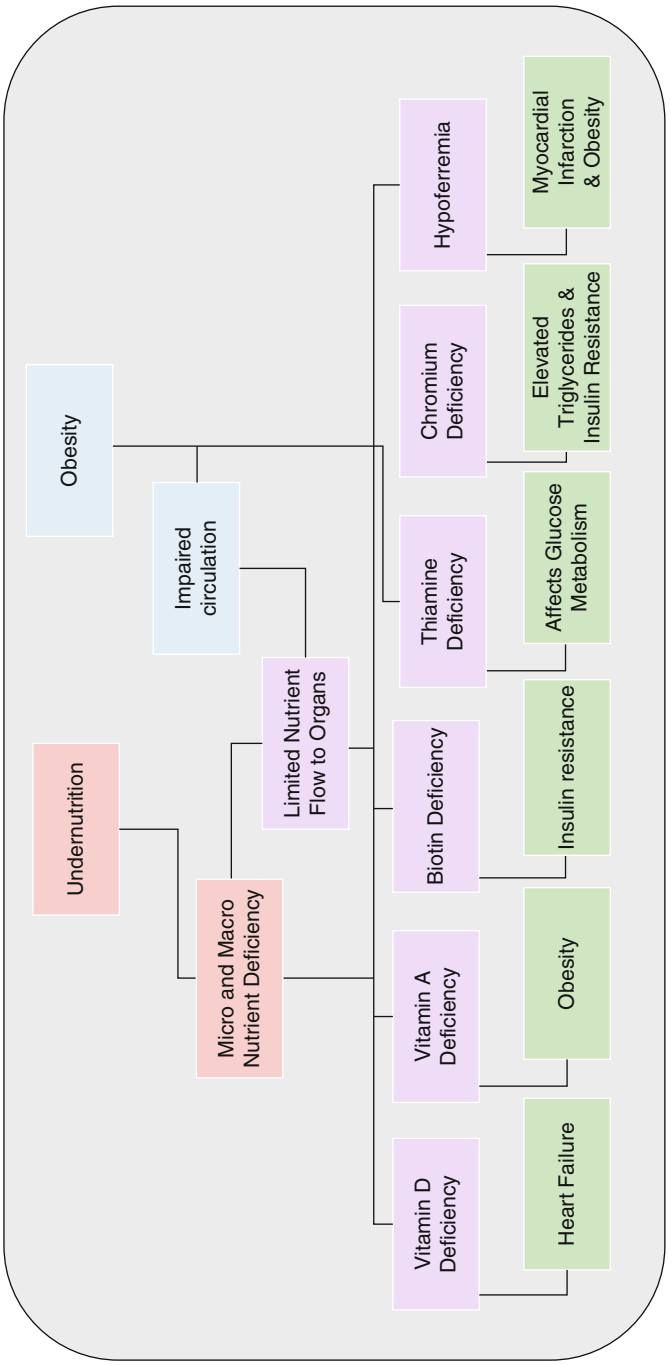

Fig. 2 Nutrient deficiencies common to obesity and undernutrition and their effects on CVD and its predictors. Undernutrition results primarily in the lack of availability of macro- and micronutrients critical for cell survival and cause CVD. Obesity causes impaired circulation and changes in signaling pathways that lead to ischemia and restrict availability of nutrients to cardiovascular cells

many growth factors and cytokines. There are two distinct complexes that activate differential signaling mechanisms via complexes formed with mTOR. These are mTOR complex 1 (mTORC1) and complex 2 (mTORC2). The mTORC1 consists of several protein units including mTOR, regulatory-associated protein of mTOR (Raptor), mammalian lethal with Sec13 protein 8 (mLST8, also known as GbL), prolinerich AKT substrate 40 kDa (PRAS40), and DEP-domain-containing mTOR interacting protein (Deptor). The mTORC2 consists of mTOR, rapamycin-insensitive companion of mTOR (Rictor), mammalian stress-activated protein kinase interacting protein (mSIN1), protein observed with Rictor-1 (Protor-1), mLST8, and Deptor (Laplante and Sabatini 2012). These complexes and the signaling mechanisms that regulate them are under extensive investigation (see: Wullschleger et al. 2006; Shende et al. 2011; Morita et al. 2013; Hancer et al. 2014; Romero et al. 2016). Here, the specific role of mTOR in the functions of cardiovascular cells is discussed. The critical roles of mTOR by itself and mTORC1 in cardiac function are highlighted by the following observations:

1. Early postnatal inactivation of cardiac mTOR in mice resulted in the animals exhibiting dilated cardiomyopathy, cardiomyocyte growth defects, apoptosis and fibrosis, and death (Mazelin et al. 2016).
2. In mice, conditional deletion of Raptor gene in the heart results in impaired adaptive hypertrophy, reduced mitochondrial content and mitochondrial respiration, and cardiomyocyte apoptosis and heart failure (Shende et al. 2011; Morita et al. 2013).
3. Active-site mTOR inhibitor (asTORi) PP242 suppresses mRNAs encoding mitochondria-related proteins (Morita et al. 2013).
4. Chronic treatment of healthy rats with low dose rapamycin, the inhibitor of mTORC1, results in cardiac fibrosis (Luck et al. 2017).
5. Chronic treatment of diabetic rats with rapamycin results in increased cardiac microRNA miR-29 expression, suppressed myeloid cell leukemia 1(MCL-1) and cardiomyocyte disorganization (Arnold et al. 2014). The critical role of MCL-1 in the heart is evident from the observation that the deletion of MCL-1 in the heart causes impaired autophagy, mitochondrial dysfunction, and is lethal to the heart (Thomas et al. 2013).

The mTORC1 is the only mTOR complex that is sensitive to amino acids (Zoncu et al. 2011). The sensitivity of mTORC1 to amino acids is mediated via the RAG GTPases (Fig. 3). Previous studies have indicated that mTORC1 inhibition results in induction of autophagy, an evolutionarily conserved process to catabolize cytoplasmic proteins and organelles. The different types of autophagy have been discussed extensively in other reviews and will not be covered here (Mizushima 2007, Xie and Klionsky 2007). However, it was also reported that during starvation, mTORC1 eventually becomes reactivated. In normal rat kidney (NRK) cells, nutrient deprivation caused fusing of multiple lysosomes with the autophagosome (Yu et al. 2010). They showed that at the end of 4 hours essentially all lysosomes were consumed into fewer and larger lysosomal-associated membrane protein 1 (LAMP1)-stained

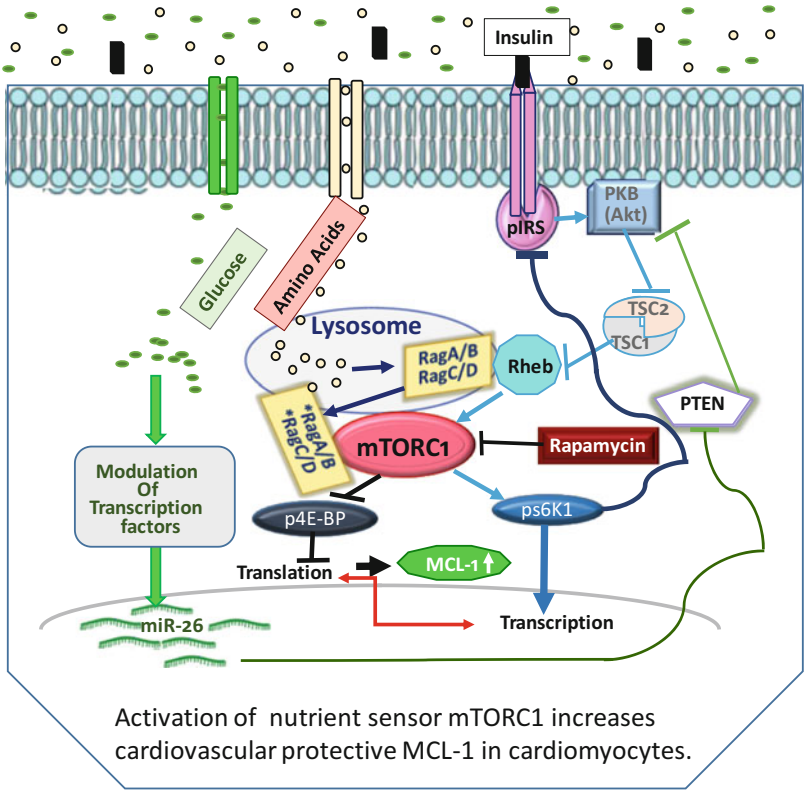

Fig. 3 Molecular mechanisms involved in the tight regulation of mTORC1. Glucose; Amino Acids; Mechanisms by which nutrients (glucose and amino acids) and growth factors (such as insulin) activate mTORC1 are shown. The RAG GTPases form heterodimers consisting of RagA or RagB bound to RagC or RagD and are localized to lysosomes. Amino acids that enter the cell activate these RAG heterodimers by promoting GTP loading of RagA/B and GDP loading of RagC/D(Yuan et al. 2013). These active Rag heterodimers directly interact with mTORC1 by binding to Raptor and recruit mTORC1 to the surface of lysosomes where it interacts with and be activated by the small GTPaseRheb (Shende et al. 2011). Rheb is regulated by growth factors such as insulin (Garami et al. 2003; Hancer et al. 2014). Insulin binds to insulin receptor and causes tyrosine phosphorylation of insulin receptor substrates (IRS1, IRS2) (Saucedo et al. 2003). IRSs, in turn will activate protein kinase B (also known as Akt). Akt phosphorylates TSC2 (tuberin) and causes it to dissociate from TSC1 (hamartin). Dissociation of TSC complex disables it from inactivating Rheb. Rheb is active in its GTP bound form. Since Rheb's ability to stay in GTP bound form depends on the inactivation of TSC complex by growth factor (insulin)-induced Akt activation, this step is a converging point for mTORC1 activation by both amino acids and growth factors (Yuan et al. 2013). Glucose activates mTORC1 by increasing microRNA miR-21 expression. miR-21 suppresses PTEN, an inhibitor of Akt. mTORC1 activates s6 K1 that initiates the feedback loop to inhibit IRS activation and thus prevent insulin signaling and induce de novo transcription. mTORC1 also inhibits 4E–BP (eukaryotic translation initiation factor 4E–binding protein) by phosphorylating it and promotes de novo translation. These effects may underlie increase in MCL-1 expression that is essential for cardioprotection during ischemia and nutrient stress

autolysosomes. However, after 12 h of starvation, lysosome size and number had largely recovered (Yuan et al. 2013).

This effect is seen across species; the authors also observed similar changes in other in vitro studies using cell lines derived from fish, amphibians, birds, and other mammals. These results were corroborated through in vivo studies following starvation in the lysosomes of the fat body of *Drosophila melanogaster* expressing LAMP1-green fluorescent protein (GFP) (Yu et al. 2010). Consistent with previous observations, mTORC1 signaling was inhibited during autophagy initiation in these models. However, prolonged starvation reactivated mTORC1 as evidenced by phosphorylation of mTORC1 substrates p70s6 kinase (s6 K1) and eukaryotic translation initiation factor 4E–binding protein (4E–BP). This reactivation of mTOR was autophagy-dependent and required the degradation of autolysosomal products. Reactivation of mTORC1 attenuated autophagy. Moreover, mTORC1 reactivation resulted in proto-lysosomal tubules and vesicles that extrude from autolysosomes and matured into functional lysosomes. Thus autophagy-mTORC1 signaling cycle is tightly and differentially regulated during the length of starvation. Given the critical role of mTORC1 signaling in the survival of cardiovascular cells, this reactivation of mTORC1 by autophagy may play a role in regulating excessive autophagy-induced cardiovascular damage. The hypothesis that reactivation of mTORC1 by autophagy can render resistance to cell death is further supported by the observation that mTORC1 activation decreases autophagy in aging (Romero et al. 2016).

While starvation and amino acid deprivation induce inhibition of mTORC1, increases in amino acids and nutrients and growth factors from overnutrition lead to overactivation of mTORC1 (Pulakat et al. 2011; Gul et al. 2012a,b). In the context of overnutrition, postprandial increases in blood glucose and the subsequent secretion of insulin by pancreatic beta cells regulate mTORC1. Insulin binds to membrane receptors to activate class I phosphatidyl inositol 3 kinase (PI3K) that, in turn, activates PKB/Akt and puts in motion the mechanisms involved in activation of mTORC1 as described earlier. High glucose activates mTORC1 by increasing microRNA miR-26 expression that inhibits expression of phosphatase and tensin homolog (PTEN) (Dey et al. 2015) (Fig. 3). However, activation of s6 K1 by mTORC1 puts in motion a negative regulatory feedback loop for Akt. Activated s6 K1 causes serine phosphorylation of IRSs that results in inhibition of IRS signaling and thus attenuates PI3K signaling (Fig. 3). Thus, mTORC1 activation prevents insulin signaling and causes insulin resistance. In fact, Hanceret al., reported that both insulin and metabolic stress induced by treatments with anisomycin, thapsigargin, or tunicamycin caused multisite serine/threonine phosphorylation of the insulin receptor substrate 1 (IRS1). These treatments also inhibited IRS1 tyrosine phosphorylation and normal insulin signaling (Hancer et al. 2014)).

Type 2 diabetes is an independent predictor of CVD and both hyperinsulinemia and hyperglycemia are toxic for cardiovascular cells. Hyperinsulinemia in the presence of insulin resistance results in overactivation of IGF receptor to promote cardiac and vascular hypertrophy. Additionally, hyperglycemia and impaired glucose tolerance induces cardiovascular glucotoxicity. These conditions lead to diastolic dysfunction with preserved ejection fraction, fibrosis, atherosclerotic plaque formation, and coronary artery disease. These structural damages to the heart and vascular system lead to

ischemia and nutrient deprivation to cardiovascular cells, causing cardiomyopathy. Therefore, scientists have hypothesized that inhibition of mTORC1 in conditions of overnutrition could be beneficial. In vivo studies using mTORC1 inhibitors such as rapamycin to suppress mTORC1 activation have shown mixed results in terms of cardiovascular protection. Short-term (up to 4 weeks or 6 weeks) mTORC1 inhibition is reported to be cardioprotective in obese and diabetic murine models (Das et al. 2014, 2015; Luck et al. 2017). However, long-term (12 weeks) rapamycin treatment caused exacerbation of type 2 diabetes and no improvement in cardiac functions in an obese diabetic murine model (Luck et al. 2017). Thus both overactivation of mTORC1 via overnutrition and chronic suppression of overactive mTORC1 in obesity via inhibitors cause cardiovascular stress and CVD.

Leptin, Angiotensin, and Cachexia-Associated Nutrient Stress on Cardiovascular Cells

Several chronic diseases including cancer, chronic infections, diabetes, and cardiovascular diseases can lead to muscle wasting syndrome or cachexia. In chronic inflammatory conditions such as cancer, serum leptin levels are significantly lower in patients despite correction for body fat (Mantovani et al. 2000). Leptin secretion is regulated by insulin, glucocorticoids, and catecholamines (Engineer and Garcia 2012). However, while leptin deficiency is associated with hyperphagia, overnutrition, and obesity, this reduction in serum leptin was not associated with greater appetite or lower energy expenditure in cancer patients. This indicates that for cancer patients, normal leptin signaling is disrupted. This reduction in leptin was concurrent with increases in inflammatory cytokines interleukin-1alpha (IL-1alpha), Interleukin 6 (IL-6), and TNFα (Mantovani et al. 2000). Increased leptin levels are associated with fibrosis and neointimal hyperplasia (Shan et al. 2008). It was observed that administering exogenous leptin at levels comparable to those found in obese humans promoted neointimal vascular smooth muscle hyperplasia in a murine femoral artery wire injury model. Moreover, hyperleptinemia (high levels of leptin) suppressed the efficacy of mTORC1 inhibitors in attenuating neointima. Researchers have suggested that hyperleptinemia in diabetics could be a reason for the increased restenosis in these patients even when they are treated with mTORC1 inhibitors (Shan et al. 2008). Leptin is also implicated in vascular extracellular remodeling. Zhang et al. reported that in 3D co-culture vessel models that mimic true blood vessels, treatment with leptin stimulated secretion of collagen types II/IV and TIMP1 (tissue inhibitor of metalloproteinases). It also increased matrix metalloproteinases MMP2/9 activity. These effects were suppressed by administration of adiponectin that acted via adiponectin receptor 1 (AdipoR1) and activation of AMP kinase (Zhang et al. 2014). These observations highlight the unique role of leptin in regulating blood vessel pathology.

In 2008, Evans et al. proposed the diagnosis of cachexia to be based on at least 5% weight loss in 12 months or less in the presence of underlying illness, plus 3 of the 5 following criteria: (1) Decreased muscle strength, (2) Fatigue, (3) Anorexia, (4) Low-

fat free mass index, and (5) Abnormal biochemistry (increased inflammatory markers (CRP, IL-6), anemia, and low serum albumin) (Evans et al. 2008). Nutritional support did not reverse this condition. These patients suffer from muscle atrophy, fatigue, weakness, and even loss of appetite. They have reduced protein synthesis and increased degradation of myofibrillar proteins. Since the heart is a muscle, this condition leads to cardiac cachexia. Chemotherapy is also an important contributor to cardiac cachexia. Weight loss, reduced muscle mass, and poor cardiovascular function are key indicators of poor quality of life and high mortality in cachexia patients. There are no effective treatments for cachexia. Studies in mice have shown that TNF-α can induce cachexia and cause myotube atrophy in vitro via activation of E3 ubiquitin ligases (Oliff et al. 1987; Li et al. 2005). However, circulating levels of TNF-α showed no correlation with weight loss and anorexia in cancer cachexia patients. Moreover, use of anti-TNF-α antibody (infliximab) in a clinical trial in cancer patients with cachexia was preemptively ended because it did not prevent or palliate cancer-associated weight loss. In fact, the patients developed greater fatigue and worse global quality of life scores (Jatoi et al. 2010). IL-6 is an inflammatory molecule that also showed an association with cachexia in tumor bearing mice. Anti-IL-6-antibody could mitigate cachexia in tumor bearing mice (Strassmann et al. 1992). However, a clinical trial using anti-IL-6 antibodies in lung cancer patients suffering from weight loss showed that though the treatment could mitigate anorexia, anemia, and fatigue, it was not effective in improving body weight (Bayliss et al. 2011).

Activation of the renin-angiotensin-system (RAS) is an important contributor to chronic inflammation that causes nutrient stress. The primary effector of RAS is angiotensin II (Ang II) that activates inflammatory pathways leading to hypertension, heart failure, and stroke via the angiotensin II type 1 receptor (AT1R). AT1R is a G-protein coupled receptor (GPCR) that activates Gi-adenylyl cyclase and Gq-phospholipase C pathways in addition to G-protein independent and β-arrestin-mediated Ras-Raf-MEK-ERK1/2 and Akt-mTORC1 pathways (Fig. 3). AT1R over-activation causes production of reactive oxygen species (ROS) and mitochondrial dysfunction that promote endothelial dysfunction, vasoconstriction, hypertension, insulin resistance, cardiac hypertrophy and fibrosis, and heart failure and stroke (Pulakat et al. 2011; Gul et al. 2012). In addition to these effects, in 1996 it was discovered that AT1R activation by Ang II causes muscle wasting (Fig. 3) (Brink et al. 1996; Yoshida and Delafontaine 2015).

AT2 Receptor (AT2R) and Protection of Cardiovascular Cells from Nutrient Stress

Angiotensin II binds and activates two different GPCRs, the AT1R and the AT2R, that have opposing actions (Fig. 4). While the AT1R-mediated signaling constitutes the inflammatory actions of RAS, the AT2R-mediated signaling results in protective and anti-inflammatory actions of RAS. Ang II acting through the AT2R induces vasodilation via the kinin/nitric oxide dependent mechanisms (Fig.4). Like the AT1R, the AT2R is also a seven transmembrane domain receptor, but it shares

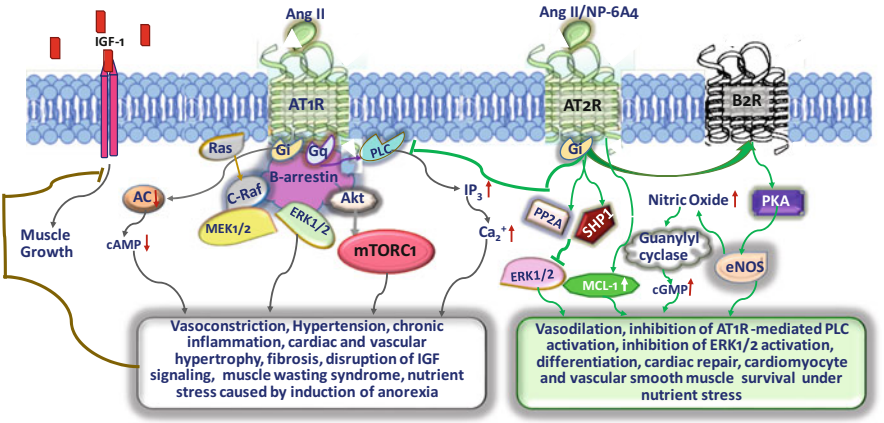

Fig. 4 Cross-talk between angiotensin II receptors AT1R and AT2R in cardiovascular cells. Signaling mechanisms activated by Ang II binding to AT1R and AT2R are shown. AT1R-mediated activation of mTORC1 could have both beneficial and detrimental effects. While mTORC1 activation is useful in maintaining cardioprotective MCL-1 expression and adaptive hypertrophy, overactivation of mTORC1 also causes insulin resistance in cardiovascular cells in the context of AT1R-mediated hypertension and chronic inflammation. Moreover, AT1R activation is implicated in muscle wasting syndrome via inhibition of IGF signaling. AT2R activation by Ang II inhibits AT1R-mediated vasoconstriction via inducing nitric oxide-cGMP axis. Moreover, NP-6A4-mediated AT2R activation improves MCL-1 expression

only 34% sequence identity with the AT1R. AT2R inhibits AT1R-mediated PLC activation (Kumar et al. 2002). Moreover, AT2R-mediated activation of protein phosphatase 2A (PP2A) and Src homology region 2 domain containing phosphatase (SHP-1) I can inhibit extracellular signal-regulated kinases 1 and 2 (ERK1/2) that is activated by the AT1R-Ras-RAf-MEK1/2 pathway (Fig. 4). Importantly, the gene that codes for AT2R, the *Agtr2*, is an X-linked gene. Studies in murine models have shown that higher expression of AT2R in female vasculature confers increased protection from hypertension and cardiovascular and renal injury (Sampson et al. 2008; Hilliard et al. 2012). AT2R is also known to localize to mitochondria and improve mitochondrial respiration. A nonpeptide AT2R agonist compound-21 is reported to reduce infarct size after myocardial infarction (Ludwig et al. 2012). Heterologous expression of *Agtr2* gene is reported to render cardioprotection from ischemic injury in murine models (Qi et al. 2012). Thus increasing the expression of *Agtr2* is a critical step in drug development to mitigate CVD, and *Agtr2* has remained as a drug target for this purpose for nearly three decades.

Myocardial infarction and ischemic heart disease are conditions that induce severe nutrient stress to cardiovascular cells. These stresses cause apoptosis, necrosis, or autophagy of these cells. NP-6A4, a new peptide agonist of the AT2R (from Novopyxis Inc., Cambridge), was more effective than β-blockers (atenolol, metoprolol, carvedilol, and nebivolol) and losartan, a widely used angiotensin receptor blocker (ARB), in improving the survival and viability of nutrient-stressed cultures

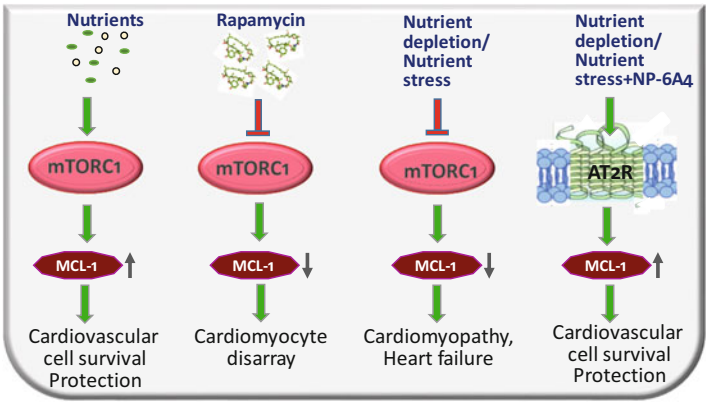

Fig. 5 Regulation of cardiovascular protective MCL-1 by nutrients, rapamycin, and NP-6A4. Nutrient stress and rapamycin treatment suppress cardioprotective MCL-1 expression. Interestingly, activation of AT2R by NP-6A4, a new AT2R agonist by Novopyxis Inc., increases MCL-1 expression in cardiovascular cells subjected to nutrient stress

of mouse cardiomyocyte HL-1 cells and human coronary artery vascular smooth muscle cells (hCAVSMCs) (Mahmood and Pulakat 2015). Moreover, β-blockers significantly suppressed and NP-6A4 increased the expression of myeloid cell leukemia 1 (MCL-1), an essential protein for cardiovascular cell survival and implicated in cell adhesion. CGP42112A, the other AT2R peptide agonist, was not as effective as NP-6A4 in mitigating the nutrient stress. Thus, NP-6A4 seems to activate a protective AT2R-MCL-1 axis in nutrient-stressed mouse and human cardiovascular cells (mouse HL-1 cells and primary cultures of hCAVSMCs). Moreover, mTORC1 inhibition by inhibitors such as rapamycin or nutrient stress suppress MCL-1 whereas NP-6A4 acting through the AT2R increases MCL-1in conditions of nutrient stress despite the fact that AT2R induces differentiation of cells rather than growth (Fig. 5) (Mahmood and Pulakat 2015). Both the AT2R and MCL-1 have important roles in mitochondrial function and the NP-6A4-AT2R-MCL-1 signaling is specifically useful to mitigate nutrient stress. These observations imply that NP-6A4 treatment could mitigate undernutrition and overnutrition induced nutrient stress of cardiovascular cells.

Policies and Protocols

Famine Research Limitations: There are some clear limitations to these observational studies. For example, the effect of various factors including seasonality, stress, famine frequency, and duration are independent variables whose effects are difficult to distinguish from those of undernutrition. To date, no study has been able to assess the contribution of these confounding factors (war time stress, exposure to extreme

temperatures, and ingestion of potentially toxic food substitutes) to famine outcomes (Lumey et al. 2011; Moore et al. 1997; Waterland et al. 2010).

Impaired Glucose Tolerance Protocol In Dutch Famine Cohort: A cohort of 94 normoglycemic men and women from the Dutch famine birth cohort were shown to have impaired glucose tolerance compared to control subjects. The disposition index (a product of insulin sensitivity and first-phase insulin response to glucose) was derived as a measure of activity of beta cells adjusted for insulin resistance. People exposed to prenatal famine showed a difference in an intravenous glucose tolerance test (Kg value −21% [95% CI −41 to −4]) (Lumey et al. 2011).

RTCA analysis of CI and NP-6A4: The cell index (CI) of HL-1 cells as determined by the Xcelligence Real-Time Cell Analyzer (RTCA) showed that the CI of HL-1 cells was the highest when treated with NP-6A4 and this effect was completely blocked by PD123319, an AT2R antagonist (Mahmood and Pulakat 2015).

Dictionary of Terms

- **The Dutch famine** – Is one of the most well studied periods of famine (1944–1945) that lasted approximately six months (Trienekens 2000; Lumey et al. 2011).
- **Cachexia or wasting syndrome** – Is associated with diseases such as cancer, AIDS, congestive heart failure, rheumatoid arthritis, and tuberculosis.
- **Hypoferremia** – Is a deficiency of iron in the blood.
- **Leptin** – activates specific leptin receptors in the hypothalamus and changes the expression of several hypothalamic neuropeptides that regulate energy intake and expenditure.
- **Neointimal hyperplasia** – Is a condition in which the vascular smooth muscle cells (primarily in the tunica intima) proliferate and migrate. This results in the arterial walls thickening and therefore reducing the space in the arterial lumen.
- **Dilated cardiomyopathy (DCM)** – Is a common cause of heart failure and occurs when the heart cannot pump blood effectively due to enlargement.
- **β-adrenergic receptor blockers (β-blockers)** – Are the standard of care for myocardial infarction and ischemic heart disease.

Summary Points

- Like obesity, starvation and chronic undernutrition can cause also cardiovascular stress and subsequent CVD.
- In utero famine exposure negatively affects birth weight, total cholesterol, glucose tolerance, triglycerides, risk of coronary heart disease, and obesity and these effects are intergenerational.

- Micronutrient deficiency occurs in conditions of starvation, but is also seen in obesity and contributes to the pathogenesis of cardiovascular disease in both populations.
- mTORC1 functions as a nutrient sensor; during the initial stage of starvation, mTORC1 activity is suppressed.
- Chronic treatment of healthy rats with low-dose mTORC1 inhibitor (rapamycin) results in cardiac fibrosis.
- Chronic treatment of diabetic rats with rapamycin results in increased cardiac microRNA miR-29 expression, suppressed myeloid cell leukemia 1(MCL-1), and cardiomyocyte disorganization.
- Both overactivation of mTORC1 via overnutrition and chronic suppression of mTORC1 causes cardiovascular stress and CVD.
- Activation of the renin-angiotensin-system (RAS) is an important contributor to chronic inflammation that causes nutrient stress.
- The primary effector of RAS is angiotensin II (Ang II) that activates inflammatory pathways leading to hypertension, heart failure, and stroke via AT1R.
- Ang II acting through the AT2R activates the anti-inflammatory arm of RAS and induces vasodilation.
- Increasing the expression of *Agtr2* is a critical step in drug development to mitigate CVD and *Agtr2* has remained as a drug target for this purpose for nearly three decades.
- NP-6A4, a new peptide agonist of the AT2R (from Novopyxis Inc., Cambridge), was more effective than β-blockers and losartan (an ARB) in improving the survival and viability of nutrient-stressed cultures of mouse cardiomyocyte HL-1 cells and human coronary artery vascular smooth muscle cells (hCAVSMCs) via activation of a protective AT2R-MCL-1 axis.
- mTORC1 inhibition by inhibitors such as rapamycin or nutrient stress suppresses MCL-1, whereas NP-6A4 acting through the AT2R increases MCL-1 in conditions of nutrient stress.
- The NP-6A4-AT2R-MCL-1 signaling is specifically useful to mitigate nutrient stress.

Abstract

As the main energy source for the human body, glucose metabolism plays multiple roles in the physiology of cancer cells. In the environment of hypoxia and low sugar, cancer cells transform the normal glucose metabolism to aerobic glycolysis autonomously, regulated by different molecules. Under conditions of glucose deprivation, cancer cells suffer from the inhibition of growth, the arrest of cell cycle, apoptosis, and autophagy, regulated by respective associated proteins and pathways. It is possible that glucose deprivation alone or in combination with pharmacological therapy would be effective in the treatment of cancer "addicted" to glycolysis. However, several experiments have demonstrated that cancer cells may develop tolerance to glucose deprivation. In this review, we discuss these issues in order to provide a clear understanding of effects of glucose starvation on cancer therapy.

Keywords

Cancer cells · Warburg effect · Oncogene · Pathway · Apoptosis · Autophagy · Tolerance to glucose deprivation

List of Abbreviations

AMP	Adenosine monophosphate
AMPK	Adenosine 5′-monophosphate (AMP)-activated protein kinase
ATG14	Autophagy-related 14
ATP	Adenosine triphosphate
BCL-2	B-cell lymphoma-2
GTP	Guanosine triphosphate
HIF1α	Hypoxia-inducible factor 1 alpha subunit
KRAS	KRAS proto-oncogene, GTPase
LC3	Autophagy marker light chain 3
MAX	MYC-associated factor X
MCL-1	Myeloid cell leukemia 1
mTORC1	Mechanistic target of rapamycin complexes 1 and 2
MYC	MYC proto-oncogene, bHLH transcription factor
NADPH	Triphosphopyridine nucleotide
PAQR3	Progestin and adipoQ receptor family member 3
PI3K/AKT	Phosphatidylinositol 3 kinase (PI3K)/protein kinase B(AKT)
PKA	Protein kinase A
PtdIns3P	Phosphatidylinositol 3-phosphate
ROS-PTP-TK	Reactive oxygen species – protein tyrosine phosphatases – tyrosine kinases
TNFα	Tumor necrosis factor-alpha
ULK1	unc-51-like autophagy activating kinase 1
UPR	Unfolded protein response

Introduction

Living cells require energy and nutrients for their proliferation, differentiation, and movement. Three principal nutrients that provide cells with energy are carbohydrates, especially glucose, lipids, and proteins (Li et al. 2016). Carbohydrate metabolism includes anaerobic glycolysis, aerobic oxidation, pentose phosphate pathway (PPP), glycogenesis, glycogenolysis, gluconeogenesis, and metabolism of other hexoses. Compared to normal cells, cancer cells require a high rate of glucose uptake to meet the energy demand to support rapid tumor progression; however, the extent of adaptive angiogenesis and blood supply are insufficient at the early stages of tumorigenesis (Ferreira et al. 2012). To survive in the hypoxic microenvironment, tumor cells utilize glycolysis instead of mitochondrial oxidative phosphorylation. Besides, tumor cells are used to adopt the less efficient way of getting ATP from substrate-level phosphorylation reactions of glycolysis even under oxygen-rich conditions (Potter et al. 2016). Another situation that cancer cells face is low glucose levels. Cancer cells must exhibit adaptive responses to glucose starvation to facilitate proliferation, migration, and progression (Xing et al. 2015). In this review, we describe how cancer cells undergo metabolic switching so as to develop tolerance to glucose deprivation and provide insights into the therapeutic approaches to target adaptive responses to glucose deprivation.

Reprogramming of Glucose Metabolism: Metabolic Change or Genetic Change, Which Occurs First?

Metabolic reprogramming has been deemed as a necessary process for the growth and proliferation of cancer cells. The switch in glucose metabolism is one of the most important metabolic alterations that occur in cancer cells. Related studies date back to the 1920s when Otto Warburg, a German scientist, pioneered investigations on cancer cell metabolism.

The Warburg Effect

The Warburg effect is a hallmark of cancer cell metabolism (Pavlova et al. 2016). Glucose metabolism in cancer cells is markedly different from that in normal cells, in that glucose is converted to lactic acid even under oxygen conditions that are normally sufficient to facilitate mitochondrial oxidative phosphorylation(aerobic glycolysis) (Fig. 1). This process involves the conversion of glucose to pyruvic acid, which is, then, converted to lactic acid. This entire metabolic reaction generates only 2 ATP molecules per molecule of glucose, while the mitochondrial tricarboxylic acid (TCA) cycle coupled with oxidative phosphorylation (OXPHOS) generates about 30 or 32 ATP molecules per glucose molecule. However, aerobic glycolysis is a mechanism that

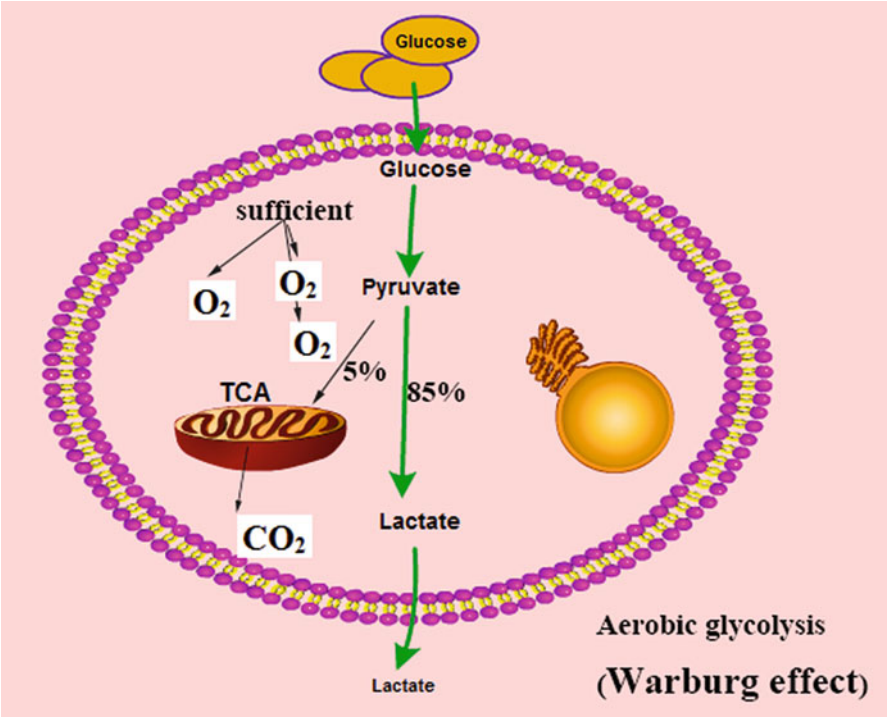

Fig. 1 The schematic diagram of Warburg effect. Glucose is converted to lactic acid even under oxygen conditions that are normally sufficient to facilitate mitochondrial oxidative phosphorylation (aerobic glycolysis)

supports the biosynthetic demands of uncontrolled cancer cell proliferation (Potter et al. 2016). The mechanism of this phenomenon has not been fully clarified yet; some studies hypothesize that it is a consequence of mitochondrial dysfunction or damage (Vander et al. 2009). Other studies focus on mutations in oncogenes and/or loss of tumor suppressor genes that are involved in tumor-linked metabolic changes.

Oncogenes, Tumor Suppressors, and Pathways

Given the large number of recent research studies on reprogramming of glucose metabolism in cancer, *MYC*, *HIF*, *KRAS*, *P53*, and AMP-activated protein kinase (AMPK) pathways, PI3K/AKT pathway, and other signaling cascades are involved.

MYC Family

Mutation in *MYC* or its overexpression is common in tumors. The MYC family consists of well-known proto-oncogenic transcription factors including MYC (CMYC), NMYC (MYCN), and LMYC (MYCL). MYC competes by mass action

to form a heterodimer with another bHLH-LZ (helix–loop–helix leucine zipper) protein, MAX, in order to bind to the E-box region in the promoters of the genes that regulate cell growth, energy production (glycolysis, glutaminolysis), cell cycle, apoptosis, anabolism, and DNA replication (Kress et al. 2015). It has been reported that cells with overexpression of *MYC* consumed more glucose than did cells with normal *MYC* expression levels (McCarthy 2015). The expression of glucose transporter 1 (GLUT1), the lactate dehydrogenase A (LDHA), and pyruvate kinase M2 (PKM2) proteins induced by the MYC-MAX heterodimer in glucose metabolism supports tumor survival in a hypoxic microenvironment.

HIF Family

Hypoxia in the tumor microenvironment usually results in the activation of the hypoxia-inducible factors (HIFs). The HIF family comprises three members, HIF1, HIF2, and HIF3, which activate transcription in a way similar to that of MYC with respect to glucose transport and glycolysis and, thus, help cells tolerate hypoxic conditions (Dang et al. 2008). All of them consist of an α subunit whose expression is oxygen-dependent and a β subunit which is constitutively expressed. The prolyl hydroxylase domain (PHD) fails to modify HIFα under conditions of insufficient oxygen, which then forms a stable heterodimer with HIFβ, and can, thereby, activate related transcription. Otherwise, HIFs function together with MYC to confer metabolic advantages that help tumor cells survive under conditions of low oxygen (Dang et al. 2008).

KRAS

There are four GTP-binding proteins in the p21ras family, namely, HRAS, KRAS, NRAS, and RRAS. Metabolic alterations due to mutations in *KRAS* during tumorigenesis are widely observed. *KRAS* encodes p21ras GTP-binding proteins that activate signaling pathways related to the proliferation of cells. $KRAS^{G12V}$ mutation and *KRAS* overexpression lead to significant metabolic alterations by inhibiting the function of the complex I of the mitochondrial-electron transport chain, increasing radical oxygen species (ROS) generation, and elevating glycolytic activity (Asati et al. 2017).

P53

The inactivation of tumor suppressor genes in addition to the activation of proto-oncogenes is associated with the switch in glucose metabolism in cancer cells. Tumor-associated *P53* mutants lose the function of inhibiting the activity of glucose-6-phosphate dehydrogenase and, thereby, increase glucose influx in the pentose phosphate pathway (Jiang et al. 2011).

AMPK

The AMP-activated protein kinase (AMPK) consists of an α subunit of which function is a catalytic kinase and β and γ subunits that are regulatory in function. Under conditions of low intracellular ATP and high intracellular AMP concentrations, AMPK is activated by AMP. In order to restore energy homeostasis, catabolic pathways are activated but anabolic pathways are suppressed (Ha et al. 2015).

PI3K/Akt/mTOR Pathway

Increased activation of the PI3K/AKT/mTOR pathway is common in tumors and helps tumor cells in meeting their energy requirements for cellular functions and biosynthesis (DeBerardinis et al. 2008). AKT is activated by PI3K and plays a vital role in enhancing glucose uptake by increasing the expression and membrane localization of the glucose transporter 1 (GLUT1) and in promoting glycolysis in cancer. The mTOR pathway that lies downstream of the PI3K/Akt signaling pathway activates protein translation and glycolysis by increasing the hypoxia-inducible factor 1 (HIF1α) protein expression level (Levy et al. 2016).

To Die or to Survive Under Low-Glucose Conditions

In the process of cancer progression, both maladaptive angiogenesis and insufficient blood supply result in significantly low levels of glucose. Although the cancer cells counteract this situation by upregulating the expression of glucose transporters, glucose-metabolizing enzymes as well as pyruvate dehydrogenase kinase (Andersen et al. 2013), some malignant cells are not able to survive glucose starvation and, hence, undergo growth inhibition, apoptosis, or necrosis and finally die (Fig. 2). It was affirmed by some studies that cancer cells subjected to glucose deprivation were more susceptible to cell death than their normal counterparts (El et al. 2011). Meanwhile the process by which cells degrade unnecessary or dysfunctional constituents, termed autophagy, could help in the survival of cells that would otherwise die. Cancer cells probably obtain energy and synthesize the building blocks of biomolecules via the lysosomal pathway of autophagy (Table 1).

Growth Inhibition and Cell Cycle Arrest

It has been shown that glucose deprivation induces cell cycle arrest and inhibition of cell growth in a wide range of cancer cells such as cells derived from hepatic cell cancer (HCC), MDA-MB-231cell line, and so on. Anabela C. Ferretti observed that the number of HCC cells in G0/G1 stage was remarkably increased under conditions of low glucose in about 36 h (Ferretti et al. 2016). In the original study, Yuji Tanaka pointed out that AMPK participated in the KDM2A-dependent (a modular protein containing JmjC and CXXC-zinc finger domains) reduction of rRNA (ribosomal RNA) transcription by de-methylating H3K36me2 in the rDNA (ribosomal DNA) promoter and controlled cell proliferation in MCF-7 cells and MDA-MB-231 cells under limited glucose availability (1 to 2 mM 2-deoxy-D-glucose treatment) (Tanaka et al. 2015).

Cell Death: Apoptosis or Necrosis

Typically, the extrinsic pathway and the intrinsic pathway (also called the mitochondrial pathway) are the two mechanisms for the activation of apoptosis (Fig. 3). The TNF ligand family members, such as tumor necrosis factor α (TNFα), CD95L/

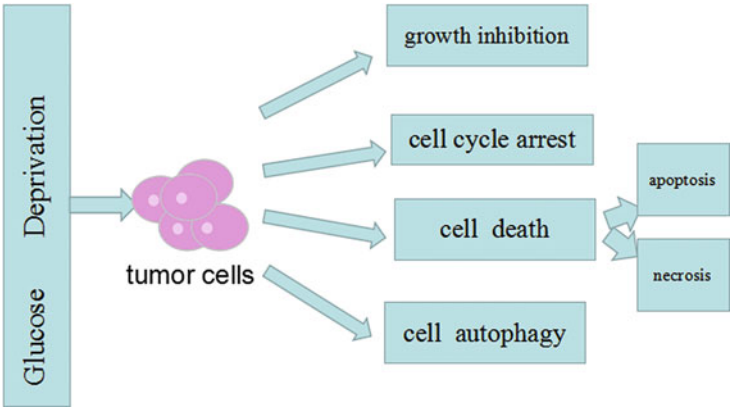

Fig. 2 The fate of cancer cells under low-glucose conditions. Tumor cells are not able to survive from glucose starvation and, hence, undergo growth inhibition, cell cycle arrest, apoptosis, or necrosis and finally die. However, cancer cells may get a chance for survival because of autophagy

FasL, and TNF-related apoptosis-inducing ligand (TRAIL), activate and recruit the Fas-associated protein with death domain (FADD), which is an adaptor protein, to the cytoplasmic death domain of the trimerized or clustered receptor. They bind to their respective receptors on the surface of the cell and undergo oligomerization so as to recruit procaspase-8 to form the death-inducing signaling complex (DISC) and eventually induce cell death by directly activating the effector caspases, caspase-3 and caspase-7. It has been reported that tumor cells subjected to glucose starvation (treatment with 2-deoxy-D-glucose) were susceptible to death induced by activation of FasL receptors. However, there was a report that glucose deprivation inhibited TRAIL-induced death (MacFarlane et al. 2012). Death by apoptosis and necrosis occurs simultaneously in glucose-deprived cells. Anabela C. Ferretti found that both apoptosis and necrosis are augmented almost 2-fold in HCC cells subjected to glucose deprivation. The activation of AMPK by AICAR (the AMPK activator) contributes to the induction of apoptosis in HCC cells after glucose deprivation. The occurrence of apoptosis in glucose-deprived cells decreases observably when the expression of AMPK is silenced. Also, PKA plays a dual role in the HCC cells after glucose deprivation. The activation of the cAMP/PKA axis induces apoptosis initially, following which PKA negatively controls AMPK-induced apoptosis by phosphorylating AMPKα (at Ser173) (Ferretti et al. 2016). R. Palorini wrote that there exists a UPR-dependent (unfolded protein Response) mechanism of death induced by glucose starvation in MDA-MB-231cells (K-RASG13D-transformed cells): the reduction of protein glycosylation, the accumulation of unfolded proteins, and the activation of c-Jun NH2-terminal kinase (JNK) through the IRE1-XBP1 UPR branch (Palorini et al. 2013). A. Garufi found that glucose deprivation induces cell death, mainly ascribed to the activation of c-Jun NH2-terminal kinase when the expression of HIPK2 (Homeodomain-interacting protein kinase 2) is not silenced (Garufi et al. 2013).

Table 1 The fate of cancer cells induced by inhibition of glucose metabolism

Treatment	Fate	Molecules implicated	Cell/tumor type	References
Glucose deprivation	Growth inhibition, G0/G1 arrest, apoptotic and necrotic death	AMPK, PKA	HCC (HepG2/C3A)	Ferretti et al. 2016
Glucose deprivation	Growth inhibition, cell apoptotic death, autophagy	PKA	NIH3T3, MDA-MB-231, and MIA PaCa-2 cells	Palorini et al. 2016

Glucose deprivation	Growth inhibition		MCF-7	Wyld et al. 2002

Glucose-deprived cancer cells are more sensitive to the apoptotic pathway associated with the BCL-2 family. The BCL-2 family consists of antiapoptotic proteins (proteins containing BH1–4 domains) and proapoptotic proteins (proteins containing BH1–3 and BH3 domains). The proteins of Bak and Bax (BH1–3 proteins) play chief roles as apoptotic activators by permeabilizing the mitochondrial membrane, facilitating the release of cytochrome c and apoptosome formation, and eventually lead to cell death. The mechanisms of death in cells exposed to low glucose levels involve the downregulation expression of antiapoptotic proteins such as BCL-2 and MCL-1 (Bhola et al. 2016). N El Mjiyad reviewed that the BH3-only proteins (Bim, PUMA, Nuxa, and Bad) contribute to the induction of apoptosis. Nicholas A. Graham demonstrated that glucose deprivation initiates the ROS-PTP-TK positive feedback amplification loop that involves the generation of reactive oxygen species (ROS) by NADPH oxidase in mitochondria, inhibition of protein tyrosine phosphatase activity by its oxidation, and increased tyrosine kinase signaling and ultimately results in ROS-mediated cell death (Graham et al. 2012).

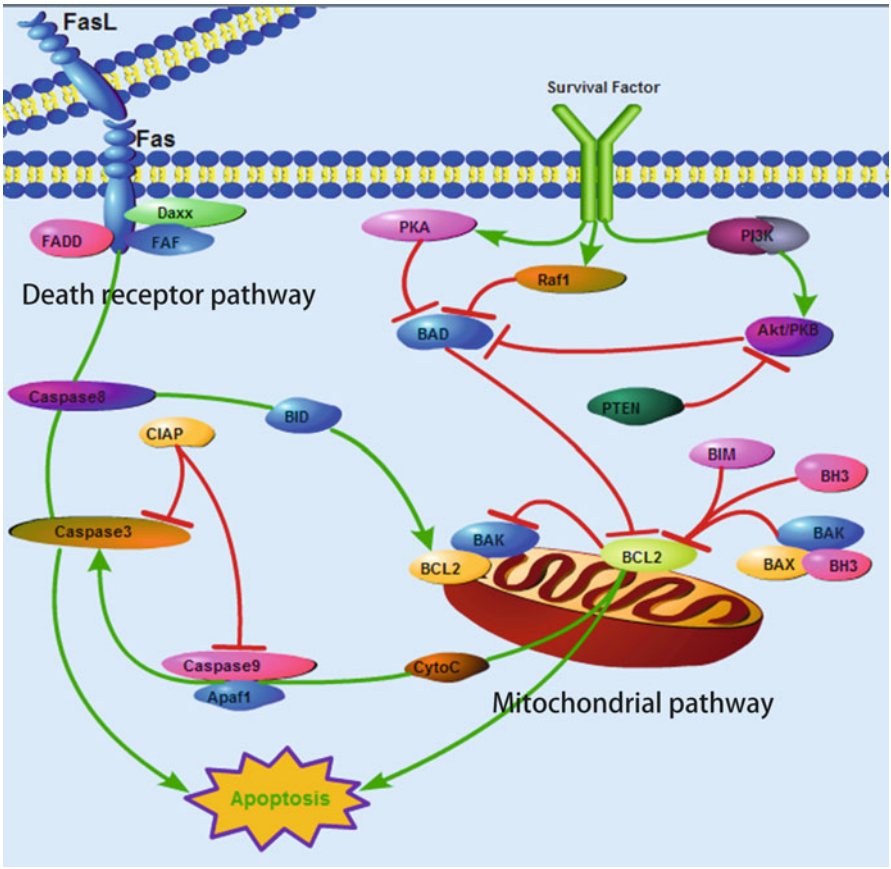

Fig. 3 The two forms of apoptosis in cancer cells. Apoptosis (type IPCD) is one form of programmed cell death (PCD) that can be activated through two dominating signaling pathways, consisting of extrinsic (death receptor pathway) and intrinsic (mitochondrial pathway) pathways. The procaspase-3 is activated at the converge point of two pathways and the target proteins (PARP proteins) of cleaved caspase-3 are activated afterward

Cell Autophagy

Autophagy is the process of self-degradation and recycling of cellular constituents involving double-membraned vesicles and lysosomes; this process also occurs when cancer cells face energy or nutrient deprivation. In order to adapt to conditions of glucose starvation, cancer cells utilize autophagy to recycle cytosolic components and organelles for use in biosynthesis. AMPK, which acts as a sensor of energy, is the positive regulator, while the mechanistic (mammalian) target of rapamycin (mTOR) complex 1 (mTORC1) is the negative regulator of autophagy (Fig. 4). The serine/threonine kinases Atg1/ULK play a pivotal role in the formation of the pre-autophagosome; they are activated when UlK1 (a mammalian homolog of yeast

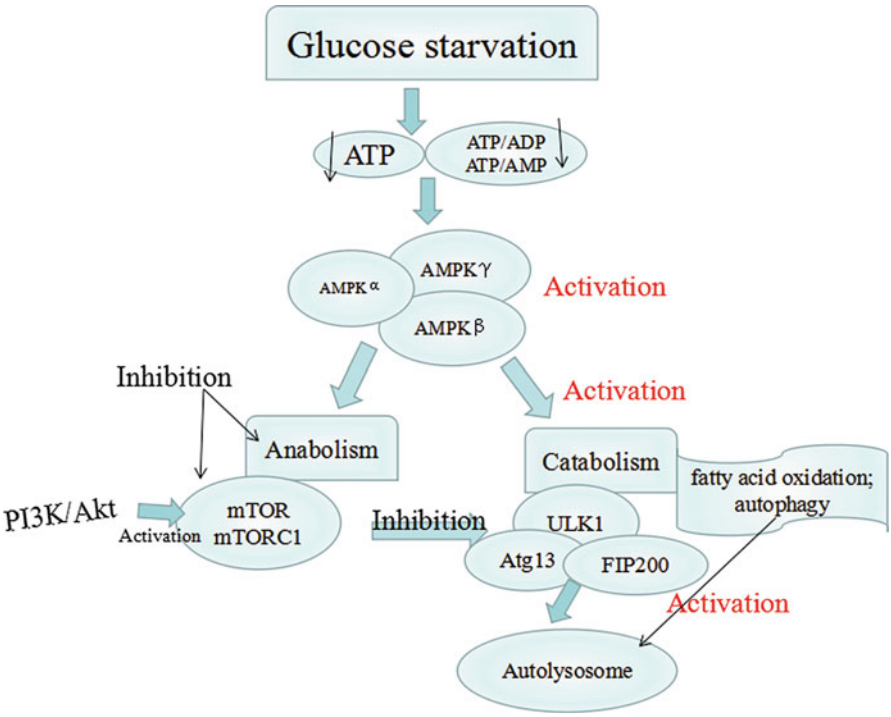

Fig. 4 Inhibition of glucose metabolism promotes catabolism and autophagy regulated by AMPK pathway. Glucose deprivation leads to loss of ATP and decreases the ratio of ATP/ADP and ATP/AMP. ATP depletion can be sensed by AMPK: this kinase, then activated, induces the inhibition of mTOR and mTORC1, leading to autophagy

Atg1, as an mTOR substrate) forms a complex with Atg13 and FIP200 and inactivated when ULK1 and Atg13 are phosphorylated by mTORC1. It has been established that tumor cells accelerate autophagy by inhibiting the activity of mTORC1 through the increased binding of hexokinase-II (HK-II) mediated by TOS motif. Cell death upon glucose deprivation is enhanced with the knockdown of HK-II (Roberts et al. 2014). AMPK directly activates the kinase ULK1, which is essential for autophagy. Moreover, upon glucose starvation, the localization of GAPDH in the nucleus increases due to the phosphorylation of Ser122 via AMPK. Inside the nucleus, GAPDH (glyceraldehyde-3-phosphate dehydrogenase) acts as a transcription factor and interacts directly with Sirtuin 1 (Sirt1, correlating well with the autophagy level in different cell systems) and activates the expression of Sirt1 (Chang et al. 2015). Rui Huang reported that LC3, which is a key initiator of autophagy, is activated in the nucleus when the nuclear deacetylase, Sirt1, deacetylates LC3 (Huang et al. 2015b). AMPK directly phosphorylates T32 of PAQR3 (a 7-transmembrane protein in the Golgi apparatus), which activates the ATG14-linked class III PI3K, resulting in the increased production of PtdIns3P as

well as autophagosome formation under conditions of low glucose (Xu et al. 2016). Otherwise, the activation of PKA attenuates UPR activation, leading to autophagy, and helps cells survive during glucose starvation.

Tolerance to Glucose Deprivation

In view of the above review, glucose starvation may be a good clinical approach for the treatment of cancer. Glucose starvation alone or in combination with chemotherapy can be considered as an effective therapeutic approach. However, some cancer cells that have switched to a high rate of glycolysis develop resistance to conditions of low glucose over a long period of time, leading to their survival and aggressiveness through the activation of a series of signaling pathways and adaptive metabolic responses (Fig. 5) (Palorini et al. 2016; Wyld et al. 2002). Chen Huang deemed that lactate might help cancer cells develop resistance to glucose deprivation (Huang et al. 2015).

Alternative Energy Sources and Related Pathways

Cells switch to other alternative energy source under conditions of low glucose. Glucose starvation, glutamine metabolism, fatty acid oxidation, and other metabolic pathways are counteractive approaches. Some researchers have shown that in order to survive, cancer cells metabolize glutamine upon glucose deprivation (Le et al. 2012). Both molecules increased by glutamine oxidation that recruits steps from the TCA cycle, and elevated glutamine metabolism for glutathione synthesis leads to cell survival in the absence of glucose (Palorini et al. 2016). In our previous research study, it was found that the metabolism of nonessential amino acids inhibited apoptosis of gastric cancer cells and mitochondria DNA copy number induced by glucose starvation (Wang et al. 2014). In response to glucose deprivation, cancer cells exhibit impaired fatty acid synthesis but promoted fatty acid oxidation by AMPK (Monica et al. 2005). The loss of phosphorylation of AMPKα at Ser173 sensitized cancer cells to cell death induced by glucose deprivation (Ferretti et al. 2016). βIII-Tubulin is a marker of resistance to chemotherapy in non-small cell lung cancer (NSCLC) and pancreatic cancer and protects cells from endoplasmic reticulum (ER) stress. It was found that the interaction between βIII-tubulin and GRP78 was increased, then a complex between glucose-regulated protein 78 (GRP78) and Akt was formed, and eventually the reliance of cancer cells on glycolytic metabolism was decreased by utilizing other nutrients (Parker et al. 2016). Cells undergo malignant transformation without sufficient glucose. Glucose deprivation in human tumors can lead to the acquisition of mutations in KRAS, which is an important epithelial-mesenchymal transition (EMT) pathway regulator (Yun et al. 2009).

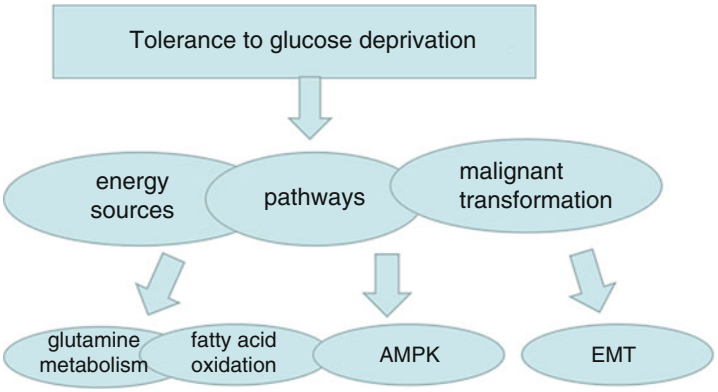

Fig. 5 Cancer cells acquire adaptive responses to glucose starvation. Tumor cells that have switched to a high rate of glycolysis develop resistance to conditions of low glucose over a long period of time

Conclusions and Future Perspectives

Compared to their normal counterparts, cancer cells usually obtain energy through reprogramming of glucose metabolism and survive in harsh environments. Tumors switch to glycolysis for energy production in response to hypoxic conditions even in oxygen-rich conditions. This adaptive response to conditions of low oxygen requires changes in cancer cells including activation of oncogenes, inactivation of tumor suppressor genes, and alterations of crucial signaling pathways. The production of lactate during glycolysis also increases the malignancy of cancer cells. On the other hand, the challenge to cancer cell survival is nutrient starvation, especially of glucose, during early tumorigenesis. The growth of cancers is impeded under conditions of low glucose or presence of 2-D glucose analogue. In some related flow cycling experiments, it was found that cancer cells enter cell cycle arrest; however, most of them cannot survive under conditions of low glucose and eventually die by apoptosis, necrosis, or autophagy. Further, low glucose sensitizes tumor cells to radiotherapy and chemotherapy. These findings suggest that the pathways in cancer metabolism could be specifically targeted for therapy. However, the emerging phenomenon that cancer cells develop tolerance to glucose deprivation poses a challenge to this possibility. The main reason for this tolerance is that cancer cells derive energy alternatively through autophagy. To further support the applicability of therapeutic strategies based on glucose starvation, some researchers have showed that "anti-glycolytic" anticancer agents together with other drugs have achieved the desired results (El Mjiyad et al. 2011; Simons et al. 2009). Further research should focus on glucose starvation and other treatments in order to realize the clinical applications of cancer therapy targeting glucose metabolism as soon as possible.

Policies and Protocols

Studying glucose metabolism in cancer cells involved two aspects: experiment model and test method.

Experiment Model

Researchers take a different treatment scheme with cancer cells in control groups and experimental groups. In control groups, cancer cells are cultivated in normal complete culture medium, while cancer cells of experimental groups are maintained in normal growth media containing no glucose supplemented with 10% serum. 2-Deoxy-D-glucose (2-DG) is applied to enhance cancer therapy in preclinical studies and can be added into the complete cell culture medium in vitro experiments.

Test Method

Researchers usually pay attention to some alterations of cells subjected to glucose starvation. In order to confirm the damage of cell viability under the condition of low glucose, cell viability assay is carried out such as cell counting kit-8 (CCK8) and 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2-H-tetrazolium bromide (MTT) assay. To measure low-glucose-induced apoptosis and cell cycle arrest, flow cytometry is a kind of detection means. JC-1 (CBIC2(3)) staining, mitochondrial DNA copy number detection, and ATP assay are used to observe the function of mitochondria. Researchers measure the expression changes of related gene by Q-PCR and associated protein by Western blot. These genes and proteins involved in glucose metabolism belong to the different pathways such as PI3K/Akt/mTOR pathway and MAPK pathway.

Dictionary of Terms

- **bHLH-LZ protein (helix–loop–helix leucine zipper)** – This is a type of protein with a secondary structure which consists of a zipper-like structure consisting of leucine, formed when the two structural domains come together.
- **Chemotherapy resistance/tolerance** – Some cells do not die when treated with drugs or other similar conditions which are usually lethal to cells; this is because of gene mutations.
- **Mutation** – Mutation is an abnormal change in the sequence of genes, at single or multiple sites such as point mutation, loss-of-function mutations, insertion mutations, and duplication mutations.
- **Oncogenes** – Some genes, usually expressed at low levels in normal cells but expressed at very high levels in cancer cells, play a vital role in the regulation of proliferation, migration, and so on.

- **Pathways** – There are some proteins owing the personal function, existing the complicated interaction, and eventually acquiring the response of cells in aspect of proliferation, migration, and so on.

Summary Points

- Glucose is the main energy source for cancer cells, participating in the activities of cell proliferation, differentiation, and movement.
- In the tumor microenvironment, cancer cells usually exhibit the Warburg effect in order to survive and reprogram glucose metabolism.
- The reprogramming of glucose metabolism involves the cross talk between pathways, including the expression alternation of oncogenes and tumor suppressor genes.
- When cancer cells are exposed to glucose deprivation, the fate of the cells varies depending on the cell types, duration of starvation, supply of other energy sources, and so on.
- The condition of low glucose can not be tolerated by most cancer cells and it can induce growth inhibition, cell cycle arrest, and apoptosis in cancer cells.
- Activation of the extrinsic and the intrinsic pathways participates in the induction of cellular apoptosis in cancer cells exposed to the low glucose. Procaspase-8 is activated by membrane-associated protein complexes (Fas-L/TNF) in the extrinsic pathway, while procaspase-9 is activated by mitochondria-associated protein in the intrinsic pathway. Then procaspase-3 is activated at the converge point of two pathways and the target proteins (PARP proteins) of cleaved caspase-3 are activated afterward.
- Autophagy could be accelerated in cancer cells under cellular stressors, like nutrient starvation (glucose starvation). The moderate activation of autophagy may enable cancer cells to survive from the low-glucose environment.
- AMPK – as an energy sensor – plays a vital role in the process of glucose metabolism.
- The reprogramming of glucose metabolism and activation or inactivation of certain pathways allow cancer cells to survive and develop resistance to "anti-glycolytic" drugs.
- Therapeutic approaches targeting glucose metabolism together with other conventional methods of treatment may prove successful in cancer treatment.

Abstract

Adaptation to food shortage requires temporal homeostatic adaptive responses to a condition of energy deficiency. Mammals have developed a wide range of mechanisms to detect and respond to episodes of malnutrition and starvation, including the capacity to adjust fuel oxidation in function of nutrient availability. Nutrient deprivation or starvation often correlates with amino acid deficiency. This chapter will outline the changes in the metabolic patterns and molecular mechanisms driving these adaptive responses at the whole body level, and particularly in white and brown adipose tissue.

Keywords

Starvation · Aminoacidemia · Essential amino acids · Protein restriction · ATF4 · FGF21 · White adipose tissue · Brown adipose tissue · Lipolysis · Thermogenesis · Energy expenditure

List of Abbreviations

AAR	Amino-acid response
ATF4	Activating transcription factor 4

Introduction

Adaptation to food shortage requires temporal homeostatic adaptive responses to a condition of energy deficiency. Mammals have developed a wide range of mechanisms to detect and respond to episodes of malnutrition and starvation, including the capacity to adjust fuel oxidation in function of nutrient availability. Nutrient deprivation or starvation often correlates with amino acid deficiency.

Amino acids are required mainly for the synthesis of proteins and other biomolecules, and they also serve as signaling molecules and an energy source. Higher organisms are unable to synthesize all amino acids in sufficient amounts to meet cellular needs. Nine amino acids are deemed essential (valine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, histidine, and tryptophan), while others become essential in certain circumstances (some illness) or during specific stages of life (pregnancy, childhood, etc.). All essential amino acids must be supplied by diet. As there is no dispensable amino acid store in mammals, the rest must be synthesized or released by protein degradation when needed.

In mammals, the blood concentration of amino acids is affected by diet. Protein malnutrition or an imbalance in dietary intake of amino acids strongly affects aminoacidemia. This is the main problem of diets in which amino acid sources are limited to plant-derived products (legumes, grains or corn), which are deficient in some amino acids. In addition, pathological situations that cause stress, such as trauma, thermal burning, sepsis, and fever, can lead to a negative nitrogen balance. Overall, the concentration of each amino acid in cells results from the balance between inputs, namely de novo synthesis, protein breakdown and diet, and outputs, which comprise protein synthesis and amino acid degradation (Fig. 1).

This chapter will outline the changes in the metabolic patterns and molecular mechanisms driving these adaptive responses at the whole body level, and particularly in white and brown adipose tissue (WAT and BAT, respectively). It will firstly summarize the mechanism for sensing the amino acid circulating levels and secondly the role of the hormone-like protein Fibroblast Growth Factor (FGF) 21 on the metabolic response to amino acids imbalance.

Amino Acid Homeostasis: Amino Acid Response (AAR)

The maintenance of amino acid homeostasis depends on the cell capacity to sense amino acid availability. While the mTOR signaling pathway monitors amino acid sufficiency and promotes protein translation and cell growth, among other processes, the depletion of amino acids is detected by the GCN2/ATF4 pathway, which in turn triggers the amino acid response (AAR) (Fig. 2).

Amino acid starvation initiates a signal transduction cascade that starts with the activation of the general control nonderepressible 2 (GCN2) kinase, the phosphorylation of eukaryotic initiation factor 2 (eIF2), and increased synthesis of activating transcription factor (ATF) 4 (Kilberg et al. 2009). GCN2 kinase is a direct sensor of amino acid supply, performing this function by binding deacylated tRNAs (Qiu et al. 2001). When levels of an indispensable amino acid fall below a given threshold, its

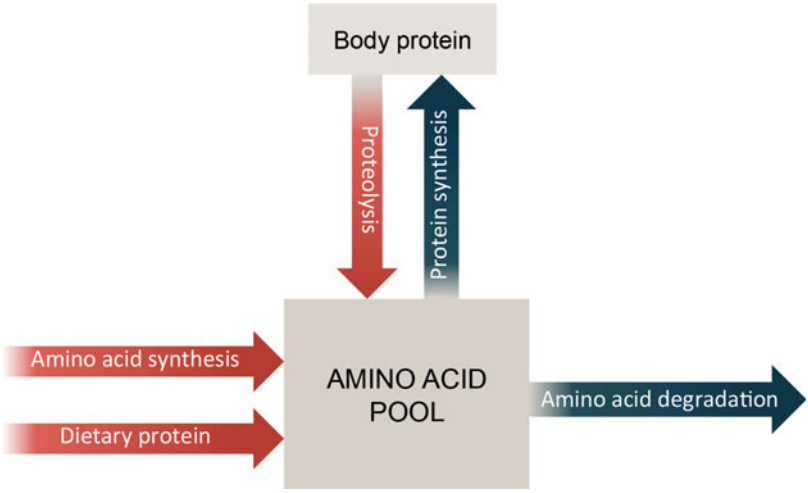

Fig. 1 Amino acid pool is a balance between the dairy inputs and outputs. The circulating amino acid levels are the result of inputs: the synthesis of amino acids, dietary protein intake, and protein degradation or proteolysis, and outputs: protein synthesis and amino acid degradation

tRNA becomes deacylated (i.e., uncharged). When activated by uncharged tRNAs, GCN2 increases eIF2α phosphorylation (Anthony et al. 2004; Hao et al. 2005), which results in the slowing or stalling of the initiation step of mRNA translation. Hence, phospho-eIF2α reduces general protein synthesis rates. Paradoxically, the delay in the re-initiation rate promotes an increase in the translation of discrete mRNAs that contain upstream open reading frames in the 5′-UTR region, including that coding for ATF4. Once induced, ATF4 directly or indirectly triggers the transcription of a subset of specific target genes in order to adapt to dietary stress (Shan et al. 2009).

The dietary content of amino acids alters metabolic pathways beyond protein homeostasis, since there is a link between amino acid intake and lipid metabolism. The synthesis of fatty acids (FAs) in the liver is diminished by GCN2-dependent inhibition of fatty acid synthase (FASN) activity and by the repression of lipogenic gene expression in liver. Leucine-deprived mice show an increase in the mobilization of lipid stores (Guo and Cavener 2007). In addition, increased expression of β-oxidation genes and decreased expression of lipogenic genes and activity of FASN in WAT and increased expression of uncoupling protein 1 (UCP1) in BAT have been observed (Cheng et al. 2010).

Metabolic Response to Protein Imbalance: The Key Role of FGF21

The fibroblast growth factor (FGF) 21 is the link between an imbalance in amino acid intake and adaptive metabolic response, and it serves to restore metabolic

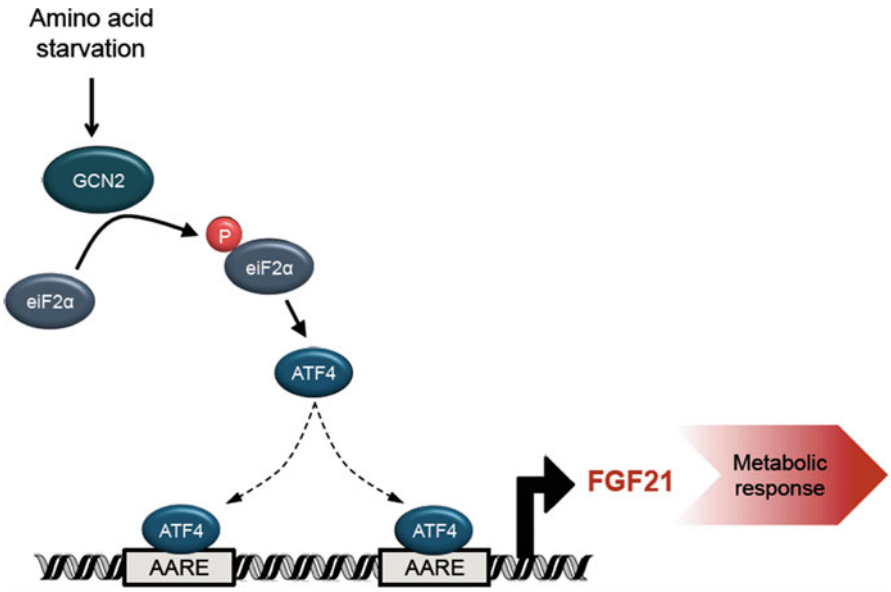

Fig. 2 The GCN2 pathway in the response to amino acids starvation. GCN2 kinase is a direct sensor of amino acid supply via binding deacylated tRNAs. When levels of an indispensable amino acid decrease enough, its tRNA becomes deacylated. When activated by uncharged tRNAs, GCN2 increases eiF2α phosphorylation. Hence, phospho-eiF2α reduces general protein synthesis rates. Paradoxically the translation of the transcription factor ATF4 and the expression of its target genes are increased

homeostasis. FGF21 is a member of the FGF family. It is predominantly produced by the liver but also by other tissues such as WAT and BAT, skeletal muscle, and pancreatic β cells (Domouzoglou and Maratos-Flier 2011). FGF21 expression in liver is under tight control by peroxisome proliferator-activated receptor alpha (PPARα). FGF21 is induced in the liver during fasting and its expression triggers a metabolic state that mimics long-term fasting. Thus, FGF21 is critical for the induction of hepatic FA oxidation (FAO), ketogenesis, and gluconeogenesis – all metabolic processes that are critical for the metabolic adaptation to starvation (Reitman 2007).

FGF21 acts as a hormone-like peptide and its signaling pathway requires FGF21 binding to a fibroblast growth factor receptor (FGFR). FGFRs are tyrosine kinase receptors, and seven isoforms have been described (1b, 1c, 2b, 2c, 3b, 3c, and 4). FGFR1c has been defined as the main mediator of FGF21 response in vivo (Yang et al. 2012) through an obligate dimerization with the co-receptor β-klotho (KLB) (Ding et al. 2012). The co-expression of these two receptors determines the sensitivity of a tissue or organ to FGF21 signaling. Regarding the signal transduction pathway, the binding of FGF21 to the FGFR-KLB dimer stimulates the phosphorylation of FGFR substrate 2α (FRS2α) and the activation of extracellular signal-regulated kinase 1/2 (ERK1/2) and Akt (Fisher and Maratos-Flier 2016) (Fig. 3).

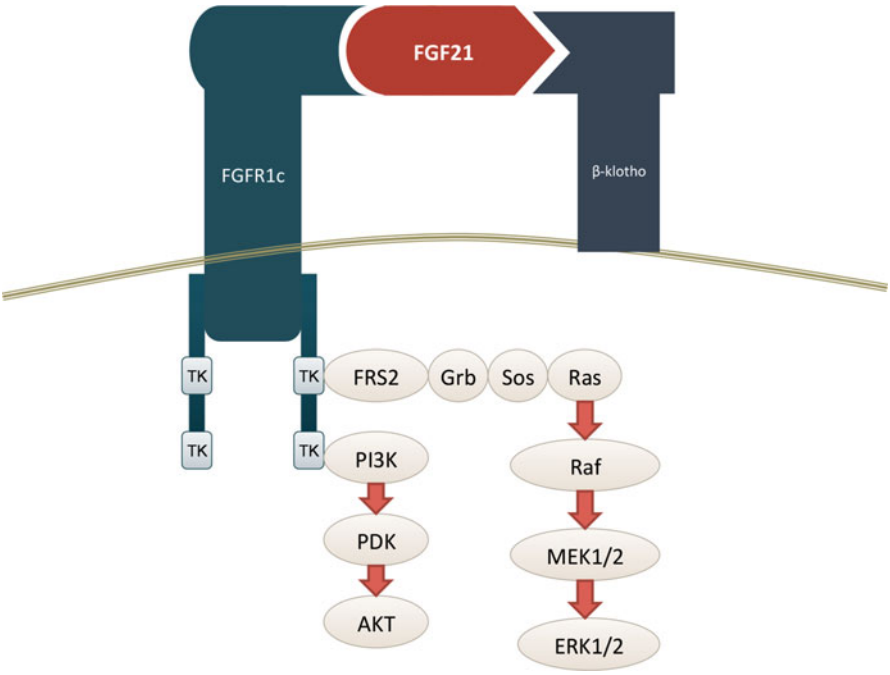

Fig. 3 The FGF21 receptor complex and signaling cascade. The binding of FGF21 to the FGFR-KLB dimer causes the tyrosine autophosphorylation of FGFR. This action facilitates the binding and activation of FGFR substrate 2α (*FRS2α*), which transduces the signal to MAPK signaling cascades via the recruitment of several adaptor molecules. The activation of extracellular signal-regulated kinase 1/2 (*ERK1/2*) and PI3K is critical to induce transcription of early response genes

The similarities between the metabolic response to essential amino acid deprivation and to the administration of recombinant FGF21 together with the induction of FGF21 under amino acid deprivation (De Sousa-Coelho et al. 2012), and the repression of the transcription and maturation of sterol regulatory element binding protein (SREBP) 1c induced by FGF21 in HepG2 cells (Zhang et al. 2011), suggest that FGF21 is a key mediator between amino acid deprivation and lipid metabolism in liver, WAT, and BAT.

Analysis of the response of FGF21-deficient mice to deprivation of the essential amino acid leucine reveals a huge increase in FGF21 expression in liver of wild-type animals, along with a repression of lipogenic genes after 7 days of deprivation. In this condition, these mice develop liver steatosis as a result of the unrepressed expression of lipogenic genes. Under leucine deprivation, the expression of lipogenic genes in WAT is also repressed, and the phosphorylation of hormone-sensitive lipase (HSL) increases. The absence of leucine also triggers an increase in the expression of UCP1 and type 2 deiodinase (Dio2) in BAT. All these effects in WAT and BAT are impaired in FGF21-deficient mice (De Sousa-Coelho et al. 2013).

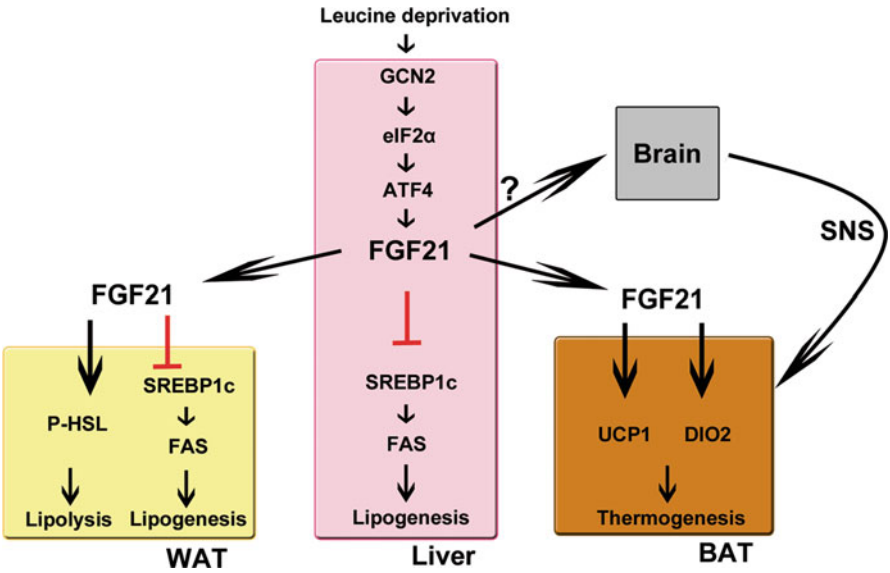

Fig. 4 Model of the FGF21 regulatory pathway under leucine deprivation. This research was originally published in Journal of Lipid Research. De Sousa-Coelho et al. 2013. Copyright © the American Society for Biochemistry and Molecular Biology

These results demonstrate the involvement of FGF21 in the regulation of lipid metabolism during amino acid starvation. These observations thus reinforce the role of this growth factor as an endocrine factor, coordinating energy homeostasis under a variety of nutritional conditions (Fig. 4).

Along the same lines, methionine-deprived mice show a phenotype comparable to that of leucine deprivation. The metabolic response to methionine deficiency includes resistance to diet-induced obesity (DIO), improved glucose homeostasis, increased FA activation and oxidation in liver, increased lipolysis in WAT, and increased Ucp1 expression in BAT (Ables et al. 2012; Lees et al. 2014; Stone et al. 2014). All these effects are coupled to an increase in circulating FGF21 levels. In fact, it has recently been shown that FGF21 is a critical mediator of the effects of dietary methionine restriction on energy expenditure, WAT remodeling, and increased insulin sensitivity, but not of the effects of this diet on hepatic gene expression (Wanders et al. 2017).

The metabolic response to protein limitation is similar to that observed under leucine or methionine restriction (Laeger et al. 2014). Serum levels of FGF21 increase in both rodents and humans subjected to low protein diets (LPDs), regardless of overall caloric intake (Morrison and Laeger 2015; Ozaki et al. 2015). LPDs are accompanied by weight loss and an increase in both food intake and energy expenditure (Laeger et al. 2014; Ozaki et al. 2015). Remarkably, neither food intake nor energy expenditure of Fgf21-deficient mice is altered by the administration of such diets (Laeger et al. 2014). Moreover, a LPD has been reported to induce thermogenic markers in BAT of obese rats (Pezeshki et al. 2016).

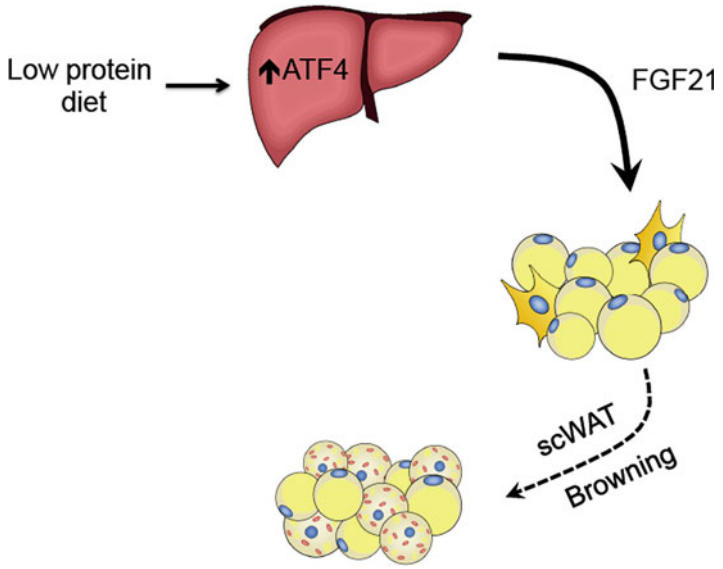

Fig. 5 Model of the FGF21 mediated response to a LPD in scWAT. In mice, a LPD induces a huge increase in liver FGF21 expression and in serum levels, which correlates with enhanced ATF4 protein levels. Also, this diet caused an FGF21-dependent browning of scWAT. This research was originally published in Molecular Nutrition and Food Research. Pérez-Martí et al. (2017); In press. Copyright © 2017, Wiley-VCH Verlag GMbH & Co. GaA

Analysis of the metabolic response of wild-type and FGF21 liver-specific knockout mice (L*Fgf21*KO) to a LPD (up to 5% of energy as protein) showed that a decrease in dietary protein content induces a huge increase in FGF21 serum levels, significant weight loss, and an increase in the expression of UCP1 in the subcutaneous WAT (scWAT) of wild-type mice. Remarkably, no effects were observed in L*Fgf21*KO mice, thereby indicating that the absence of FGF21 blunts or completely blocks the response to a LPD in this mouse model. These observations thus reveal that FGF21 is likely to be involved in the metabolic Response to Protein-restricted diets (Pérez-Martí et al. 2017) (Fig. 5).

Moreover, ketogenic diets (KDs), which are widely known to induce FGF21 expression, are usually low in carbohydrates and proteins but rich in fat. The protein content of KDs underlies the increased levels of circulating FGF21, since protein supplementation but not carbohydrate supplementation blunts this induction (Bielohuby et al. 2011). This effect could also explain the induction of FGF21 observed in high carbohydrate diets (HCDs), which are characterized by low protein content.

Finally, in humans, the analysis of protein intake through nutritional questionnaires and the determination of the serum levels of FGF21 in individuals randomly selected from two nodes of the PREDIMED (*Prevención con Dieta Mediterránea*) trial show like in the animal model, an inverse correlation between circulating FGF21 levels and protein intake (Pérez-Martí et al. 2017) (Fig. 6).

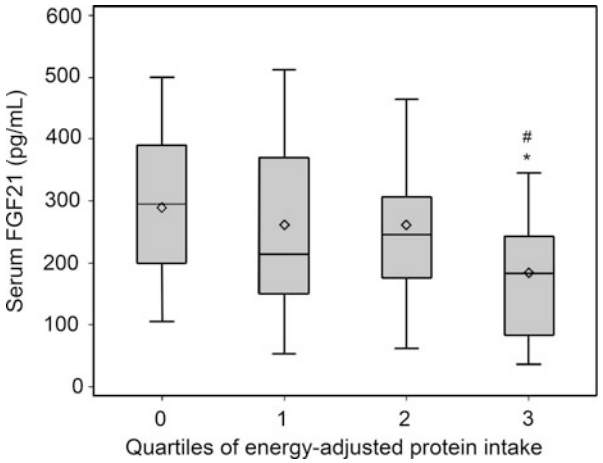

Fig. 6 Circulating FGF21 levels correlate negatively with protein intake in humans. Plasma FGF21 concentration divided into quartiles of protein intake adjusted for the calorie intake of 78 participants in the PREDIMED trial. Error bars represent the mean ± SEM. * $p < 0.05$ from 1st quartile; # $p < 0.05$ from the 2nd quartile. This research was originally published in Molecular Nutrition and Food Research. Adipose Tissue as the Main Target of the Effects of FGF21

Adipose tissue is the main target tissue of FGF21 and the major mediator of its beneficial effects. While the physiological effects of FGF21 during fasting remain elusive, most data on its signaling in WAT derive from studies in which it was pharmacologically administered or overexpressed in obese mice. Nevertheless, depending on its source, FGF21 shows paradoxical actions on WAT. Fgf21-over-expressing mice show induced lipolysis (Inagaki et al. 2007; Li et al. 2009). In contrast, FGF21-knockout mice present enhanced lipolysis in late fasting (Hotta et al. 2009). In addition, while FGF21 suppresses lipolysis in mouse and human adipocytes (Arner et al. 2008), this process is induced by peroxisome proliferator activating receptor gamma (PPARγ) in WAT upon feeding, thus stimulating adipogenesis (Dutchak et al. 2012; Muise et al. 2008). Regarding glucose metabolism, FGF21 induces glucose uptake in 3T3L1 adipocytes by increasing glucose transporter 1 (GLUT1), independently of insulin action (Kharitonenkov et al. 2005). Moreover, later studies reported increased glucose uptake in both WAT and BAT of lean mice infused with FGF21 and fed a chow diet (Camporez et al. 2013). In summary, in WAT, FGF21 induces genes involved in glucose uptake, lipogenesis, and lipolysis, depending on the metabolic state of the adipocytes. These apparently contradictory observations may be explained by compensatory effects of genetic modifications in mice, a different nutritional status, and different FGF21 concentrations reached between pharmacological administration and physiological secretion. WAT is not only a FGF21 target tissue but also a mediator of the effects of this growth factor. In this regard, the glucose- and insulin-sensitizing effects of FGF21

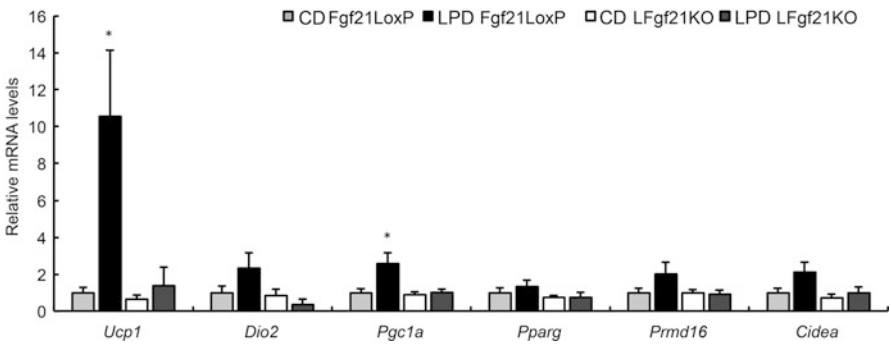

Fig. 7 Hepatic FGF21 is required for inducing thermogenic gene expression during a LPD. Ucp1, Dio2, Pgc1α, Pparγ, Prmd16, and Cidea expression was measured by qRT-PCR in mouse scWAT. Error bars represent the mean ± SEM. * $p < 0.05$ versus Fgf21LoxP mice fed a CD ($n = 7$–9/group). This research was originally published in Molecular Nutrition and Food Research. Pérez-Martí et al. 2017; In press. Copyright © 2017, Wiley-VCH Verlag GMbH & Co. KGaA

require the production and secretion of adiponectin from WAT. Accordingly, FGF21 stimulates this mechanism in rodents, and adiponectin-knockout mice fail to reproduce the sensitizing effects of FGF21 (Lin et al. 2013). Similarly, FGF21 also reduces the levels of sphingolipid ceramides. These lipids have been associated with insulin resistance caused by lipotoxicity. By inducing adiponectin secretion, FGF21 diminishes the accumulation of ceramides in obese animals (Holland et al. 2013). Overall, despite some contradictory effects of FGF21 in adipose fat depots, adipose tissue is considered indispensable for the physiological and pharmacological effects of this growth factor. Finally, FGF21 induces the expression of Ucp1, thus producing the so-called WAT browning in an autocrine, paracrine or endocrine fashion (De Sousa-Coelho et al. 2013; Fisher et al. 2012; Pérez-Martí et al. 2017). Browning occurs in multilocular beige adipocytes in specific susceptible WAT depots, such as inguinal and perirenal tissue, through an increase in the expression of genes involved in thermogenesis, and it confers a brown fat-like phenotype to white adipocytes (Fig. 7).

BAT is a FGF21 target tissue since it expresses FGFR1 and KLB; however, this tissue is also a source of FGF21. In BAT, FGF21 stimulates glucose uptake and thermogenesis through the induction of UCP1 in the interscapular depot in an autocrine and paracrine fashion (Hondares et al. 2011). Upon exposure to cold, FGF21 expression is increased in BAT and other cold-sensitive fat depots in the β-adrenergic/ATF2-dependent pathway (Chartoumpekis et al. 2011; Fisher et al. 2012; Hondares et al. 2011). In this regard, Fgf21-deficient mice respond poorly to cold exposure and show greater shivering.

The mechanisms underlying the action of FGF21 on BAT/WAT are still not well understood. Part of the FGF21-induced activation of the thermogenic program is driven by PPARγ coactivator 1 alpha (PGC1α), as FGF21 increases the protein levels of this coactivator. Similarly, Pgc1a-knockout mice show an impaired response to FGF21 (Fisher et al. 2012). Furthermore, hepatic FGF21-mediated

thermogenesis has also been described in response to maternal milk consumption in neonatal pups (Hondares et al. 2010) and also in situations of metabolic stress, for example, upon amino acid restriction (De Sousa-Coelho et al. 2013). These observations suggest that the hepatic FGF21-mediated increase in thermogenic capacity is an adaptive response to metabolic stress. It has been proposed that the effect of FGF21 on energy expenditure and weight loss may be due to an increased thermogenic capacity of BAT and WAT (browning). However, recent experiments in Ucp1-null mice and interscapular BAT-excised mice show that when FGF21 is administered pharmacologically, UCP1 is not required for the improvement of the glucose, cholesterol, and free FA profile. However, the increment in metabolic rate associated with the administration of FGF21 is diminished in these mice (Bernardo et al. 2015; Samms et al. 2015; Véniant et al. 2015). These data suggest that the metabolic benefits of FGF21 are partly UCP1-independent.

Molecular Mechanisms for the FGF21 Induction in Response to Protein Intake

FGF21 is induced by amino acid deprivation both in HepG2 cultured cells and mouse liver, but not in WAT or BAT, and FGF21 is a target gene for the transcription factor ATF4. These results add FGF21 gene induction to the transcriptional program triggered by increased levels of ATF4 in response to amino acid starvation and offer a new mechanism for the induction of FGF21 expression under nutrient deprivation (De Sousa-Coelho et al. 2012).

GCN2, a kinase that acts as a sensor of amino acid supply (Qiu et al. 2001), and PPARα are indispensable for the induction of FGF21 in response to protein restriction. In this regard, the respective knockout mice present blunted induction of FGF21 when fed a LPD. To date, there is no evidence of PPARα activation in response to a LPD, thus suggesting that PPARα plays a role in the constitutive expression of FGF21. In contrast, GCN2-dependent phosphorylation of eIF2α increases in response to a LPD, resulting in greater ATF4 protein levels (Anthony et al. 2004; Guo and Cavener 2007). Therefore, the GCN2/eIF2α/ATF4 cascade emerges as the main signaling pathway in the induction of FGF21 by protein restriction. As has been mentioned before, ATF4 directly or indirectly triggers the transcription of a subset of specific target genes, including FGF21, to modulate many cellular processes in order to adapt to amino acid deficiency (De Sousa-Coelho et al. 2012; Shan et al. 2009). However, it is worth mentioning that LPD administration to Pparα-KO and Gcn2-KO mice still induces FGF21 expression (Laeger et al. 2014). This observation suggests that additional signaling pathways are involved in triggering the increase in FGF21 expression in response to protein restriction. GCN2-independent mechanisms that induce hepatic FGF21 in response to methionine-restricted diets have recently been described (Wanders et al. 2016). These results point to a noncanonical PERK/nuclear respiratory factor 2 (NRF2) pathway in liver as an alternative mechanism used to sense and respond to methionine restriction when GCN2 is absent. Along the same lines, during long-term dietary protein restriction, the absence of GCN2 is compensated upstream of ATF4 in

order to maintain FGF21 induction (Laeger et al. 2016). In summary, amino acid-deficient diets diminish aminoacidemia and trigger the AAR, thereby resulting in elevated FGF21 levels. The contribution of each single amino acid to the modulation of FGF21 and how a deficiency in specific types of dietary protein alters FGF21 expression require further study.

Hepatic mTORC1 activity is also related to FGF21 expression. The mTOR-signaling pathway monitors amino acid sufficiency and promotes protein translation and cell growth, among other processes. In this case, liver-specific Tsc1 knockout mice, which present mTORC1 hyperactivity in the liver, show increased expression of FGF21 and depleted levels of glutamine (Cornu et al. 2014). Moreover, when these animals are treated with rapamycin (mTORC1 inhibitor) or glutamine, the increase in FGF21 is blunted. Finally, in human hepatic tumors, mTORC1 activation also correlates with FGF21 levels (Cornu et al. 2014). It has been proposed that the mechanism underling the increase in FGF21 expression occurs through PGC1α; however, additional mechanisms could be involved and it is feasible that depleted glutamine levels trigger the AAR.

Alternative Situations that Cause a Negative Nitrogen Balance and Change FGF21 Expression

In addition, pathological conditions caused by various forms of stress, such as trauma, thermal burning, sepsis, and fever, can lead to a negative nitrogen balance. In this context, several scenarios that alter aminoacidemia also lead to an increase in FGF21 expression. The absence of slc6a19 (neutral amino acid transporter) causes a lack of systemic neutral amino acids, resulting in an increase in FGF21 transcription (Jiang et al. 2015). In mice, treatment with the antileukemic agent asparaginase depletes circulating asparagine and glutamine levels, thereby promoting FGF21 expression (Wilson et al. 2015), and skeletal muscle-specific knockout mice for glucocorticoid receptor (GR) show reduced alanine flux from skeletal muscle during fasting, resulting in an increase in FGF21 plasma levels (Shimizu et al. 2015). Hence, it is likely that many other situations that reduce amino acid availability also lead to an induction of FGF21 expression.

Concluding Remarks

To summarize, here we define the molecular Mechanisms by which amino acid starvation or LPDs exert their metabolic effects through the induction of hepatic FGF21 expression and increased thermogenic gene expression in different fat depots. Furthermore, given the data collected from humans, manipulation of dietary protein content emerges as an approach to modulate circulating FGF21 levels and thus an alternative to its pharmacological administration.

Policies and Protocols

Gene Expression Analysis

This chapter described how a particular dietary pattern changes the mRNA expression profile of some metabolic regulatory genes. Nowadays, gene expression is analyzed by quantitative PCR (qPCR). Briefly, tissues or organs to be analyzed are extracted from the animals and immediately frozen at −80 °C. Total RNA from different tissues are extracted using phenolic derivatives such as TriReagent solution. To perform the gene expression assays, the RNA is converted to single-stranded DNA (cDNA) that can be used as a template to amplify by PCR, specific regions from the genes of interest. The qPCR is based on a fluorescence reporter molecule – the most usual are TaqMan® probe or SYBR® Green dye – that monitor the amount of target amplicon. In this case, the fluorescence is directly proportional to the initial quantity of the target template (cDNA) and it is reflections of the amount of target mRNA. The calculi of the expression levels must be normalized with housekeeping genes (it is highly recommended to use more than one) and is expressed as a fold induction, a comparison between the number of cycles of amplification needed to detect the fluorescence (Ct) with the gene of interest in control animals and in treated ones after the normalization by the Ct of the housekeeping genes in both conditions.

Protein Analysis

Western Blot and ELISA are two experimental approaches to the study of protein levels. In both cases, total protein extracts need to be obtained. The protein analyses can be done from cell cultures, tissues, and organs or from plasma/serum/blood/urine. In the case of organs and tissues, those must be homogenized before the purification. The protein extraction from cells requires the lysis of the cells prior purification. In both cases, this first step is done with a detergent – the most used are NP40, SDS, or Triton. Later, the proteins are solubilized and purified from the cell debris. The proteins from liquid samples are already in solution and the only critical step could be the need to concentrate the sample.

Finally and after total protein quantification, the next step is the detection of a specific protein. Western Blot and ELISA are both based on an antibody-antigen reaction. In the case of Western Blot, the proteins are resolved by electrophoresis in a SDS-polyacrylamide gel, transferred to a PVDF or nylon membrane and detected in the membrane using a specific antibody against the target protein. This primary antibody could be linked to a detection method (fluorescence molecule or an enzyme that catalyzes a reaction easy to quantify), but in most of the cases it is necessary to add a second antibody that recognizes the first one and that is linked to the detection method. In the case of ELISA, the binding between antigen (target protein) and antibody takes place in a well plate and the detection method is usually a colorimetric method, but the proof of concept is the same than in Western Blot.

Generation of Tissue Specific Knockout Mice

The goal of this protocol is the generation of a genetically modified mouse in which the function of a particular gene has been eliminated in one specific tissue. To generate tissue-specific knockout mice, two previously genetically modified mice need to be crossed. In the first animal, the genetic modification consists in the introduction of a tag (a DNA sequence called loxP, for instance) in the gene which function will be altered. The genetic modification of the second mice is the introduction of the gene that encodes for an enzyme called Cre recombinase. The Cre recombinase gene is introduced in mice targeted to be expressed only in a particular tissue. In mice resulting from the crossing between the previous two, the Cre recombinase recognizes the loxP sequence and as a result of its enzymatic activity the region flanked by loxP sequences is deleted. This deletion means the loss of function of the target gene only in the tissues where the Cre recombinase is expressed. **The animal experimental policies** stablish that: all the animal protocols must be approved by the corresponding Animal Ethics Committee of the Institution and/or Country where the experiments will be made.

Dictionary of Terms

- **Essential amino acids** – Amino acids that cannot be synthesized by higher organisms and consequently must be supplied by diet.
- **Lipolysis** – Mobilization of fatty acids from fat depots.
- **Thermogenesis** – Heat production in brown adipose tissue by disconnection of ATP synthesis from the electron transport chain.
- **Signal transduction** – Transmission of an input signal through a cell by a series of molecular events mainly cascades of protein phosphorylation.
- **Specific knockout mice** – A genetically engineered mouse in which the function of a particular gene has been abolished only in a specific tissue.
- **Browning** – The appearance of cells with a brown fat-like aspect in specific susceptible white adipose tissue depots.

Summary Points

- This chapter reviews the changes in the metabolic patterns induced during amino acids starvation and the molecular mechanisms driving these changes at the whole body and particularly in both white and brown adipose tissue.
- The dietary amino acids content alters metabolic pathways beyond protein homeostasis since there is a link between amino acids intake and lipid metabolism.
- The synthesis of fatty acids in liver is diminished by a repression of the lipogenic genes expression and inhibition of the activity of fatty acid synthase.
- Leucine deprivation causes an increased mobilization of lipid stores

- Leucine deprivation or protein restriction causes a change in the gene expression pattern that includes: increased expression of β-oxidation genes and decreased expression of lipogenic genes in white adipose tissue, and increased expression of uncoupling protein 1 (UCP1) in brown adipose tissue.
- Amino acid starvation initiates a signal transduction cascade starting with the activation of general control nonderepressible 2 (GCN2) kinase.
- Paradoxically, with the overall protein synthesis stopped, the synthesis of activating transcription factor 4 (ATF4) is increased.
- Activating transcription factor 4 (ATF4) directly or indirectly induces the transcription of a subset of specific target genes, including fibroblast growth factor 21 (FGF21), to modulate many cellular processes to adapt to amino acid deficiency or protein restriction.
- Fibroblast growth factor 21 (FGF21) plays a relevant role in the regulation of lipid metabolism during amino acid starvation and protein restriction coordinating energy homeostasis.
- Amino acid starvation or a protein-restricted diet induce a fibroblast growth factor 21 (FGF21)-dependent weight loss and increased uncoupling protein 1 (UCP1) expression in the subcutaneous white adipose tissue.

Fasting Influences Conditioned Memory for Food Preference Through the Orexin System: Hypothesis Gained from Studies in the Rat

114

Barbara Ferry and Patricia Duchamp-Viret

Contents

Abstract

A large variety of behaviors that are essential for animal survival depend on the processing and perception of surrounding smells present in the natural environment. In particular, food-search behavior, which is conditioned by hunger, is directly driven by the perception of odors associated with food, and feeding status modulates olfactory sensitivity. The orexigenic hypothalamic peptide orexin A, one of the main central and peripheral hormones that triggers food intake, has been shown to increase olfactory sensitivity in various experimental conditions including the conditioned odor aversion learning paradigm. Conditioned odor aversion is an associative task that corresponds to the association between an olfactory conditioned stimulus and a delayed gastric malaise. Previous studies have shown that this association is formed only if the delay separating the

conditioned stimulus presentation from the malaise is short, suggesting that the memory trace of the odor is relatively unstable. To test the selective impact of the orexin system in olfactory sensitivity, a recent study compared the effects of fasting and of central infusion of orexin A during the acquisition of conditioned odor aversion. Results showed that the increased olfactory sensitivity induced by fasting or by orexin infusion was accompanied by enhanced conditioned odor aversion learning performances. In reference to the duration of action of orexin, the present work details the results obtained during the successive conditioned odor aversion extinction tests and suggests a hypothesis concerning the role of the orexin component of fasting on the memory processes underlying the odor-malaise association during conditioned odor aversion. Moreover, referring to previous data in the literature, we suggest a functional circuit model where fasting modulates olfactory memory processes through direct and/or indirect activation of particular orexin brain targets including the olfactory bulb, the locus coeruleus, and the amygdala.

Introduction

A large variety of behaviors that are essential for animal survival depend on the sensory processing and perception of odor cues present in the natural environment. Food-search behavior, which is conditioned by hunger, is directly driven by the perception of odors associated with food items (Le Magnen 1959). In turn, several studies have demonstrated that nutritional status influences odor processing. For

example, the olfactory bulb activity was shown to be directly modulated according to hunger and satiation status (Apelbaum et al. 2005; Pager 1974; Pager et al. 1972; Pager 1978; Royet et al. 1983). Such a modulation supports results showing that fasting enhanced odor detection in rats, whereas satiety reduced detection of odors in general (Aimé et al. 2007), or of one odorant specifically associated with the food type involved in the satiation (O'Doherty et al. 2000; Mulligan et al. 2002). The literature suggests that the CNS regulates food-search behavior by modulating the detection threshold of the food odorant items through centrifugal innervations (Doucette et al. 2007; Doucette and Restrepo 2008; Fletcher and Chen 2010), and a large body of data indicate that the hypothalamus plays an important role in this process. Firstly, anatomic characterization of the lateral hypothalamus has shown the existence of a functional loop between hypothalamic orexin system (OX) and structures involved in the first levels of odor processing (i.e., olfactory mucosa, bulb and piriform cortex) (Peyron et al. 1998; Nambu et al. 1999; Caillol et al. 2003; Shibata et al. 2008; Hahn and Swanson 2010; Sakurai 2005; Swanson et al. 2005). Secondly, the crucial role of the hypothalamus, and in particular of orexigenic (appetite-stimulating) and anorexigenic (appetite-inhibiting) neurochemicals, in appetite regulation and energy balance has long been established (see Rodgers et al. 2002 for review). Thirdly, among the multitude of neurochemicals found in the hypothalamus, OX peptides (orexin A (OX A) and orexin B (OX B)) have been shown to be strongly involved in the regulation not only of feeding and energy metabolism (see Willie et al. 2001 for review) but also of olfactory sensitivity.

In particular, we have shown that intracerbroventricular (icv) infusion of OX A increased olfactory detection performance in the same way as physiologically induced fasting in the rat (Aimé et al. 2007; Julliard et al. 2007). Fourthly, the two classes of receptors for OX A and for OX B are expressed in olfactory bulb (OB) neurons (Caillol et al. 2003) and OX A impacts mitral cell activity (Hardy et al. 2005). In addition, central infusion of OX A increased OB Fos responses to food odor in both fasted and satiated animals (Prud'Homme et al. 2009). All these results indicate that orexins, mainly OX A and secondarily OX B, are involved in the control of feeding behavior by modulating olfactory sensitivity.

It is, however, very unlikely that olfactory sensitivity is completely dissociated from olfactory memory. Rusiniak et al. (1982) and Slotnick et al. (1997) showed that the more intense the odor, the stronger the memory of its association with a reinforcement. Interestingly, other than its projection on the primary olfactory centers, the hypothalamic OX neurons project to various structures involved in olfactory associative learning (see Rodgers et al. 2002 for review). Moreover, OX system was shown to be involved in the memory processes underlying various kinds of learning (Telegdy and Adamik 2002; Jaeger et al. 2002; Di Sebastiano et al. 2010; Mair and Hembrook 2008) and in particular in conditioned flavor aversion paradigms (Touzani and Sclafani 2002). Thus, OX system may be involved in odor memory formation, directly, by modulating olfactory sensitivity, and indirectly, by activating particular hypothalamus target regions.

In a natural environment, the relevance of the odor coming from a food source encountered by an animal during food-search is a crucial key, determining approach

and ingestion of the food. Whether the odor of the food is new to the animal or has previously acquired a hedonic valence during a first intake experience will condition either attraction or avoidance. Acquisition of hedonic valence by a food item has been shown to result from conditioned learning during which the sensory stimuli characterizing a particular food (odor and taste) become associated with the positive (energy input) or negative (gastric malaise, poisoning) consequences of the ingestion of the food, so that processing the odor and taste stimuli will cue the appropriate agonistic or antagonistic responses (Rescorla 1988; Mackintosh 1991; Holland 1990). These kinds of association have been experimentally studied for years (Nigrosh et al. 1975; Slotnick 1984; Slotnick and Katz 1974), and conditioned food aversion paradigms, such as conditioned taste or odor/taste-potentiated odor aversion learning, have provided fundamental insights into the mechanisms and CNS structures involved in food-reward/food-poisoning associations (see Miranda 2012 for review).

Conditioned Odor Aversion Learning Paradigm and Orexin

One such paradigm, conditioned odor aversion (COA), is a trace conditioning paradigm of avoidance of a tasteless odorized solution (conditioned stimulus (CS)) the ingestion of which precedes gastric malaise (unconditioned stimulus (US)). COA is a robust long-lasting learned association that can be obtained with only a single CS–US pairing (Hankins et al. 1973; Lorden et al. 1970; Taukulis 1974). In contrast to the well-known conditioned taste aversion paradigm, COA is normally obtained only if the interval between CS and US is shorter than 30 min (Andrews and Braveman 1975; Bouton et al. 1986; Garcia et al. 1966), suggesting that the memory trace of the odor, which must be maintained during the interstimulus interval (ISI) in order to be associated with the US, is subject to rapid decay. Our team's investigations of the neurobiological substrate involved in COA showed that the basolateral nucleus of the amygdala (BLA) plays a critical role in the acquisition of odor-US associations by modulating the odor memory trace during the ISI (Ferry et al. 1995; Ferry and Di Scala 1997, 2000).

Taking these data together with the fact that (i) OX neurons project to the amygdala and (ii) hypothalamic OX neurons are activated by cues associated with consummatory rewards such as food (Harris et al. 2005) suggests that the OX system may play a role in the learning and memory processes linked to higher cognitive aspects of feeding.

In order to test this hypothesis, a series of studies have been aimed at evaluating the effect of manipulation of OX A level in the brain system during COA learning. Using icv microinjection technique, we have been able to show that fasting induced by 24-h food-deprivation as well as preacquisition central OX A infusion potentiated the memory processes underlying the association between the olfactory CS and the delayed US in the rat, thus rendering the association between the odor CS and the US possible even though the ISI delay is longer than 35 min. Moreover, this effect was

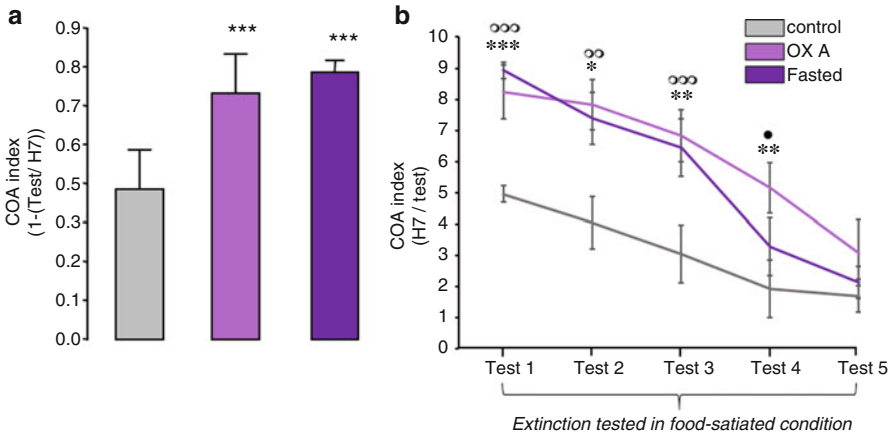

Fig. 1 Effects of icv infusion of orexin A (10 µg/3 µl, OX A group), icv infusion of artificial CSF (3 µl, aCSF group) and food-deprivation (Fasted group) during COA acquisition on performance measured during the test (48 h after acquisition) and extinction (5 consecutive testing days) when the ISI was about 35 min. (**a**) Bars represent mean COA index of the form "1-(water intake measured during the test/water intake measured the day before acquisition H7" (±S.E.M.) calculated for the various groups during the test measured in satiated condition. An index close to 1.0 represents a strong COA. ***: $p < 0.001$ compared to the control group. (**b**) Curves represent the COA index of the form "water intake measured the day before the acquisition H7/water intake measured during the test" (±S.E.M.) for each group from testing days 1 to 5. The Fasted group was food-deprived only during acquisition. All animals were tested while food satiated. *, **, and ***: $P < 0.05$, $P < 0.01$ and $P < 0.001$ between OX A and control group. ○○ and ○○○: $P < 0.01$ and 0.001 between Fasted and control group. ●: $P < 0.05$ between OX A and Fasted group

independent from the fasting-induced enhancement of stress level (Ferry and Duchamp-Viret 2014; Fig. 1).

Referring to the fact that COA is a trace conditioning that results from several processes that follow one another over time, these data have shed some light on the processes that have been influenced by the activation of OX system. During acquisition, CS and US processing are followed by association of the two stimuli. Then, the CS-US association is consolidated and finally retrieved during the test when the CS is presented for the second time. Some studies have shown that behavioral effects of icv OX A infusion, such as feeding and drinking behavior (Sakurai et al. 1998; Edwards et al. 1999, Kunii et al. 1999) or olfactory hypersensitivity (Julliard et al. 2007), persist for at least 3 h. Therefore, the effects of fasting and OX A infusion obtained on COA resulted from changes in the processes of acquisition and/or consolidation taking place 2 days after, when COA was tested in satiated condition.

Effect of Fasting and OX A Infusion on Acquisition of the Task

As discussed earlier, the acquisition of COA reflects the association between the memory trace of the olfactory CS and the delayed visceral US (see Bures and

Buresova 1990; Roldan and Bures 1994). Several studies have shown that, when ingested, a tasteless olfactory stimulus acquires a strong aversive value, even with CS–US intervals equivalent to those generally used for tastes (Slotnick et al. 1997; Rusiniak et al. 1982; Bouton et al. 1986); however, COA can only be acquired if the interstimulus interval (ISI) is kept under 30 min, suggesting that the CS trace is subject to gradual decay over time (Miranda et al. 2007; Ferry et al. 2006; Inui et al. 2006). Moreover, Rusiniak et al. (1982) and Slotnick et al. (1997) have shown that the effectiveness of an olfactory CS in inducing strong COA when paired with a delayed illness is directly related to the intensity of the CS used during acquisition. Thus, in the light of previous studies showing 24-h fasting and icv OX A infusion increase olfactory sensitivity (Julliard et al. 2007), it is possible that the potentiation of COA observed in the study of Ferry and Duchamp-Viret (2014) resulted from the enhanced perception of the CS that lengthened its memory trace duration thus rendering possible its association to toxicosis occurring with a delay longer than 30 min (Ferry et al. 1995, 1996).

Effect of Fasting and OX A on Consolidation of the Task

Previous works have proposed that consolidation involves two types of process: synaptic consolidation, accomplished within the first minutes to hours after the CS-US association has been acquired; and system consolidation, involving reorganization of the brain circuits encoding the memory, which takes weeks, months, or even years to be accomplished (Dudai 1996; Dudai and Morris 2000). Considering the duration of OX A action when infused icv, it may be suggested that the enhanced COA observed in our study was mediated by enhanced synaptic consolidation of the memory processes underlying COA in OX A containing structures such as hippocampus, amygdala, piriform cortex, or entorhinal cortex that have been previously involved in such learning (Marcus et al. 2001; Campbell et al. 2017; Caillol et al. 2003; Ferry et al. 1996, 2006; Ferry and Di Scala 1997; Chapuis et al. 2009).

Together, these data show that physiological as well as OX A-induced fasting status affected COA through changes in memory processes occurring during the acquisition of a CS-US association and/or during the synaptic consolidation of this association.

Hypothesis on the Neurobiological Substrate Mediating Fasting and OX A Effects on COA Learning and Memory

The neurobiological substrate through which OX may influence the memory processes underlying food conditioned learning remains to be elucidated; however, some reports open up a number of possible hypotheses involving hypothalamic projection targets.

As mentioned before, olfactory sensitivity cannot be dissociated from olfactory memory, and some data suggest that the indirect effects of fasting and OX A on the

olfactory memory trace formation through increased olfactory sensitivity may involve the OB. Firstly, in addition to its well-documented role in detection and discrimination, the OB is involved in memory processes underlying various kinds of olfactory learning in adult rats (see Mandairon and Linster 2009 for review). Moreover, the OB receives direct OX innervation from the lateral hypothalamus (LH) (De Lecea et al. 1998; Peyron et al. 1998; Sakurai et al. 1998, Shibata et al. 2008), and an increase in OB electrophysiological response induced by fasting and OX has been described (Pager et al. 1972; Gervais and Pager 1982; Apelbaum and Chaput 2003; Apelbaum et al. 2005 and Hardy et al. 2005). In addition, Prud'Homme et al. (2009) found that OX antagonist treatment blocked the enhancement of OB Fos responses to a food odor. Secondly, some evidence suggests that the OX neurons terminating in the locus coeruleus (LC) may provide a second indirect pathway for orexinergic modulation of olfactory processing: direct OX fibers innervate the LC (Horvath et al. 1999) and activation of OX receptors in the LC increases cell firing of intrinsic noradrenergic (NA) neurons (Hagan et al. 1999; Trivedi et al. 1998). In addition, the LC projects over 40% of its neurons directly into the OB (McLean et al. 1989), and this large noradrenergic input has been shown to modulate OB excitability, olfactory perception, and olfactory learning and memory abilities (see Devore and Linster 2012 for review).

Taken altogether, these data suggest that the fasting-induced increase in olfactory sensitivity described in the literature probably involves the OXsystem in the OB. Moreover, and in the light of the work by Escanilla et al. (2012), it may be suggested that this increased olfactory sensitivity resulted directly from OX system activation in OB (Hardy et al. 2005) and/or indirectly through the effect of LC-OX system activation on norepinephrine (NA) release in the OB; activation of both systems may simultaneously influence the strength of olfactory memory through enhanced olfactory processing (stimulus detection and discrimination).

Among all the other possible ways the OX A may have influenced COA, anatomical and behavioral data suggest that the amygdala could be an important part of the circuit involved in the memory processes underlying this learning (Ardeshiri et al. 2017; Campbell et al. 2017; Sears et al. 2013; Petrovich 2013).

Orexinergic innervation of the extended amygdala (including the basolateral amygdala (BLA)) was clearly described by Schmitt et al. (2012). OX A administered into the LH significantly elevated cFos-immunoreactivity in the amygdala (Mullett et al. 2000) and fasting increased OX mRNA levels in the amygdala (Lu et al. 2000). OX applied in acute rat brain slices activated neurons in the amygdala (Bisetti et al. 2006). Moreover, the amygdala receives OB and visceral inputs (Saper and Loewy 1980; Inui et al. 2006) and may be a nodal point at which olfactory and neuroendocrine stimuli are integrated to modulate feeding behavior (King 2006).

Otherwise, a large amount of data indicate that the amygdala, and more precisely the BLA, is involved in the processes underlying the formation of the olfactory memory trace and its maintenance across the ISI during COA (Ferry et al. 1995; Ferry and Di Scala 1997, 2000). Although a direct effect of starvation-induced OX release in the amygdala on COA cannot be excluded, to our knowledge, the

involvement of the OX system in the amygdala has never been demonstrated in learning and memory.

On the other hand, some data indicate that the enhancing effect of starvation on COA memory processes could be indirectly mediated by activation of the NA system in the amygdala. The LC projects strongly onto the amygdala (Fallon et al. 1978), and the BLA β-adrenergic system is involved in the memory processes underlying the association between odor and delayed US during COA (Miranda et al. 2007).

Given the direct action of LH orexinergic neurons on the LC (Horvath et al. 1999), activation of the LC-amygdala NA system during processing of the new odor CS may be potentiated by fasting-induced OX release. Possibly, the strength of the olfactory memory trace, and/or its association to the US, was influenced by activation of this pathway in the Fasted and OX A groups.

Taken together, all the above-mentioned data suggest hypothalamic OX release during fasting enhances learning performance through a direct or indirect influence on a circuit involving different structures such as the LC, amygdala, and OB, which receive LH-OX projections (Ferry 2014). In reference to previous models in which the multiple feedback and feedforward interactions between olfactory and non-olfactory areas contribute to complex processes (Cleland and Linster 2005; Sullivan et al. 2000; Linster and Cleland 2002; Yuan et al. 2003; Aston-Jones and Cohen 2005; Miranda 2012), we propose that the activation of the LH-OX systems induced by fasting reinforces the role of each structure in the circuit by enhancing the neural processes underlying attention and olfactory memory through direct and/or indirect influences (Fig. 2).

Of course the list of structures included in this model is not exhaustive, and involvement of other feedback and feedforward interactions between these structures and others (e.g., piriform cortex, entorhinal cortex, orbitofrontal cortex, hippocampus) will have to be considered in order to achieve a more realistic idea of the circuit actually involved in food conditioned learning (see Ferry et al. 2006; Chapuis et al. 2009; Wilson and Sullivan 2011; Sahay et al. 2011, Chapuis et al. 2013).

Conclusion

Feeding behavior is part of a complex integrated adaptive system, governed by the brain, in which the processing of metabolic signals reflecting the animal's nutritional state (gastrointestinal distention, blood glucose, feeding peptides such as OX) and of olfactory signals indicative of food determines the appropriate response to a food source. However, the differentiation between palatable and unpalatable items that conditions ingestive behavior often depends on previous experience during which the odor of the food acquired a hedonic valence after feeding, through CS-US associative learning, where the CS is represented by the taste and odor of food and the US is represented by the positive (nutritional) or negative (intoxication) post-ingestion value. By showing that OX A system influenced the memory processes underlying the CS-US association during COA, the present study introduces a new mechanism by which the LH-OX system may influence the processes that enable

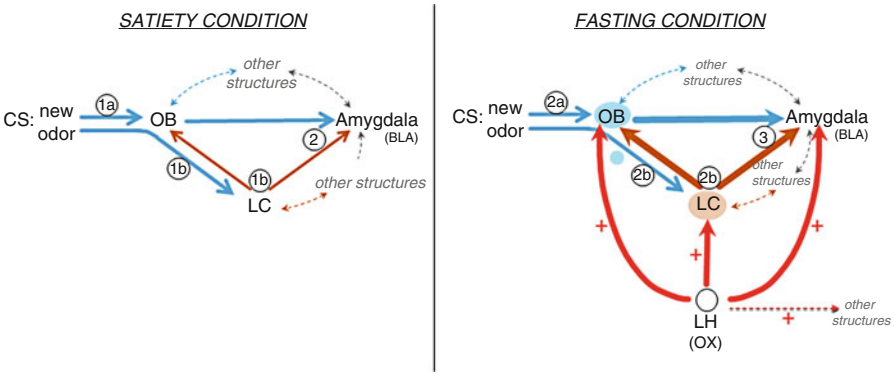

Fig. 2 Representation of a hypothetic model according to which OX A terminating in regions such as the OB, LC, and amygdala may constitute a pathway for orexinergic modulation of the olfactory memory trace formation underlying COA. The left panel represents the sequence of events that may take place during presentation of a new olfactory CS *in the satiated condition*. (1a) Olfactory CS induces activation of the OB. (1b) The novelty of the olfactory CS induces LC activation, which results in NE release in the OB and BLA. (2) The olfactory information is transmitted to the BLA where the odor trace is formed pending its association with the US. This sequence of events results in normal COA. The right panel represents the sequence of events that may take place during presentation of a new olfactory CS *in the fasting condition*. (1) Fasting induces release of OX A in the OB, BLA, and LC, preparing the system to respond to any food-odor event. (2a) Olfactory CS induces activation of the OB, potentiated by activation of the OX A system and LC-mediated NE system in the OB. In the fasting condition, CS leads to improved olfactory detection and processing. (2b) The novelty of the olfactory CS induces LC activation, resulting in enhanced NE release in the OB and BLA. (3) The enhanced olfactory information is transmitted to the BLA. Combined with OX A system activation, LC-mediated NE release in the BLA and potentiated OB activation, the olfactory memory trace strengthened or lengthened, and can thus be associated to a delayed US. This sequence of events results in enhanced COA

animals to learn to select food available in the environment and to adapt their behavior to previous experience through a modulation of complex neural circuit activity. Finally, the OX system represents a critical link between peripheral energy balance and central nervous system mechanisms that coordinate olfactory processing and memory, especially in the physiological state of fasting.

Policies and Protocols

Results described in this study were obtained using a conditioned odor aversion (COA) task in the rat. For this, naïve male adult Long-Evans rats were implanted 2 mm above the left lateral cerebral ventricle with a stainless steel guide cannula (12 mm long; 23 gauge) following a surgical procedure described in the handbook of Best Practices in Neurostereotaxic Neurosurgery (Ferry 2014). After 10 days of postsurgery recovery period, rats were habituated to have access to water once a day during 15 min during 7 days. Twenty-four hours before COA acquisition, animals were food deprived. On the conditioning day (Day 8), animals received a

microinjection of 3 μl of a solution of orexin A (1 nM). Twenty minutes after microinfusion, animals had access to the olfactory CS during 15 min and received a single i.p. injection of 0.15 M Lithium Chloride. On Days 9 and 10, rats received water during 15 min according the water deprivation schedule. From Days 11 to 15, COA was assessed by presenting the olfactory CS during each daily sessions. All testing sessions were conducted under a food-satiated condition. All experimental sessions were carried out during the light portion of the cycle between 11:00 a.m. and 1:00 p.m. All procedures involving animals and their care conformed to the institutional guidelines, which comply with international laws and policies (directive 2010/63/European Community). Permission references were 69–387517 for BF and 69387 0202 for PV. After completion of the last behavioral testing, the brain of all implanted rats was subject to histological analysis in order to confirm correct location of the canula track placement.

Dictionary of Terms

- Fasting - Physiological state induced by giving an exact amount of food only once a day in order to keep the animals at 90% of their initial weigh.
- **Conditioned odor aversion learning** – Results from an association between an olfactory stimulus (usually odorized water intake) and an aversive unconditioned stimulus (usually a gastric malaise induced by an intraperitoneal injection of lithium chloride). Conditioned odor aversion can only be acquired if the time interval between the presentation of the olfactory stimulus from the gastric malaise is kept under 30 min, suggesting that the memory trace of the olfactory stimulus is subject to gradual decay over time.
- **Food conditioned learning** – Results from three successive processes. The acquisition during which the conditioned stimulus is associated with the unconditioned stimulus; the consolidation during which the conditioned stimulus – unconditioned stimulus association in memorized and the retrieval during which the presentation of the conditioned stimulus induces the recovery of the previously acquired association and elicits an aversive response.
- Unconditioned stimulus - Stimulus that elicits an unconditioned response. Presented in association with a conditioned stimulus, it can be positive (a food reward) or aversive (a gastric malaise, an electric footshock. . .).
- **Microinfusion** – This technique is used for a reversible and discrete manipulation of a particular structure in the brain in order to test its implication in a specific learning or/and memory process.

Summary Points

- Fasting enhanced odor detection in rats, whereas satiety reduced detection of odors.
- Central nervous system regulates food-search behavior by modulating the detection threshold of the food odorant items through centrifugal innervations.

- Feeding status modulates olfactory sensitivity through central orexin system activation.
- Fasting as well as central orexin system activation enhances olfactory memory during conditioned odor aversion learning.
- Our data suggest that fasting modulates olfactory memory through direct and/or indirect activation of particular orexin brain targets.

Abstract

An attempt is made, herein, to reconcile, and integrate, the various phenomena associated with magnesium deficiency and etiology of various cardiovascular disorders, including atherogenesis and systemic inflammation, particularly as it pertains to the aging population. A number of human and ongoing experimental studies are reviewed, which appear to indicate that magnesium deficiency is overlooked by the medical and civilian communities, and is, actually, of world-wide, epidemic proportions and growing. We show, through various human and animal studies, the roles of a dysfunctional microcirculation in development of systemic inflammation and atherogenesis and their relationships to generation of sphingolipids, platelet-activating factor, and reactive oxygen species. We also review the significance of measuring serum, plasma, and whole blood levels of ionized Mg in human subjects and patients suspected of Mg-deficient states. This review also brings the reader's attention to the critical importance of telomeres and telomerase in the aging process and Mg deficiency. Various molecular pathways which underlie the cardiovascular pathophysiological changes in Mg deficiency are presented and discussed. Finally, we discuss the utility of supplementing drinking waters with Mg^{2+} to improve the longevity of the aged and the quality of life.

4-HNE	4-Hydroxy-2-nonenal
8-OH-dG	8-Hydroxydeoxyguanosine
Ca^{2+}	Free ionic calcium
CS	Ceramide synthase
CV	Cardiovascular
CVS	Cardiovascular system
DAG	Diacylglycerol
H_2O_2	Hydrogen peroxide
IHD	Ischemic heart disease
IL	Interleukin
LDL	Low-density lipoprotein
MgD	Magnesium deficiency
NF-kB	Nuclear factor-kappa B
NMRS	Nuclear magnetic resonance spectroscopy
N-SMAse	Neutral sphingomyelinase
PAF	Platelet-activating factor
PC	Phosphatidylcholine
RNS	Reactive nitrogen species
ROS	Reactive oxygen species
SCD	Sudden cardiac death
SM	Sphingomyelin
SMAses	Sphingomyelinases
SMS	Sphingomyelin synthase
SPT	Serine palmitoyl-CoA transferase
TNF-alpha	Tumor necrosis factor-alpha
VSM	Vascular smooth muscle

Introduction

Over the past 100-plus years, a great deal of scientific evidence has accumulated, from numerous sources, that multiple, diverse control mechanisms, including physiological, biochemical, nutritional, and epigenetic factors, are responsible for the normal functions of the cardiovascular system (CVS) and in the aging process. These diverse homeostatic factors maintain the patency of blood vessels, cardiac output, and the fluidity of the blood. Numerous pathophysiological processes in peripheral blood vessels and the chambers of the heart can result in alterations of vascular wall geometry, disturbances in oxygenation, and the nutritional status of the blood vessels and myocardium as well as the tissues they perfuse.

Although multiple theories and hypotheses have been generated to account for the hypertrophy of resistance blood vessels (i.e., arterioles, metarterioles, and small arteries) in the etiology of the aging process, atherogenesis, inflammation, essential hypertension, and cardiac failure, there is no agreement as to the precise (controlling) mechanisms.

Disturbances in diet are known to promote lipid deposition and inflammatory responses and accelerate the growth and transformation of smooth muscle cells in the vascular walls, promoting cardiac dysfunctions (Kumar et al. 2015). Interestingly, autopsies of young children (e.g., as early as 5–6 years of age), who have died as a consequence of accidents, have often demonstrated early signs of atherogenesis (i.e., fatty streaks) on aortic and carotid arterial blood vessel walls (Seelig 1980). By the time humans reach 70–80 years of age, many blood vessels (particularly arteries in the heart and brain) become more rigid with increased levels of calcium (Ca^{2+}) and fibrin deposits, vast numbers of lipid deposits with plaques on the inner walls, inflammatory lesions, and concomitant rises in arterial blood pressure and progressive lowering of cardiac output. Although numerous studies have been brought forth, over the past 100 years, precise reasons for these pathophysiological alterations remain nebulous (Majno and Joris 2004; Kumar et al. 2015).

Several epidemiological studies in North America, the UK, and Europe have shown that people consuming Western-type diets are low in magnesium (Mg) content (i.e., <30–50% of the RDA for Mg) (Altura and Altura 1984b, 1985, 1990, 1995b, 2007; Ford and Mokdad 2003; Mosfegh et al. 2009). Many of these Western-type diets, in the USA, demonstrate that 60–80% of Americans are consuming only 185–235 mg of Mg/day. Low Mg content of drinking water, found in areas of soft-water and Mg-poor soil, is associated with high incidences of ischemic heart disease (IHD), coronary vasospasm, hypertension, and sudden cardiac death (SCD) (Crawford and Crawford 1967; Marier 1978; Chipperfield and Chipperfield 1979; Turlapaty and Altura 1980; Altura et al. 1984, 1992b, c; Altura and Altura 1985, 1995b, c, d, e, 1996a, 1997b, 2007; Leary 1986; Marx and Neutra 1997). The myocardial level of Mg has consistently been observed to be lower in subjects dying from IHD and SCD in soft-water areas than those subjects living in hard-water areas (Crawford and Crawford 1967; Altura 1979; Turlapaty and Altura 1980; Leary 1986; Altura and Altura 1995a, 2007; Marx and Neutra 1997). Both animal and human studies have shown an inverse relationship between dietary intake of Mg and atherosclerosis (Turlapaty and Altura 1980; Altura and Altura 1995b, 2007; BT Altura et al. 1990a; Song et al. 2005; King et al. 2009).

Mg plays an essential role in more than 500 enzymatic reactions in the body and is required for all energy-generating reactions and oxidative phosphorylation (Altura and Altura 1984c; Altura et al. 2016a; de Baaj et al. 2015; Hartwig 2001). Mg is a natural Ca^{2+} channel blocker on myocardial and vascular smooth muscle (VSM) (Altura et al. 1981, 1997a, 1998; Turlapaty and Altura 1978; Altura and Altura 1974, 1981a, b; Zhang et al. 1992; Yang et al. 2000a). Mg can be termed a natural statin in that it lowers blood cholesterol, LDL, and triglycerides as well as acts like a peripheral vasodilator agent (Altura and Altura 1974, 1995b; Turlapaty and Altura 1980; Altura et al. 2009; Nishio et al. 1988). Hypermagnesemic diets have been shown to ameliorate hypertension and atherogenesis (Altura and Altura 1984b, c, 1985, 1994, 1995e, 1997b; BT Altura et al. 1990a; dean 2017; Ravin et al. 2001; Altura et al. 2003a; Maier 2012; Saris et al. 2000).

Using sensitive, newly designed Mg^{2+}-selective electrodes, it has been shown that patients with hypertension, IHD, cardiac failure, diabetes, gestational diabetes, renal-induced vascular damage, atherosclerosis, vascular-related headaches, and strokes

exhibit significant depletion of serum/plasma and whole blood-ionized, but not total, Mg levels (Altura 1994; Altura and Altura 1991, 1994, 1995a, b; BT Altura and Altura 1992, 1994b; Handwerker et al. 1993; Markell et al. 1993a, b; Resnick et al. 1993, 1997; Altura et al. 1992c; Mauskop et al. 1995a, b; BT Altura et al. 1992b, c, 1994a, b, c, d, 1997b, c; Yang et al. 2000a, b, c; Bardicef et al. 1995). In this context, dietary deficiency of Mg has been demonstrated, in rats, rabbits, and people to provoke vascular remodeling concomitant with hypertension, inflammation, and atherosclerosis (i.e., arteriolar wall hypertrophy and alterations in the matrices) (Altura and Altura 1981c, 1984b, 1995a, b, d, e, 1996; Altura et al. 1984, 1992b, c, 1993b, 1994a, b, c, 1996, 2003b, 2016a; BT Altura et al. 1990, 2016a, 2017a; King et al. 2009). Moreover, a few years ago, dietary deficiency of Mg^{2+} had been demonstrated to cause an acceleration of the aging process by unknown mechanisms (Killilea and Ames 2008).

Aging is now agreed to be critical in the etiology of metabolic decline in most human subjects as they close in on their 65th–70th birthdays. Many subjects at these ages show signs of metabolic decline, atherosclerosis, high blood pressure, renal failure, liver failure, endothelial cell dysfunctions, CV diseases, and often type 2 diabetes mellitus, which eventually contribute to IHD, congestive heart failure, and SCD by their 75th–85th birthdays. It is important, here, to point out, to the reader, that all of these attributes/characteristics have been associated with the presence of Mg-deficient states in both humans and experimental animals (Altura and Altura 1980, 1983; Altura 1979; Altura and Altura 1981c, 1984c, 1992a, 1995a, b, 1996a, b, 1997a, b, 2016a, c, e; Markell et al. 1993a, b; Wu et al. 1991, 1994; BT Altura et al. 1994, 1997a, b; Handwerker et al. 1993; Rayssiguier et al. 1993; Resnick et al. 1993, 1997; Scott et al. 1996; Schecter et al. 2000; Djurhuus et al. 1999; Maier 2012; Mazur et al. 2007; de Baaj et al. 2015). The aging process is also associated with an increase in the levels of proinflammatory cytokines in tissues and cells as well as oxidation of tissues, cells, and cell membranes (both external and internal) (for recent reviews, see Malavolta and Mocchegiani 2016). Due to the presence of increasing serum and tissue levels of proinflammatory cytokines with increased years, it has been stated that aging is an inflammatory disease (for recent reviews, see Malavolta and Mocchegiani 2016). It is, thus, of considerable interest to note, here, that recent findings in Mg-deficient animals and tissues, as well as cells and membranes of these animals, exhibit elevated levels of the proinflammatory cytokines and chemokines such as IL-1a, IL-1b, IL-6, TNF-alpha, and diverse macrophage factors, among others (Malpeuch-Brugere et al. 2000; Altura et al. 2003a, b, 2012, 2014, 2016a, b, d, 2017a; King et al. 2005; Mazur et al. 2007; Weglicki 2012; Shah et al. 2014). Of these cytokines and chemokines, TNF-alpha is known to be associated negatively with telomerase activities in several cell types in the aging process (Matsutomi et al. 2003; Wong and Collins 2003; Dong et al. 2005; Fleisig and Wong 2012; Lin et al. 2012; Hockemeyer and Collins 2015). In view of such a constellation of findings and reports, our laboratories, approximately 30 years ago, wondered whether there might be a central metabolic pathway(s) that might be activated or set into motion by Mg deficiency, which could play a major role(s) in the aging process and lead to declines in CV functions resulting in atherogenesis, systemic inflammatory diseases, cardiac failure, IHD, and SCD.

Using proton nuclear magnetic resonance spectroscopy (^{1}H-NMRS) and phosphorus-31 nuclear magnetic resonance spectroscopy (^{31}P-NMRS), it has been reported (almost 20 years ago) that low-Mg^{2+} environments ($[Mg^{2+}]_0$) resulted in causing sustained changes in membrane phospholipids and several second messengers (including DAG), as well as the activation of apoptotic pathways, membrane oxidation, membrane lipid peroxidation, and truncation of membrane fatty acids (Morrill et al. 1997, 1998; Altura et al. 2009). Decreases in $[Mg^{2+}]_0$ resulted in a fall in membrane sphingomyelin (SM) and phosphatidylcholine (PC) (Morrill et al. 1997); intracellular ceramide formation and activation of neutral sphingomyelinase (N-SMAse) were found to be inversely proportional to Mg^{2+} (Morrill et al. 1998). Ceramides, either released or generated as a consequence of neutral and acid sphingomyelinases (SMAses) acting on SM or synthesized de novo, are now known to play important, critical roles in fundamental life processes such as angiogenesis, cell proliferation, immunoinflammatory responses, atherogenesis, programmed cell death, and the aging process (Dbalbo et al. 1998; Andrieu-Abadie et al. 2001; Birbes et al. 2001; Altura et al. 2002, 2016a; Hannun and Obeid 2017; Merrill 2002; Crivello et al. 2005; Panjarian et al. 2008; Hage-Sleiman et al. 2013). Recent reports indicate that Mg deficiency (MgD) can induce upregulation of all major enzymes needed for cellular synthesis of ceramides in intact cardiac tissues and VSM cells (Morrill et al. 1997, 1998; Altura et al. 2009, 2010a, b, 2012, 2014, 2016a; Shah et al. 2011, 2014). The de novo synthesis of ceramide is brought about via the action of serine palmitoyl-CoA transferase (SPT), 3-ketosphinganine reductase, ceramide synthase (CS), dihydroceramide desaturase, and SM synthase (SMS) (Merrill 2002; Hanada 2003; Hannun and Obeid 2017). Variation of $[Mg^{2+}]_0$ was shown to control the cellular levels of SM, PC, DAG, sphingosine, and ceramide in all types of CV tissues and cells by our group. It is now known that low $[Mg^{2+}]_0$ can produce cellular synthesis and release of ceramide in CV tissues and cells via upregulation of SPT 1 and SPT 2, CS, and SMS synthase as well as via what has been termed "a salvage pathway" (Altura et al. 2010a, b, 2012, 2014; Shah et al. 2011, 2014). Since ceramides play key roles in programmed cell death (e.g., apoptosis, necroptosis, ferroptosis) in cardiac and VSM cells, these findings are probably quite important in the aging process, particularly as programmed cell death is now known to be a sine qua non of senescence (for reviews, see D'Antona 2016; Malavolta and Mocchegiani 2016). In the normal aging process, telomeres are critical in regulating genome integrity and hence chromosomal integrity (Matsutomi et al. 2003; Wong and Collins 2003; Dong et al. 2005; Fleisig and Wong 2012; Tollervey and Lunyak 2012; Lin et al. 2012).

Below, recent findings are reviewed which lead one to believe that unrecognized MgD is a major underlying, unrecognized reason for why and how dietary deficiency of Mg is causing diverse CV diseases, atherosclerosis, IHD, cardiac failure, and premature aging which, unless recognized and treated, will result in premature death of millions of people.

Dysfunction of the Microcirculation in Developing Systemic Inflammation and Atherogenesis During Mg-Deficient States: Relation to Sphingolipids

Twenty years ago, Ross and colleagues advanced the hypothesis that atherosclerosis is an inflammatory disease brought about by injury to the endothelial surfaces of blood vessels in the macro- and microcirculations (see Ross 1999, for summary of hypothesis). Ross's hypothesis stated that different forms of injury will result in numerous dysfunctions in the homeostatic properties of the endothelium, e.g., an increase in the adhesiveness of leukocytes and/or platelets, alterations in the procoagulant properties, formation/release of cytokines/chemokines, and release of multiple growth factors. Much of Ross's injury hypothesis is actually derived from prescient lectures Rudolph Virchow enunciated in 1858 (Virchow 1858). Inflammation is usually defined as a response of microcirculatory blood vessels and the tissues they perfuse to infections and damaged tissues, which bring cells and host-defense molecules directly from the circulation to all the diverse sites where they are required to eliminate/degrade the offending agent(s) and initiate repair processes (for reviews, see Majno and Joris 2004; Kumar et al. 2015). The major mediators of these defense mechanisms include white blood cells, phagocytic leukocytes, antibodies, chemokines, and complement proteins. Most of these cells and protein molecules are recruited when needed from the circulating blood itself. The inflammatory process brings these cells and molecules to the damaged or necrotic tissues. The absence of the inflammatory process would allow infections to continue unchecked, prevent wounds from healing, and result in festering sores/wounds. A typical inflammatory process develops in a sequential manner: recognition of the offending agent(s) by host cells and molecules, recruitment of leukocytes and plasma proteins (e.g., antibodies, complement fractions), activation of the leukocytes and plasma proteins to destroy and eliminate all offending substances, control and termination of the reaction(s), and finally repair of the damaged tissue(s). During the normal inflammatory process, leukocytes migrate across the venous capillary walls through the endothelium due to increases in permeability and move to the site(s) of injury via chemotaxis. The normal mediators for this process to take place are adhesion molecules, Ca^{2+}, cytokines and chemokines, and more recently sphingolipids like ceramide. Interestingly, all of these mediators are needed for atherogenesis and are released in increasing concentrations in MgD (Altura and Altura 1995e, 2007, 2016b, Altura et al. 2003a, b, 2010b, 2012, 2014, 2016a, b, c; Maier 2012; King et al. 2005; Shah et al. 2011, 2014; Weglicki 2012).

If, however, the inflammatory response is not curtailed, or effectively neutralized, the inflammatory response will go on and stimulate migration and proliferation of VSM cells and protein components to initiate and form an intermediate lesion (i.e., the beginning of the atherosclerotic process). Moreover, if these processes go on unabated, the arterial walls will thicken and initially dilate to compensate, to a point, and then undergo a remodeling process in which the normal contractile VSM cells are transformed into new

noncontractile, secretory phenotypes (Ross 1999; Majno and Joris 2004; Kumar et al. 2015). At every stage of this process, macrophages, monocytes, and T lymphocytes will be attracted to the arterial-endothelial walls. Activation of these cells results in the release of hydrolytic enzymes, cytokines, chemokines, Ca^{2+}, and numerous growth factors as stated above. These factors will sustain and perpetuate the atherogenic process forming, eventually, fibrous tissue and further enlargement of the lesion, which will overlie a core of lipid resulting in plaques and necrotic tissue. MgD states have been shown by our group, and others, to result in a release of numerous enzymes (seen in the atherogenic process), cytokines, chemokines, and growth factors involved in the early stages of the atherosclerotic process exhibiting lesions and plaques on the inner endothelial surfaces (BT Altura et al. 1990; Mazur et al. 2007; Altura et al. 2012, 2014; Maier 2012; Weglicki 2012). In developing atherosclerosis, each plaque has a cap that retains cholesterol, and inflammations inside the cap can dissolve the fibers, but, suddenly, the cap ruptures, spilling cholesterol into the insides of the arteries which can promptly cause clots that can completely block the flow of blood into the microcirculation of the surrounding tissues causing permanent tissue damage and necrosis. It is now known that ceramides and other sphingolipids (e.g., sphingosine and sphingosine-1-phosphate) are found in MgD-induced atherogenic lesions in the arterial walls of rabbits (Altura and Altura 1995a, 2016, unpublished findings). Moreover, using high-magnification, in situ video microscopy (up to 6,500x normal) of the splanchnic, cerebral, and skeletal muscle microvasculatures, it has been demonstrated that ceramides and other sphingolipids cause alterations in postcapillary venular permeability, loss of venular tone, vasospasm, and transudation of leukocytes, monocytes, and T lymphocytes across these microvascular walls into the surrounding perivascular tissue spaces, representing inflammatory reactions (Altura et al. 2002, 2016a, unpublished findings). It has also been noted that similar pathophysiological events have been shown in splanchnic and skeletal muscle microvasculatures in MgD rabbits exhibiting atherosclerotic lesions (Altura et al. 2016a, unpublished findings). Moreover, it has been reported that MgD leads to an upregulation of N-SMAse and acid SMAse, resulting in increased serum and tissue levels of ceramide (Morrill et al. 1998; Altura et al. 2012, 2014; Shah et al. 2014, unpublished findings). We believe such findings, collectively, in rats and rabbits are more than coincidental and must perforce be considered, if found in humans, to be the forerunners of systemic inflammatory responses and initiation of a progressive decline in CV functions leading to atherosclerosis, hypertension, coronary artery diseases, IHD, and SCD. It follows, in our opinion, that this sequela of events takes place in aging people as they reach their 65th–70th years. The aging process, in people, is associated with an increase in the levels of proinflammatory substances in tissues and cells, similar to those we found in the MgD animals. Are these changes found in MgD states correlated to telomere and telomerase activities?

Telomeres, Telomerases, DNA Damage/Fragmentation, Oxidative Stress, Cell Death, and Mg

Telomeric DNAs are highly conserved molecules among all eukaryocytes (Wong and Collins 2003; Fleisig and Wong 2012; Lin et al. 2012). Telomeres are found at the ends of the chromosomes, consisting of short nucleotide repeats and specialized proteins, which are regulated by telomerases (Wong and Collins 2003; Fleisig and Wong 2012; Lin et al. 2012). Chromosomes devoid of telomeres or low telomerase activity usually undergo apoptosis or necroptosis, or both (Matsutomi et al. 2003; Wong and Collins 2003; Dong et al. 2005). Thus, cells with normal telomerase activities are thought to survive periods of oxidative and peroxidative stress (e.g., production of reactive oxygen and nitrogen species) and curtail apoptosis, necroptosis, and the aging process (Matsutomi et al. 2003; Wong and Collins 2003; Dong et al. 2005; Fleisig and Wong 2012; Lin et al. 2012; Hockemeyer and Collins 2015). It should be noted, here, that normal amounts of telomerases in all cell types are required to promote efficient cell cycle kinetics and normal cell growth (Matsutomi et al. 2003; Dong et al. 2005; Hockemeyer and Collins 2015).

MgD is well-known to promote disturbances in cell cycle kinetics (Rubin 1982; Walker 1986; Vernon 1988) via reactive oxygen (ROS) and reactive nitrogen species (RNS), most likely acting to downregulate telomerases) (Shah et al. 2014). A number of studies have recently reported distinct relationships between certain dietary markers and telomere length (for review, see Lin et al. 2012). It has recently been shown that MgD states, both in vivo and in vitro, promote oxidative stress and membrane lipid peroxidation, DNA damage/fragmentation, elevated cellular levels of Ca^{2+}, dysfunction of cardiac bioenergetics, upregulation and accumulation of the tumor suppressor protein p53, upregulation of multiple enzymes which regulate sphingolipid metabolism, accumulation of ceramides, cell death regulation (i.e., apoptosis, necroptosis, ferroptosis), and downregulation of telomerases (Altura et al. 2009, 2010a, b, 2012, 2014, 2016a, b, 2017a, b; Shah et al. 2011, 2014). Recent studies of short-term MgD, and with single VSM cells, in primary culture exposed to low Mg^{2+}, seem to indicate that ceramide and p53 act in concert to downregulate telomerase (Shah et al. 2014). In addition, it has been shown that increased MgD in experimental animals results in increasing levels of multiple cytokines (i.e., IL-1a, IL-1b, IL-2, Il-4, IL-6, IL-10, IL-12, and IL-16, among others) as well as diverse chemokines in blood, all four chambers of the heart, peripheral blood vessels (e.g., aorta, carotid arteries, coronary arteries), and cerebral blood vessels (e.g., cerebral artery, middle cerebral arteries) (Altura et al. 2012, 2014, unpublished findings). Clearly, these increasing levels of cytokines and chemokines, with increasing MgD, could be considered forerunners of the aging process, particularly as it is known that MgD causes concomitant increases in blood pressure, coronary and cerebral arterial and arteriolar vasospasm, vasospasms of umbilical-placental blood vessels, decreases in microcirculatory blood flows, increased levels of Ca^{2+} in both VSM cells and cardiac myocytes, decreased cardiac output, and decreased cardiac contractility (1981, 1984; Altura and Altura 1971, 1974, 1978, 1981a, 1984b, 1987, 1996, 2007;

Altura and Altura 1982; Turlapaty and Altura 1980; Altura et al. 1984, 1987, 1992, 1996, 1997c, 2003a, b, 2016a; Wu et al. 1994; Yang et al. 2000a, b, c; Shah et al. 2014). Measurement of the levels of the five major enzymes responsible for hydrolysis of SM and de novo synthesis and release of ceramide (reviewed above) was found in these CV tissues to be inversely proportional to the concentrations of Mg^{2+} in the blood (Altura et al. 2010a, b, 2012, 2014, 2016a; Shah et al. 2011, 2014). In this context, it must be pointed out that the aging populations in both North America and Europe demonstrate decreasing dietary intakes of Mg/day, often decreasing below 150 mg of Mg/day. Could these rising levels of cytokines, chemokines, and ceramide, observed in MgD states, be causally related to the decline in CV functions and onset of CV diseases in the aging process?

Recently, it has been demonstrated in animals, subjected to mild MgD for 21 days, that telomerase levels are downregulated and coupled to fragmentation and oxidation of DNA as well as to increased levels of the tumor suppressor gene, p53 (Altura et al. 2010; Shah et al. 2014). Regression analyses indicated extremely high degrees of correlation (i.e., $r > 0.94$; $P < 0.001$). Such data supports the idea that MgD could lead to multiple mutations in the genomes of multiple cell types found in the initiation of systemic inflammatory lesions, atherogenesis, congestive heart failure, IHD, and SCD. P53 is known to play an important role not only as a tumor suppressor but in promoting survival of numerous cell types under stresses as seen in developing atherosclerotic plaques and alterations in the phenotypes of vascular smooth muscle cells (Dbalbo et al. 1998; McDonald And Owens 2007; Mercer et al. 2007; Meek 2009). Previous studies from our group (Altura and Altura 2007; Altura et al. 2012, 2014, 2016; Shah et al. 2014), when viewed in the light of these findings, would lend additional support to the hypothesis that mutations and transformations of VSM cells, endothelial cells, and cardiac myocytes caused by MgD, fragmentation of DNA, and oxidation of DNA (all observed in atherogenesis, hypertension, strokes, and IHD) may play major roles in the aging process, thus leading to multiple CV changes, including inflammations of the vascular and cardiac walls (see above), high blood pressure (due to formed element changes, release of ceramides, release of cytokines and chemokines, excess arterial wall lipid depositions and peroxidation, etc.), cardiac dysfunctions, and eventual cardiac failure. We believe this constellation of pathophysiological effects of MgD is consistent with "genotoxic effects" of MgD we suggested several years ago.

Genotoxic Effects of MgD: Effects on NF-kB and Proto-Oncogenes

Approximately two decades ago, using experimental animals (i.e., rats, dogs, and subhuman primates), it was reported that short-term MgD, by itself, produced in intact CV tissues and VSM cells (in primary culture) what could be considered genotoxic effects of low dietary Mg intake, as internal and external cellular membranes became oxidized with DNA fragmentation, and the cells demonstrated lipid peroxidation with formation of ROS (e.g., H_2O_2, hydroxyl radicals, ferrylmyoglobin, and superoxide, among others) and RNS species (e.g., NO, peroxynitrite), activation

of nuclear factor-kB (NF-kB), and proto-oncogenes, along with alterations in the nucleus and nucleolus of the CV cells (Wu et al. 1994; Altura and Altura 1996a; Morrill et al. 1997, 1998; Altura et al. 1993a, b, 2001, 2003a, b, 2010, 2012; Shah et al. 2011). In these studies, it was found that the major enzymes needed to produce many of these ROS and RNS substances, namely, NADPH oxidases, nitric oxide synthases, and xanthine oxidase, were all upregulated in CV tissues and cells from animals exposed to MgD diets. More recently, it was found that CV tissues and cells, excised from rats placed on 21 days of MgD diets, exhibited five- to tenfold increases in both 8-hydroxydeoxyguanosine (a marker of specific DNA oxidation) and 4-hydroxy-2-nonenal (4-HNE) in VSM cells and cardiac myocytes (Shah et al. 2014; Altura et al. 2016a), the latter being a well-known inducer of hydrogen peroxide and DNA methylation (Mikhed et al. 2015; Luczaj et al. 2017). Such data supports the idea that the progressive downregulation of telomerases, noted above, when coupled to these cellular and molecular findings and the upregulation of p53 (Altura et al. 2010) provide impetus for the hypothesis that MgD could lead to multiple mutations in the genomes of multiple cell types and thus be a prelude for premature aging. Previous findings on atherogenesis in MgD (BT Altura et al. 1990), when viewed in light of the latter, would lend support to the concept that mutations and transformations of VSM, endothelial, and cardiac myocyte cells caused by formation of ceramides, ROS, and RNS most likely play major roles in systemic inflammatory lesions, atherosclerosis, aging, IHD, and SCD (Altura et al. 2016a).

The findings of upregulation of NF-kB and several proto-oncogenes (i.e., c-Fos and c-Jun) in MgD states (Altura et al. 2003a, b, 2012, 2014; Shah et al. 2014) are very important for our hypothesis as these molecules are two major regulators of growth, differentiation, cell migration, and programmed cell death (e.g., apoptosis, necroptosis, ferroptosis) (for reviews, see Kumar et al. 2015; Moriwaki and Chan 2016; Serasanambati and Chilakapti 2016). NF-kB is a transcription factor and a pleiotrophic regulator of numerous genes involved in hypertension, inflammatory responses, atherogenesis, and aging (for reviews, see Barnes and Karin 1997; Hayden and Ghosh 2011). Both NF-kB and proto-oncogenes are thought to be critical in numerous vascular disease processes such as inflammation, cell transformations, and cell migration. However, it has not been clear as to how or what factor(s) initiates these molecules to be activated under diverse circumstances. Experimental findings, based on intact animals and primary cell cultures, have shown that either inhibition of NF-kB activation or inhibition of ceramide release and its de novo formation prevent a whole sequelae of events which would normally lead to downregulation of telomerases, oxidation, peroxidation, formation of 8-OH-dG, formation of 4-HNE, apoptosis, and activation of p53 (Altura et al. 2010, 2012, 2014, 2016a, 2017a). Although it has not, as yet, been determined whether inhibition of ceramide formation/release or inhibition of NF-kB activation will prevent MgD-induced atherogenesis or systemic inflammatory conditions, in intact animals, preliminary studies on intact rabbits appear to yield promising results so far. Recent in vivo and in vitro investigations, in our laboratories, seem to indicate that another important factor in MgD, aging, and vascular diseases, may have been overlooked until now.

Potential Roles of Platelet-Activating Factor (PAF)

A little more than 20 years ago, using ^{1}H-NMRS, on single VSM cells and excised canine and rat aortic, coronary, and cerebral arterial vessels, it was reported that a fairly rapid synthesis of PAF was observed when the cells and tissues were exposed to low $[Mg^{2+}]_0$ (unpublished findings, 1995). In addition, the spectra suggested that Mg^{2+}-deficient environments led to very rapid formation of PAF and PAF-like lipids (Morrill et al. 1997). PAF is manufactured from a specific subclass of phosphatidylcholines which contain an ether, instead of an ester, bond at the *sn-1* position of the glycerol backbone. This phospholipid is a minor part of low-density lipoprotein (LDL), which we and others have found to be elevated in blood and tissues of magnesium-deficient animals and human subjects who demonstrate lowered levels of serum-ionized Mg (Rayssiguier et al. 1993; BT Altura et al. 1990; Altura et al. 2009, unpublished findings). LDL is a major component in blood cells, such as leukocytes, and, along with ox-LDL, is a major pro-atherogenic substance (Ross 1999). A polyunsaturated fatty acid such as arachidonate is found in the *sn-2* position in the subclass of phosphatidylcholine molecules, and hydrolysis of this precursor phospholipid forms arachidonate for eicosanoid synthesis (Fruwirth et al. 2007). Acetylation of the other reaction product, viz., alkyl-lysophosphatidylcholine, along with acetyl-CoA finalizes the synthesis of PAF, both enzymes being tightly regulated (Fruwirth et al. 2007). It is important to note, here, that because the precursors of PAF contain polysaturated fatty acids, they are very susceptible to oxidative attack, often resulting in a number of structural products that resemble PAF (i.e., PAF-like lipids) (Fruwirth et al. 2007). It is now known that lowering $[Mg^{2+}]_0$ in primary cells results in changes in phosphatidylcholine levels and production of several PAF-like molecules (Morrill et al. 1997), most of which can act directly on G1-coupled PAF receptors (Fruwirth et al. 2007; Zimmerman et al. 2002). Using VSM cells in primary culture, Altura and colleagues recently found that the rapid rises in PAF and PAF-like lipids noted on lowering $[Mg^{2+}]_0$ could either be inhibited or ameliorated when specific PAF inhibitors were employed along with the cultured VSM cells (Altura et al. 2016a). It was also noted that formation of ceramides along with PAF formation, as well as activation of NF-kB, proto-oncogenes (i.e., c-Fos, c-Jun), and p53, in concert with oxidation and peroxidation of the VSM membranes was greatly attenuated (Altura et al. 2016a). DNA damage/fragmentation was also attenuated by incubation of the MgD cells with specific PAF-receptor blockers (unpublished findings). These new findings, collectively, point to an important role of PAF and PAF-like lipids in the sequelae of events noted in MgD states. We believe these new findings may also have direct bearing on the decline in functions of the CV system in aging, thus probably being a major factor in the systemic inflammatory and atherogenic states normally observed in aged individuals.

Microvascular Remodeling, DNA Damage, Epigenetics, and Telomerase

From the above, it should become clear that the microcirculation, during the aging process, must undergo numerous structural remodeling modifications. For example, close examination of the various bodily microvasculatures demonstrates the following: stiffening of arteries and arterioles, decreases in peripheral blood flows, alterations in vascular permeability of the microvessels (particularly the postcapillary venules), alterations in reactivity of the microvessels to circulating and released vasoactive substances (including sphingolipids and PAF), vasodilation and vasoconstriction of arterioles and metarterioles, modulation of cellular cytoskeletal properties of the arterial and arteriolar walls, proliferation of various cells in the arterial and arteriolar walls, migration, and finally death of many of the VSM cells or their transformation into secretory and foamlike cells (Majno and Joris 2004; Staiculescu et al. 2014; Kumar et al. 2015). Extensive ongoing, in vivo and in vitro studies, using diverse VSM and endothelial cells, indicate that progressive MgD results in progressive vasospasm of arterial and arteriolar vessels via a number of molecular signaling pathways, including activation of mitogen-activated protein kinases, activation of tyrosine protein kinases, activation of P-I-3 kinases, membrane entry and intracellular release of Ca^{2+}, formation/release of diverse vasoactive ROS and RNS molecules (see below), and activation of diverse PKC isozymes (Altura 1981, 1984, 1987; Altura and Altura 1971, 1974, 1978, 1984a, b, 1995d, e, 1996b, 2007; Altura et al. 1987, 1992c, 1993b, 1997c, 2001, 2003a, b, 2014; BT Altura and Altura 1984c, 1987; Li et al. 2007; Morrill et al. 1997, 1998; Shah et al. 2011; Turlapaty and Altura 1978, 1980a; Turlapaty et al. 1988; Yang et al. 2000a, b, c; Zhang et al. 1992, 1993; Zheng et al. 2000, 2011). The reader should consult these latter references for how MgD activates these pathways in VSM and endothelial cells.

It should be recalled, here, that atherosclerotic plaques in the vascular walls of hypertensive human subjects demonstrate considerable DNA damage, activation of DNA repair pathways, increased expression of proto-oncogenes, activation of NF-kB, increased expression of p53, increased expression of PAF, oxidation of DNA, lipid peroxidation, apoptosis, and necroptosis (Lee and Blair 2001; Fruwirth et al. 2007; McDonald and Owens, 2007; Jackson and Bartek 2009; Gray et al. 2015; Razani and Raines 2015). In this context, we have found all of these pathobiological alterations in MgD experimental animals (see above). We do not believe this is a "mere" coincidence. Experimentally, MgD results in accelerated atherosclerotic plaques in rabbit and mouse arterial walls (BT Altura et al. 1990a; Ravin et al. 2001), which have been associated with increased levels of p53 (Altura et al. 2010b) and PAF (Fruwirth et al. 2007; Montrucchio et al. 2000; Altura et al. 2016a) in the thickened atherosclerotic plaques along with decreased levels of telomerase (Altura et al. 2016a, unpublished findings). We, thus, hypothesize that MgD states must perforce play key roles in the generation of atherosclerotic plaques, coronary arterial diseases, hypertension, and IHD via the upregulation of N-SMAses, acid SMAses,

ceramide synthase, PAF generation, and ceramide production as well as down-regulation of telomerases, particularly as the majority of individuals who consume Western-type diets have 45–75% shortfalls in daily Mg intake. All of the foregoing events could be expected to be accelerated in the aging population, particularly in old age and in nursing homes where the daily intakes of Mg often approach deficits near 80–90% (Seelig 1980; Barbagallo et al. 2009).

Various bodily modifications take place daily and over various periods of time via epigenetics (Mikhed et al. 2015; Chatterjee and Eccles 2015). Epigenetic modifications are chromatin-based modifications that alter expression of genes without altering the DNA sequence itself (Tollervey and Lunyak 2012; Ghavifekr et al. 2013; Chatterjee and Eccles 2015; Mikhed et al. 2015). The most common epigenetic modifications include methylation of DNA, translational modification of histone protein, and RNA-induced mechanisms (i.e., micro-RNA and long noncoding RNA) (Tollervey and Lunyak 2012; Ghavifekr et al. 2013; Mikhed et al. 2015). These biochemical and molecular events can modulate the tertiary structure and, therefore, the accessibility of promoter DNAs or encoding transcription factors and numerous regulatory molecules that, in the end, finally alter transcription (Tollervey and Lunyak 2012; Ghavifekr et al. 2013; Chatterjee and Eccles 2013; Mikhed et al. 2015). In these ways, epigenetic pathways become pivotal in the regulation of VSM, endothelial, and cardiac myocyte gene expressions. Alterations in gene expression, for example, would be expected to change a normal contractile VSM cell into a cell that becomes a synthetic, secretory machine for numerous factors needed for atherogenesis (i.e., cytokines, chemokines, growth factors, etc.). The normal contractile VSM cell would no longer function to control microvascular blood flows and their proper distribution into the coronary, cerebral, and peripheral microvascular beds (see above). Very recently, our laboratories have found supporting data for this hypothesis in MgD animals; VSM and cardiac muscle cells were found to demonstrate DNA modifications, including methylation, modification of histone proteins, and alterations in noncoding RNA (Altura et al. unpublished findings). We are now convinced that MgD states can alter transcription and determination of key proteins and lipids. Currently, our laboratories are setting up studies to determine whether aging patients exhibit similar alterations. But, what can be done to prevent or ameliorate such epigenetic modifications of tissues and cells?

Bioavailable Mg Intake and Prevention of Cardiovascular Diseases

Last, but not least, the foregoing results, collectively, bolster the idea, expressed previously, that water intake (e.g., from tap waters, well waters, bottled waters, beverages using tap/well/spring waters, or desalinated waters) in humans should contain at least 25–40 mg of Mg/liter (Altura et al. 2009, 2010a, b, 2012, 2014; Shah et al. 2011, 2014). The latter inclusion in our diets should go a long way toward the

prevention of CV diseases and ameliorate the aging process of bodily tissues and cells in humans worldwide. In 2009, the World Health Organization recommended guidelines of 25–40 mg/l of Mg^{2+} to be included in drinking waters for human consumption (Altura and Altura 2009).

Policies and Protocols

From the foregoing, it is becoming clear that there is a growing, worldwide epidemic of MgD, particularly among the aging. It is also becoming clear that most all CV diseases are likely due, at least in part, to MgD. We believe, due to the rapid advances in molecular biology and technology, the continued study of MgD states will yield invaluable information on how to increase life expectancy, awareness of better nutrition, as well as the quality of life. Continued investigation of the diverse molecular pathways which underlie the specific mechanisms of how MgD causes inflammation and atherogenesis should perforce produce exciting new ventures into the fields of molecular genetics and epigenetics. It is also apparent that drinking waters supplemented with Mg^{2+} will prove beneficial to the elderly, particularly to people living in nursing homes and to people living in nutritionally deprived countries, an area which should be focused on in future studies of MgD.

Summary Points

- Cardiovascular disorders, including atherogenesis and systemic inflammation, are particularly important to the aging population.
- Magnesium deficiency is overlooked by the medical and civilian communities and is, actually, of worldwide epidemic proportions and growing.

Other Points

Supplementing drinking waters with Mg^{2+} may improve the longevity of the aged and the quality of life.

Acknowledgments The authors appreciate the invaluable technical assistance of J.P. Liu, Krishnan D. Patel, A. Gebrewold, A. Zhang, T. Zheng, W. Li, C. Parillo, A. Carella, and T.S. Shah without whose outstanding help our studies could not have been carried out. Some of the original works reviewed in this chapter were supported, in part, by N.I.H. research grants to B.M. Altura and B.T. Altura. These included funding from the National Heart, Lung, and Blood Institute, the National Institute on Drug Abuse, the National Institute on Mental Health, and the National Institute on Alcoholism and Alcohol Abuse. Due to space limitations, the authors could not cite many publications. We apologize to those scientists and physicians that are not cited.

malnutrition is widespread. While severe child malnutrition in the form of kwashiorkor has become rare in most other developing countries, thousands for children in the DRC are suffering from this disease. Since its early description kwashiorkor among children has been related the consumption of a monotonous diet low in protein. It has also been postulated that kwashiorkor is caused by an excess in free radicals and that protective pathways are compromised in kwashiorkor with these pathways requiring micronutrients in the form of antioxidants. Kwashiorkor typically occurs in areas with severe food insecurity, and in the DRC food insecurity is especially prevalent in the rural areas. The national prevalence of children with edema in the DRC has been reported to be as high as 4% with the highest proportion of children with edema living in the rural areas. The diet in most areas of the DRC is monotonous. Cassava is the major and it is severed with different side dishes including cassava leaves. Animal products are consumed occasionally and wild food constitutes a safety net during periods of shortage. The relation between diet and kwashiorkor in children in the DRC has been investigated in historical longitudinal study. The diet in the study area is low in diversity and the major staples include cassava and maize. Children who did not develop kwashiorkor had consumed food items that were rich in β-carotene while those who did develop kwashiorkor had not.

Introduction

The Democratic Republic of Congo (DRC), a former Belgian colony, is located in central Africa. It has a population of 69 million (The World Bank 2013) and is thereby the fourth most populated country in Africa. It is divided into 26 provinces including the city province of Kinshasa (see Fig. 1 map). The DRC holds a wealth of natural resources including a diversity of mineral and forest resources (The World Bank 2013). It is classified as the 5th most biodiverse country on the earth (Termote et al. 2012). The country has an environment that is favorable to agriculture that in many areas allows for two harvests per year (Rossi et al. 2006). Despite its wealth in natural resources, DRC's population is among the poorest in the world. Based on its poor scores with regards to income and health, it is by Human Development Index ranked as the 176, out of 188, poorest countries in the world (UNDP 2015). There is a rural–urban gap in poverty disfavoring rural areas where eight out of ten

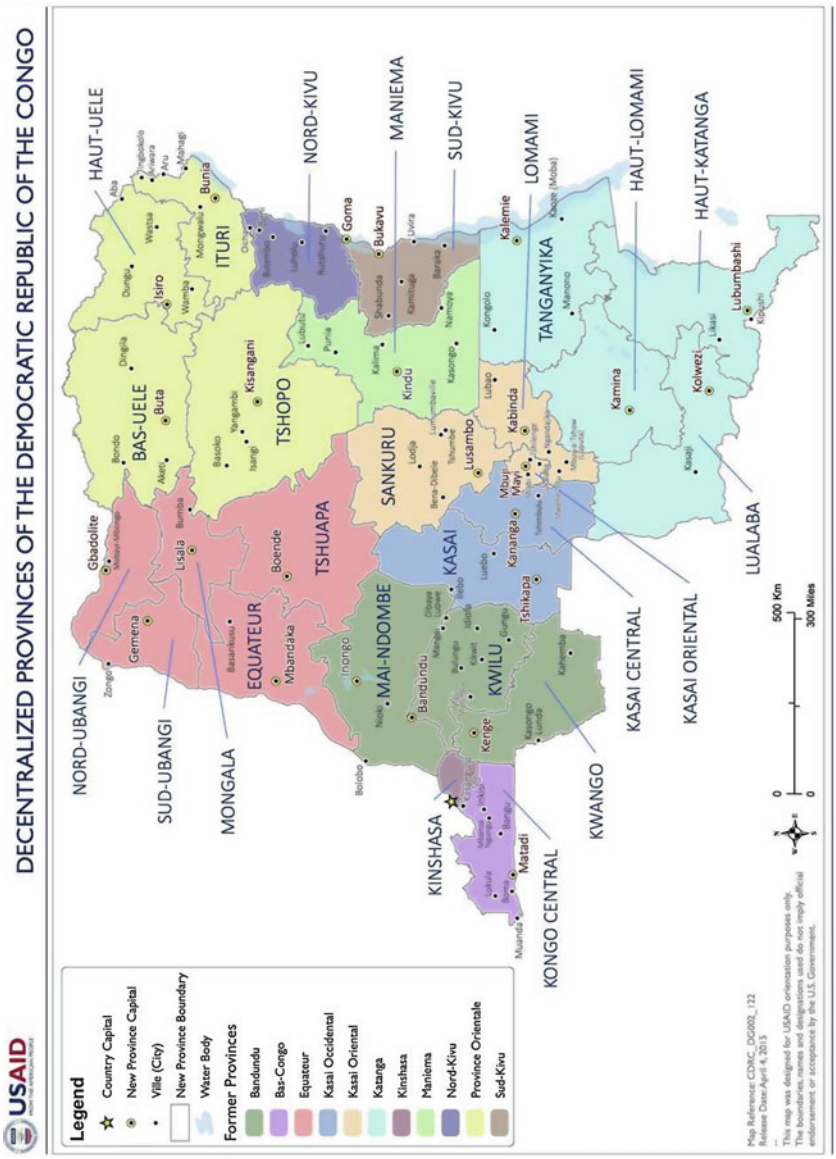

Fig. 1 Map of the Democratic Republic of Congo (Source: USAID 2015, http://www.ocnus.net/artman2/publish/Africa_8/Kabila%20-%20Plan%20B%20for%20the%20Congo.shtml)

households are living below the poverty line of 1.25 dollars a day, while in urban areas it is less than seven out of ten (The World Bank 2013). Agriculture makes up about 70% of people's livelihood and the agricultural sector is dominated by subsistence agriculture (Ministre du Plan et Révolution de la Modernité de la RDC 2015). Since 1997 and until now, the political situation in the country has been characterized by civil wars. The death toll of the civil war, 1998–2004, has been estimated to 3.9 million (Coghlan et al. 2006). The conflicts have restricted the country's ability to promote development and food production and thus improve food security (Weijs et al. 2012; Kandala et al. 2011). Hence, DRC is still strongly dependent on foreign aid (République Démocratique du Congo 2014).

Whereas many other countries in sub-Saharan Africa have been able to reduce the number of people suffering from malnutrition, prevalence of malnutrition in the forms of stunting, wasting and underweight in the DRC is among the highest in sub-Saharan Africa (République Démocratique du Congo 2014). Many children are also suffering from severe malnutrition.

including marasmus and kwashiorkor. In other parts of the world, kwashiorkor has become very rare, but in the DRC thousands of children are still suffering from this disease.

What is Kwashiorkor?

The earliest description of kwashiorkor can be dated back to biblical times. The Jamaican physician Cecilia Williams, working in what is now Ghana, was in an article from 1933 (republished in 1983) the first to describe kwashiorkor in Africa. In a Lancet article from 1935, she gave the disease its African name kwashiorkor (Williams 1935). The name was given after the notion in the Ga language of the coastal Ghana, *kwa ni oshi korkor,* and was translated by Williams as the disease that the deposed child gets when the next is born. Williams suggested that the disease was associated with a monotonous diet, and given that maize was the main source of supplementary food, she suggested that some amino acid or protein deficiency could not be excluded as causing the disease.

Kwashiorkor along with marasmus and marasmic kwashiorkor are classified as syndromes of clinical severe childhood malnutrition. Kwashiorkor and marasmic kwashiorkor are identified by edema (swelling of body tissues as a result of fluid accumulation), whereas marasmus is defined as a nonedematous form of extreme wasting (Figs. 2 and 3). Edema is the most important and defining feature of kwashiorkor (Heikens and Manary 2009) (Fig. 4). There are significant variations of edema severity (Epomedicine 2017). It is classified as mild when it occurs in feet only, moderate when it occurs in legs and feet and lower arms, and severe when it is present on face and arms. Children with kwashiorkor may also develop skin lesions common on the extremities (Heilskov et al. 2014) (Fig. 5). Hair abnormalities are striking when the disease process is of a long duration. Abnormalities include straight hair, dyspigmentation, and thin hair. Fatty liver resulting in enlargement of

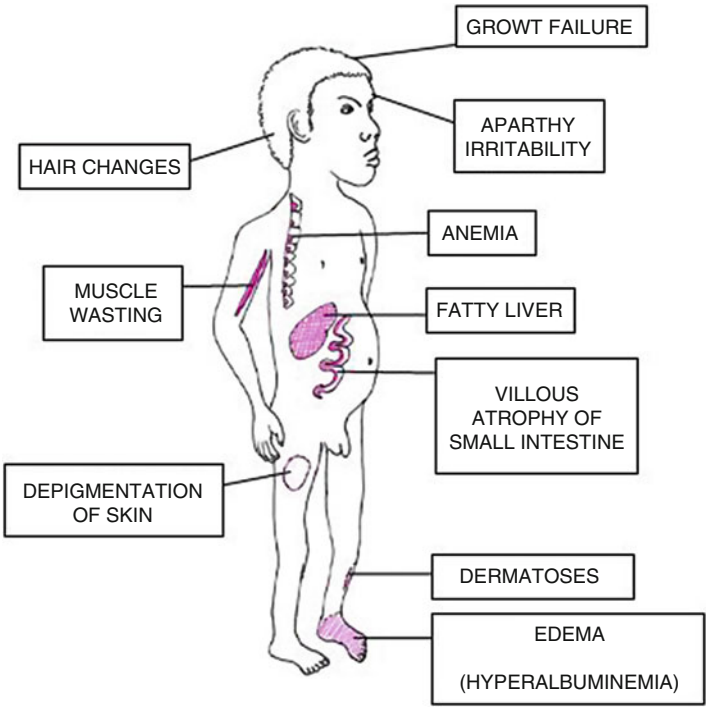

Fig. 2 Signs of kwashiorkor drawing by Hallgeir Kismul

the liver is also commonly reported as a feature of kwashiorkor (Frenk et al. 1958; Truswell and Miller 1993). The disease has been associated with a high risk of death (Briend et al. 1987; Talbert et al. 2012).

The Global Burden of Kwashiorkor

Kwashiorkor is prevalent in several parts of sub-Saharan Africa and is also found in communities in Asia and in South and Central America. Very few cases have been reported from high-income countries. The disease is still an important public health problem especially in rural areas where children consume a diet low in dietary diversity, often consisting of two major staples.

Kwashiorkor is a transitional condition and typically those who suffer from the disease recover after a few weeks of case management or die from the disease (Williams 1935). This makes it difficult to capture the magnitude of kwashiorkor in cross-sectional surveys that report prevalence of malnutrition (CMAM Forum 2015). A report attempting to describe the burden of kwashiorkor in low-income countries concluded that prevalence of kwashiorkor in most countries was less than

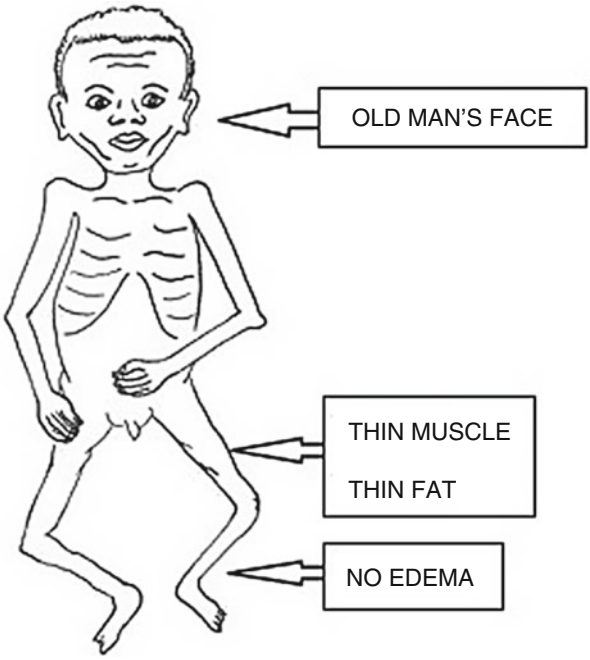

Fig. 3 Signs of marasmus drawing by Hallgeir Kismul

Fig. 4 Child from the Democratic Republic of Congo with kwashiorkor showing pitting oedema photo with permission from Branly Mbunga Kilola

Fig. 5 Child from the Democratic Republic of Congo with kwashiorkor showing skin lesions, photo with permission from Branly Mbunga Kilola

1% (CMAM Forum 2015). Then again some countries reported rates between 1% and 2% including Yemen, Zimbabwe, and the DRC.

The Etiology of Kwashiorkor

The development of kwashiorkor has been linked to diet and metabolism. Until the 1980s Kwashiorkor was with marasmus classified as a form of protein-energy malnutrition. Kwashiorkor was seen as a result of children consuming a diet high in energy but low in protein. This consumption pattern leads to pathological abnormalities such as edema and fatty liver (Whitehead and Alleyne 1972). The hypothesis was challenged and studies found that the diet of children who developed kwashiorkor was not characterized by a low intake of protein when compared with the diet of children who developed marasmus (Gopalan 1992). In the early 1980s, it was postulated that kwashiorkor was caused by an excess of free.

radicals. According to this suggestion, protective pathways were compromised in kwashiorkor. These pathways require the supply of micronutrients in the form of antioxidants, which could be deficient in kwashiorkor, thus causing a loss of the protective pathways (Golden and Ramdath 1987). Some population studies have challenged the free radical hypothesis. As an example a randomized control trial of children aged 1–4 years assessed the efficiency of providing antioxidants to prevent kwashiorkor (Ciliberto et al. 2005). This study failed to show that the supplementation of antioxidants prevented the children from developing kwashiorkor. Still other studies have shown that there is apparently a lack of micronutrition in the diet of children who develop kwashiorkor (Kismul et al. 2014). A child with kwashiorkor typically lives in environments where the diet is restricted to cooked but starchy foods including cassava and maize. The diet characteristically lacks vegetables and fruits. These are natural sources of micronutrients and dietary antioxidants.

The literature has described relations between breastfeeding and presence of kwashiorkor. Apparently children who have developed kwashiorkor are less likely to have been breastfed in comparison with those who have not developed kwashiorkor (Rytter et al. 2015). Prolonged breastfeeding and supplementation with solid food have been associated with a substantial reduction of clinical malnutrition in the form of kwashiorkor and marasmus (Cousens et al. 1993).

Although there is an apparent relation between diet and the development of kwashiorkor, there still exist many uncertainties as to the cause of kwashiorkor. A number of hypotheses are put forward and are being tested to better understand the etiology of kwashiorkor. As an example abnormal gut microbiota has been suggested as a factor contributing to the development of the syndrome. The hypothesis has been tested in animal and population studies (Subramanian et al. 2014). This literature suggests that there is a link between the consumption of a nutrient-poor diet, abnormal microbiota, and the development of kwashiorkor (Smith et al. 2013).

Moreover, abnormal gut microbiota has been related to environmental enteric dysfunction (Crane et al. 2015).

Food Insecurity in the DRC

Food security is considered an underlying factor with implications for children's and adults nutritional status and is manifest at the household level. Food insecurity is a major problem in the DRC, and according to the recent Integrated Food Security Phase Classification (IPC) of 2016, over 5 million of the country's population are in acute food security and livelihood crisis (IPC 2017). In the DRC, malnutrition is most widespread in the rural areas (The World Bank 2013; Kandala et al. 2011). There are several factors that constraint food production in the rural areas. The majority of the rural population depends on rainfed subsistence farming cultivating land less than 2 acres (WFP 2014). The farmers use traditional farming techniques and all operations are carried out manually. Poor access to seeds both improved varieties and traditional is considered a major obstacle to agricultural production (WFP 2014). Furthermore, other agricultural inputs including fertilizers and pesticides are more or less unavailable. Poor infrastructure also puts constraints on the possibility of developing agriculture especially cash cropping. The infrastructure, roads and waterways connecting local communities, agricultural land, and markets, has been described as "in an advanced stage of deterioration" (Mathys and Remancus 2010).

The IPC report subdivides the country with regard to food insecurity in 4 regions (IPC 2017):

1. The regions severely affected by armed conflicts, typically in the Eastern DRC.
2. The regions susceptible to climatic and natural changes including floods, El Nino, outbreaks, etc., in the Eastern and central provinces of the country.
3. The regions under the pressure of internal displaced populations and refugees, these are provinces along the border.
4. The regions under chronic food insecurity comprising northern and central provinces. They are characterized by extreme poverty and ill access to social services.

People living in the capital Kinshasa are in comparison with people residing in other provinces food secure. The most food insecure provinces are typically landlocked provinces that are extremely difficult to reach. In such areas, manufactured goods including food are sold at very high price, whereas cash cropping is difficult to develop. In the most food insecure provinces, people rely upon artisanal mining. In these provinces, there is a tendency that people neglect food production and these provinces have to import much of its food. Provinces affected by war including South Kivu are also food insecure. The land in South Kivu is fertile, but shortage of land and landlessness are problems closely related to food insecurity. Several food insecure provinces face problems due to influx of internal as well as refugees from neighboring countries (Mathys and Remancus 2010).

Malnutrition in the DRC

The Demographic and Health Survey (DHS) from 2013/14 provides data on the prevalence of malnutrition in children in 2013 in the DRC (République Démocratique du Congo 2014). According to the survey, 43% of the children below 5 years suffered from stunting, 8% from wasting, and 23% from underweight. The DRC thereby had among the highest proportions of children suffering from stunting in the world.

While the most recent DHS report from 2013/14 (République Démocratique du Congo 2007) does not contain data on kwashiorkor, this information is included in the DHS from 2007 (République Démocratique du Congo 2007). This report informs that 4.1% of the children below 5 years had edema with the largest proportion of children with edema in the age category 9–11 months. There were no gender differences in the occurrence of edema. On.

the other hand the report demonstrates a rural urban gap and most of the children with edema lived in the rural areas. There were also important regional differences as to occurrence of edema. In particular Orientale and South Kivu provinces had high prevalence of children with edema. The former province is depending on artisanal mining and the latter province has over the last decades been affected by civil war. It is also reported that children with edema were most likely to live in the poorest households.

Diet in the DRC

The diet in the DRC depends on regional context and there are also important differences between diet in rural and urban areas (Bervoets and Lassance 1959; Termote et al. 2012). Cassava root is the main staple food crop in most parts of the country. In the northern regions, cassava is served with cassava leaves as a side dish. In addition cassava is provided with different vegetables, legumes, and fish. In the western part of the country, cassava is typically consumed with vegetables and fish. In the south, maize is the major staple food and is consumed with vegetables and legumes. Cassava is also a major staple in the eastern part of the country, but food such as sweet potatoes and beans are commonly consumed. In the urban areas, cereals play a more important role in the diet than in the rural parts of the country. Animal products such as meat and egg are only eaten occasionally, whereas dairy products are rarely consumed. Wild edible plant and bush meat are components of food production especially in the rural areas and wild food constitutes a safety net during periods of food shortage. The most import wild plants consumed include wild yam, wild nuts, wild leafy vegetables, and various wild fruits. In addition bush meat and fish are part of the diet in areas located to the vicinity of forests and rivers. However, even in areas characterized by being very rich in biodiversity, wild edible plants are insufficiently consumed to increase nutrition security or dietary adequacy (Termote et al. 2012).

Typically the Congolese consume one to two meals per day. The major meal usually consists of a stiff porridge made from cassava or maize flour. The porridge is often served with a stew made of cassava leaves, spinach, and okra. Typically only a minority enrich the porridge with vegetable, fruits, fish, and meat. Meat is rarely consumed. If there are any left-overs, these are consumed for breakfast the next day. In between meals, people drink tea and palm wine and eat various fruits. For the households that do not produce their own fruits and vegetables, the cost of purchasing such food items at the market is often too high.

For the meals, water is collected from deep tube wells or from streams in the forests. During meals, household members are served the same food, but split into groups; women and young children in one group, older children in another and men in the third.

Infant Feeding

Breastfeeding is universally accepted and practiced in the DRC and 99% of infants 0–5 months of age have been breastfed (République Démocratique du Congo 2014). Normally breastfeeding continues up to 2 years and 67% of toddlers 18–23 months are breasted. Early complementary feeding is common and more than half (60%) of the infants in the DRC experienced mixed feeding by 0–2 months (République Démocratique du Congo 2007). In addition to water, early complementary food consists of a gruel basically made from porridge and cassava-leaf stew. Women's workload is a major obstacle to women practicing exclusively breastfeeding (Burns et al. 2016; Babakazo et al. 2015). In the rural areas women are required to cultivate, gather food, and collect firewood. While the mothers work in the field, their young children are left with relatives and neighbors who provide them with food. At the age of 7 months, the children are provided with solid food mostly in the form of porridge. As the children grow older, their diet does not change substantially. The children continue to eat porridge and other family food as they grow older.

Diet and Kwashiorkor in Northwest DRC: The Bwamanda Study

Bwamanda is one among the 516 health zones in the DRC and is located in the South-Ubangi province in the northwest part of the DRC. Health services are provided by a central hospital and 10 associated health centers. These health facilities serve a population of approximately 200,000. The hospital provides essential health services including some degree of nutritional rehabilitation services. The Ngbaka is the dominant ethnic group in the area and are predominantly subsistence farmers. The major crops cultivated in the area are cassava and maize. Besides crop production, the farmers grow vegetables such as sweet potatoes, taro, green leafy vegetable, and fruits such as papaya and African pear. The Ngbaka are also involved in gathering wild vegetables and fruits. A number of water bodies and small rivers

support local fishing. The natural resources in the area are widely dispersed restraining local people's access to wild food.

Agriculture production is constrained by a number of factors. Farming techniques are traditional and very labor intensive. All operations are done by hand, farmers do not have access to draught animals and fertilizers are unavailable. Some farmers therefore face labor shortage during critical agricultural periods. Farmers can reduce this problem of seasonal bottlenecks by participating in reciprocal farm workgroups involving relatives and neighbors. In Bwamanda farmers who take part in such groups are usually in better positions to diversify their food production. As in other parts of the DRC, a number of distal factors constraints the development of local food production and major obstacle to production is access to agricultural inputs, particularly seeds. Furthermore, poor infrastructure restricts the farmers' ability to expand into cash crop production.

The low farm production diversity contributes to little diversity in the diet. The Ngbaka normally eat two meals per day. The major meal is served in the evening and it consists of *ka.*

a stiff porridge made from cassava and maize flour. The dish is served with a side dish: a stew made of cassava leaves and palm oil. Sometimes the stew is enriched with fish and groundnuts. The leftovers are eaten for breakfast the next day. In between the meals, people eat fruits and drink tea and palm wine. Infants are mainly breastfed up to the age of 7 months at which point solid food is introduced. Early complementary food consists of a gruel made from *ka* and cassava-leaf stew.

A secondary analysis of a historical material from Bwamanda was undertaken, with the field study carried out between 1989 and 1991 (Kismul et al. 2014). The Bwamanda study is a dynamic population study. Three-monthly contacts were organized making up 15 months of follow-up with totally 6 contacts. During the first round, 4328 children below the age of 6 years were enrolled and at the end of the study 5567 children had been included. The children were examined for kwashiorkor and pitting edema on feet and ankles were used as the major criteria for determining the presence of the disease. Marasmus was assessed by inspection of abnormal visibility of skeletal structures and by absence or near-absence of palpable gluteus muscle without presence of edema. Children's nutritional status was also assessed through anthropometric assessment and children's weight and length/height was measured. As a part of the study, a nonquantitative 24-h recall was carried out. The recall contained the 41 commonly most consumed food items in the area. The respondents, the children's caretakers in most cases the biological mother, provided "yes" or "no" answers to the question if the children had consumed the listed items. First, in the statistical analysis the percentage of food consumed before children developed kwashiorkor was tabulated. Second, causal factors for kwashiorkor including diet and infectious diseases were analyzed. Table 1 describes the food items eaten by children during the survey round before children developed kwashiorkor. Maize, cassava roots, and cassava leaves were the major food consumed by the children. Kwashiorkor has been associated with a low intake of protein rich food. Then again the table shows that children who developed kwashiorkor and marasmus as well as children who did not develop these diseases had eaten food items that are

Table 1 Consumption of different food items in the survey round preceding the development of kwashiorkor (n = 37) and non-development of kwashiorkor (n = 8108) and development of marasmus (n = 374) in children between 6 and 50 months of age.(Kismul et al. 2014).

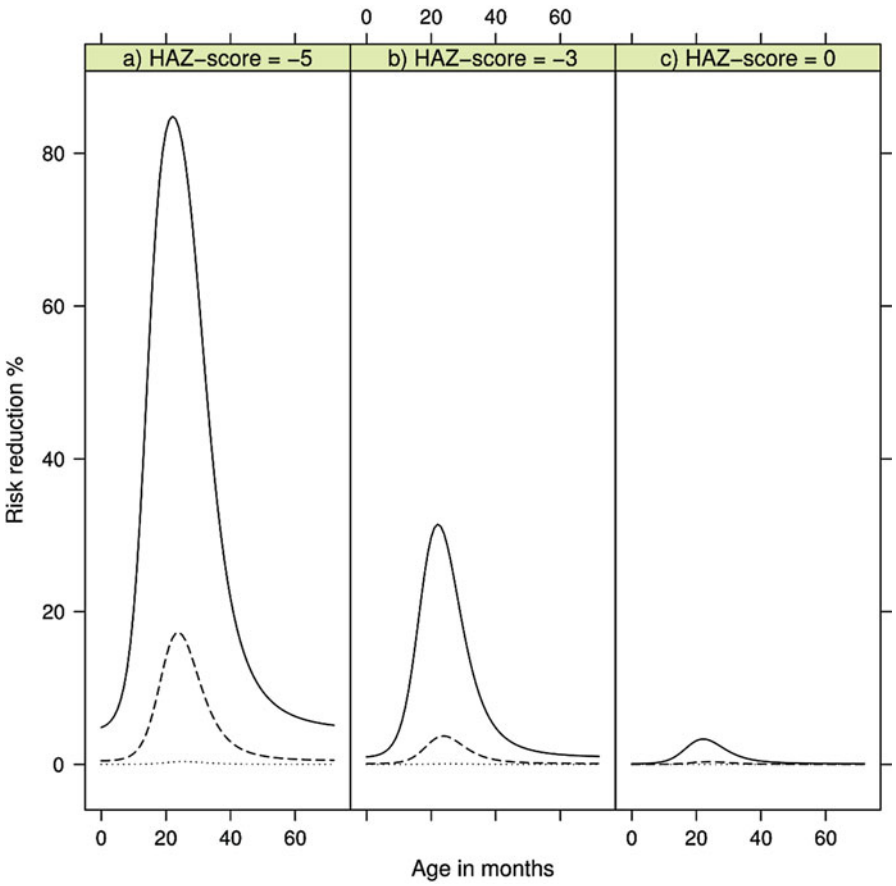

Fig. 6 Risk reduction for developing kwashiorkor showing reduction of consuming β-carotene rich products according to age in months. The dotted line is risk reduction after 2 months, dashed line after 4 months, and solid line after 6 months, (**a**) shows risk reduction for a child with a height-for-age Z-score (HAZ) of minus five, (**b**) for a child with HAZ of minus three, and (**c**) a child with HAZ of zero. HAZ-scores are based on the WHO-2006 Child Growth Standards (Kismul et al. 2014)

rich in proteins. These food items included caterpillar, egg, meat, and egg. In terms of consumption of these food items, there were no significant differences between children with kwashiorkor and children with marasmus and children without any of these diseases. On the other hand a significant higher proportion of children who did not develop kwashiorkor had consumed papaya, sweet potatoes, and "other vegetables," with the latter term comprising taro leaves, wild vegetables, and fruits. These food items are characterized by their high content of β-carotene. The statistical analysis demonstrated that the risk of developing kwashiorkor in children who were chronically malnourished increased the longer the children did not consume food that contained β-carotene Fig. 6 illustrates how the risk of developing kwashiorkor is reduced by eating food that is rich in β-carotene.

To summarize the Ngbaka live in environment characterized by food insecurity and in particular farmers who are not able to overcome labor constraints are susceptible to food and nutrition insecurity. In addition distal factors limit farmers' ability to develop a more diverse food production. The diet in the area is monotonous and cassava and maize are the major food items consumed by young children. In this food and nutritional unsecure environment, children are at high risk of developing different forms of malnutrition. The consumption of a monotonous diet that does not include vegetable and fruits increase the risk of chronically malnourished children to develop severe forms of malnutrition such as kwashiorkor.

Conclusion

Kwashiorkor in Africa has been related to diet since its first description. Kwashiorkor occurs in situations characterized by food insecurity and famine. Furthermore, kwashiorkor has been related to the consumption of a monotonous diet often characterized by the absence of.

consumption of fruit and vegetables. Thousands of children in the DRC are living in this type of environment and they are at high risk of developing kwashiorkor. Nutritional programs in the DRC need in particular to focus on rural areas with particular attention to provinces with high prevalence of malnutrition. It is especially important to assist ongoing efforts that aim at stimulating the consumption of a varied diet through improved agricultural and horticultural production.

Policies and Protocols

Protocol

Children with kwashiorkor can be treated with ready-to-use therapeutic food (RUTF), a home-based treatment carried out within a model for community-based management of acute malnutrition (Trehan and Manary 2015). RUTF is a high-energy, lipid-based spread. The powder ingredients are embedded in lipid-rich paste. The result is an energy dense food that resists microbial contamination (Briend 2001). Treatment with RUTF is provided for children with uncomplicated kwashiorkor (Manary et al. 2009), as it is also applied by PRONANUT, the national nutrition program which further recommends association with an antibiotic, and, where needed, vitamin A and an antimalarial (Manary et al. 2009). These are children who are treated in their early stage of illness. Children who are treated later in the stage of the illness may have a number of complications. These children should receive individual treatment. For these children, extended

nutritional supplementation as well as enrolment in nutritional program can be insufficient.

Policies

The strategy to reduce severe child malnutrition in the form of kwashiorkor should build on an approach that acknowledges how underlying, immediate, and basic factors determine the development of kwashiorkor. It is important to tackle factors at all three levels and recognize that addressing factors at only one level will have restricted effect on the development of kwashiorkor.

The development of kwashiorkor in the DRC occurs in situations characterized by severe poverty and food insecurity. To reduce severe malnutrition, there is a need for significant changes at the macro level. Policies that aim at reducing malnutrition should therefore be directly related to policies that put emphasis on economic growth and poverty reduction.

At the immediate level, it is important to address the problem of food insecurity. It is essential to target children living poor food insecure households in rural areas. These children are especially at high risk of developing kwashiorkor. People living in rural areas of the DRC are predominantly semisubsistence farmers. Food security policies should attend to causes leading to low production and little diversity in food production among small-scale farmers. Policies should especially improve better access to agricultural extension and agricultural inputs such as seeds, fertilizers, and credit. In terms of diversity in agricultural production, it is important to promote the cultivation of crops and fruits that are rich in β-carotene. Furthermore, improvements in food production and consumption rely on infrastructure development and farmers in particular need better access to markets for sale of their agricultural produce. Strategies that aim at reducing malnutrition through strengthening small-scale agricultural production should in particular target households with few resources in form of land, labor, and capital.

At the basic level, policies should promote nutrition-specific interventions. Such interventions could be effective ways of reducing the incidence of kwashiorkor. The diet in many areas of the DRC is to a large extent based on cassava and maize. Children are therefore at high risk of developing vitamin A deficiency. Vitamin A supplementation might be an effective way of reducing malnutrition including severe malnutrition.

Dictionary of Terms

- **Clinical severe childhood malnutrition** – A term used for the three clinical syndromes of clinical severe malnutrition including marasmus, kwashiorkor, and marasmic kwashiorkor.
- **Complementary feeding** – A process that start when breast milk no longer is enough to meet the nutritional needs of the infant other foods and liquids are needed, along with breast milk.

- **Diet** – A term that is commonly defined as the food that a person eats every day. It can be portrayed with regards to chemical composition in terms of nutrient content or described as food and food groups.
- **Free radical** – Is an atom or groups of atoms with an unpaired number of electrons. It can be formed when oxygen interacts with certain molecules.
- **Kwashiorkor** – A form of severe malnutrition where the presence of edema is the most significant feature.
- **Marasmus** – Nonedematous severe child malnutrition and characterized by extreme wasting
- **Edema** – Swelling of body tissues as a result of fluid accumulation.

Summary Points

- Kwashiorkor typically occurs among children in areas that are characterized by severe food and nutrition insecurity.
- Kwashiorkor has since its early description among children in Africa been related to the consumption of a monotonous diet.
- Earlier kwashiorkor was considered as a result of children consuming a diet high in energy but low in protein.
- Scholars have postulated that kwashiorkor is caused by an excess of free radicals. According to this suggestion, protective pathways are compromised in kwashiorkor. The pathways require the supply of micronutrients in the form of antioxidants.
- Food insecurity is a major problem in the DRC with food insecurity and child malnutrition being most widespread in the rural areas.
- Cassava root is the main staple food crop in most parts of the DRC and it is often eaten with a side dish such as stew made of cassava leaves.
- Animal products such as meat and egg are only eaten occasionally, whereas dairy products are rarely consumed.
- A longitudinal study examining the relation between diet and kwashiorkor has been carried out using material from Bwamanda an area in northwest Congo.
- The study demonstrated that the risk of developing kwashiorkor in children who were chronically malnourished increased the longer the children did not consume food that contained β-carotene.

Double Burden of Underweight and Overweight: The Example of Bangladesh

117

Mohammad Enamul Hoque

Contents

Abstract

Many low- to middle-income countries (LMICs) in the world are presently facing an epidemiological paradox, namely, a double burden of underweight and overweight, with the prevalence of both underweight and overweight simultaneously. Such double burden of malnutrition in many of these countries is a result of the rapid increase in the prevalence of an overweight burden while an underweight burden continues to persist. Considering the increasing overweight and persistent underweight found in many developing countries, a nutritional transition is going on in the LMICs, especially in countries of the Indian subcontinent including Bangladesh.

A rising trend of prevalence of overweight both in urban and rural areas among the population in Bangladesh was observed. The prevalence of overweight exceeded that of underweight in 2014. A higher average annual rate of reduction of overweight was found among the wealthy, highly educated, and urban women, while a higher average annual rate of increase was found among the poor, uneducated, and rural women. In addition, a large variation between rural and urban areas was observed in the prevalence of overweight among children and adults in Bangladesh. The overweight children and adults were mainly from urban areas.

The presence of a double burden of underweight and overweight in adult males and females was observed in Bangladesh. However, the prevalence of overweight has increased significantly during the last three decades both in rural and urban areas. Reasons for the increase in the overweight prevalence may be attributable to current economic development in the country. Future research is needed to determine the driving force of the higher growth rates of overweight and to work out the reasons for the rapid increase of the overweight burden among the poor, uneducated, and rural people. As the burden of overweight is predicted to increase in the future, it is also important to estimate the future economic burden attributable to the overweight burden in Bangladesh.

Double Burden of Underweight and Overweight in Bangladesh

Introduction

In the past, overweight and obesity has generally been considered as a public health problem of developed countries. However, several studies suggested that this public health problem is now spreading in the low- to middle-income countries

(LMICs) undergoing rapid economic transition, demographic changes, and urbanization (Popkin 2001, 2004; Monteiro et al. 2002, 2004). While overweight and obesity prevalence is rapidly increasing, the prevalence of underweight persists in many of these countries. This leads to a phenomenon referred to as a double burden of malnutrition, that is, coexistence of underweight and overweight in a population (Popkin et al. 2012; Kapoor and Anand 2002; Popkin 1994; Ke-You and Da-Wei 2001; Corsi et al. 2011; do Ha et al. 2011). Considering the increasing overweight and persistent underweight found in many LMICs, a paradox in the nutritional transition has emerged. Such nutritional transition is a consequence of changes in pattern of health and socioeconomic factors (Popkin 2004; Monteiro et al. 2002), increased consumption of energy-dense food (Popkin 1994; do Ha et al. 2011), higher dependence on technology-based activities (Popkin 1994, 2004; do Ha et al. 2011), and growth of urbanization (Popkin et al. 2012; Kapoor and Anand 2002; Popkin 1994; do Ha et al. 2011). The changes in food habits and dietary patterns along with changes in physical activity patterns are responsible for nutritional transition – from nutritional deficiency to over sufficiency disorders. The consequence of such nutritional transition is the increasing epidemic of an overweight coupled with underweight burden.

Like many LMICs in the world, Bangladesh was the habitat of leaner and underweight people, and thus for decades the major public health concern of Bangladesh was reducing underweight burden. With an urban population of around 35% (Worldometers 2015), continuous economic development, rapid industrialization, and market globalization along with higher incomes and wealth inequity among rural and urban people have made a significant impact on epidemiological and nutritional transition in Bangladesh. In addition, in the recent decades, several changes such as increased consumption of food outside the home, taking more energy-dense food, and drinking a lot of sugar-sweetened beverages have occurred in Bangladesh. Several recent studies have mentioned that the prevalence of overweight is increasing in Bangladesh (Balarajan and Villamor 2009; Shafique et al. 2007; Hoque et al. 2015), which is now facing a double burden of underweight and overweight problems.

Trend of Underweight

Globally, the underweight prevalence is decreasing (Corsi et al. 2011; Ahmed et al. 2012a; Black et al. 2008). In the developing regions, the proportion of children under 5 years who are underweight declined from 29% to 18% during 1990 and 2010 (UN 2012). However, despite such improvement, the global maternal and child underweight burden is still alarmingly high, with an estimated 112 million children under 5 years being underweight (Ahmed et al. 2012b). Among Asian countries, although the underweight prevalence is decreasing, it is still high. The underweight rate ranges between 20% and 50% in countries such as China, India, Indonesia, Thailand, and Vietnam (Stevens et al. 2012). Although historically women in Bangladesh have experienced chronic nutritional deficiency, national data indicates the decline of

underweight from 50.3% to 18.6% during 1996 (NIPORT 1996) and 2014 (NIPORT 2014). The prevalence of underweight among women aged 15–49 years decreased by 32% during the period 1996 (NIPORT 1996) and 2014 (NIPORT 2014). In 2014, approximately 21% of rural women and 12% of urban women were classified as underweight (NIPORT 2014).

The prevalence of underweight (weight-for-age Z-score < -2) among children under 5 years of age in 1996 (NIPORT 1996) was more than 55%. Though this prevalence decreased to 47% in 2000, little change was observed until 2007 (NIPORT 2007) when the prevalence began to decrease again and dropped to 32.6% in 2014 (NIPORT 2014). From 1996 (NIPORT, 1196) to 2014 (NIPORT 2014), the prevalence of underweight among children aged less than 5 years decreased by 24%. However, in 2014 the prevalence of underweight (32.6%) among children under 5 years of age was still high in Bangladesh, with over one-third underweight (NIPORT 2014).

Trend of Overweight and Obesity

The prevalence of overweight and obesity is increasing globally. The prevalence of overweight increased globally between 1980 and 2013 from 28.8% to 36.9% in men and from 29.8% to 38% in women (Ng et al. 2014). Kelly et al. (2008) predicted that in 2030, globally an estimated 2.2 billion adults will be overweight and further one billion will be obese. The prevalence of overweight has increased significantly in the last decades, with substantial variation in levels and trends across countries and within regions.

The prevalence of overweight and obesity in Bangladesh is especially increasing among women (Shafique et al. 2007; Stevens et al. 2012). In 1996–1997, the prevalence of overweight and obesity in reproductive-age women in Bangladesh was 2.7% (NIPORT 2007). In 2014 (NIPORT 2014), the rate of overweight and obesity among this group of women reached 39.2%, with an average yearly increment of 2.02%. At the national level, the mean body mass index (BMI) of women increased to 3.5 kg/m^2 points, from 18.8 kg/m^2 in 1996 (NIPORT 1996) to 22.3 kg/m^2 in 2014 (NIPORT 2014). During 1996 and 2014, the mean BMI increased among women both in rural (3.1 kg/m^2) and urban (3.3 kg/m^2) areas of Bangladesh. Over the last 18 years, mean BMI among the rural and urban women of Bangladesh increased by 0.17 kg/m^2 and 0.18 kg/m^2 per year, respectively.

A recent study (Hoque et al. 2015) provided information on existing double burden of underweight and overweight among both genders in Bangladesh, though underweight dominates in both cases. The study also suggested that there are important gender differences in the prevalence of underweight and overweight among the adult population of the country. Adults living in urban areas were more likely to be overweight compared with adults living in rural areas. On the other hand, adults living in rural areas were more likely to be underweight compared with adults living in urban areas.

Consequences of Double Burden of Underweight and Overweight

The existence of both underweight and overweight concurrently in a developing country adds pressure to the health system of this country, as resources are already limited in general. This has an impact on both public health and the economy of a country.

Public Health Burden

Both underweight and overweight are important risk factors for mortality and morbidity of various diseases. Underweight is associated with increased comorbidities, including osteoporosis, diabetes, infertility, and asthma (Sairenchi et al. 2008; Zheng et al. 2011). Underweight is also associated with increased risk of death in Asian populations (Ni Mhurchu et al. 2004). Maternal underweight also has adverse effects on pregnancy outcome. On the other hand, overweight and obesity are risk factors for cardiovascular disease (CVD), cancer, type 2 diabetes, and hypertension (Ni Mhurchu et al. 2004; WHO 2009). It is estimated that overweight and obesity alone are responsible for 3 million deaths every year worldwide (Mendez et al. 2005). In 2010, worldwide overweight and obesity were responsible for 3.4 million deaths and caused 3.8% of disability-adjusted life years (DALYs).

Economic Burden

The increasing burden of overweight and obesity coupled with the existence of the underweight problem creates an increasing threat to the overall health status of a country's citizen and on its health-care system. The cost associated with this double burden is expected to be immense and to have an impact on individuals, families, and the country. This health disorder negatively affects the health-related quality of life of individuals (Muennig et al. 2006). Households may incur expenditure related to treatment for diseases occurring from being underweight or overweight. This may also be associated with the reduction of economic growth of the country as this burden adversely affects various factors of economic growth – labor supply, productivity, investment, and education.

Several studies using data from Asian countries, other than those of the Indian subcontinent, have been conducted to measure the economic burden of overweight; and they have identified the total economic toll of overweight to be between 1.5% (Pitayatienanan et al. 2014) and 9.9% (Ko 2008) of a country's total health-care expenditure (THCE). In the case of countries of the Indian subcontinent, the economic burden seems to be immense as well. Like many developing countries in the world, out-of-pocket (OOP) payments are the major source of financing health care in countries of the Indian subcontinent. Households have to finance large and unpredictable costs, both medical and nonmedical, from household budget. Such

dependence on OOP payment for health services may lead to a catastrophic burden for households and may also have an impact on reducing economic growth through less investment by households in economic activities and education of children.

Nutritional Transition

With the global tsunami of overweight and obesity (Monteiro et al. 2002), the wave is also splashing in Bangladesh which is home to some of the leanest population in the world. Overweight and obesity has become a serious and growing problem of the country over the past decades. The overall prevalence of overweight and obesity is lower among urban children and adolescents than would be expected of an affluent society. This lower prevalence may be due to the existence of slums in these urban areas, and thus the urban poor and urban affluent seem to have very different obesity trajectories. The health status of children and adolescents in urban slums is very poor, so it is obvious that when combining these urban slum children with the other urban children, the total pooled prevalence of overweight among urban children and adolescents is reduced, substantially.

In case of Bangladesh, the prevalence of underweight women decreased from 50.1% in 1996 (NIPORT 1996) to 18.6% in 2014 (NIPORT 2014), whereas the prevalence of overweight women increased from 2.92% in 1996 (NIPORT 1996) to 39.2% in 2014 (NIPORT 2014). Prevalence of undernutrition of women decreased more than 60%, whereas prevalence of overweight women increased by more than 1000%. This has resulted in a shift from a greater prevalence of underweight to a greater prevalence of overweight. The prevalence of overweight increased in the last three decades, and in 2014 the prevalence of overweight superseded that of underweight. It is apparent that a nutritional transition is happening in Bangladesh. The reasons for such nutritional transition are multidimensional and are described below.

Economic Development of Bangladesh and Health Trend

The nutritional transition in a country occurs in consort with the economic growth of that country (Mendez et al. 2005). In the last decades, Bangladesh has gone through significant socioeconomic developments. According to World Bank data (World Bank 2017), the gross domestic product (GDP) has increased consistently in Bangladesh at around 6% per year for the last couple of decades and has increased from 53.31 billion US$ in 2000 to 221.41 billion US$ in 2016. The personnel remittance received in the country has increased from 778 million US$ in 1990 to 15 billion US$ in 2015 (UNDP 2014). The percentage of population below the national poverty line fell from 56.6% in 1991 to 31.5% in 2010 (World Bank 2017). During 1990 to 2016, the life expectancy at birth increased from 60 years to 72.2 years (World Bank 2017). Over the same period, the mortality rate of children under 5 years decreased from 143.7 per 1000 to 34 per 1000 (World Bank 2017). In addition, the secondary school enrolment rate increased from 20% in 1990 to 64% in 2016. The mobile cellular subscription increased from 6% in 2005 to 78% in 2016 (World Bank 2017). As a result, between 1990 and 2015, Bangladesh's Human Development Index increased from 0.386 to 0.579 (UNDP 2014), an increase of 50%. The trend in

Bangladesh's socioeconomic development is reflected with nutritional transition in the country as the overweight prevalence is increasing and underweight prevalence is decreasing.

Lifestyle Change

Bangladesh is one of the most densely populated countries in the world. In the recent decades, urbanization has risen very fast, with around 3.5% urban population growths annually (Monteiro et al. 2002). In urban areas there is a lack of parks, playgrounds, and even community walkways. All these have impact on physical activity and sedentary behavior, leading to higher ownership of vehicles and increased use of cars. Moreover, use of modern amenities (mobile telephones, electricity), increased time spent viewing television, and playing computer games have impacts on the increasing prevalence of the overweight burden. Nationally the rate of television watching has increased from 20.5% in 2004 (NIPORT 2004) to 50.9% in 2014 (NIPORT 2014).

The increasing wealth, due to increasing GDP, leads people with higher disposal incomes and thus more ready cash at hand than before. Furthermore, the globalization of the food market, availability of canned food in modern supermarkets, and changes in food distribution channels have contributed to changes in dietary habits within families. Increasingly, individuals eat outside the home or buy readily available takeaway food which characteristically refined carbohydrates, meat product, and energy-dense food with added sugar. As the food supply chain in Bangladesh changes, people are becoming accustomed to regularly having breakfast at local restaurants. Readymade cooking ingredients have become widely available, and women do not need to spend a lot of time collecting and preparing these ingredients. A recent survey found that rural women spent 17.7 h per day on average in noneconomic activities (BBS 2010). In contrast, the women growth rate in labor force is higher than men (8.7% vs. 1.4%) in 2010 (BBS 2010). However, this higher increasing participation of women in labor force may be due to an expanding garment sector in recent decades, as most of the garment workers are young women. Though the salary in the garment sector is very low, these young women have cash ready to be used to consume basic food to protect them from undernutrition. All these factors contribute to the increasing prevalence of overweight in the country. In addition, due to higher access to technology, people have moved from labor-intensive activities to capital-intensive activities, such as using tractors in agricultural production. Due to the growing trend in manufacturing, especially the garment sector, people are involved more in less energy-intensive services than before.

There are many such trends impacting on the overweight burden in Bangladesh. It was observed that in 2014 (NIPORT 2014) the prevalence of overweight among urban women was as high as 53.2% and among the richest group the prevalence of overweight was as high as 64.7%. Such high rate of overweight prevalence is comparable to other high-income countries like Canada and Singapore and is even higher than many high-income Asian countries like South Korea and Japan (Monteiro et al. 2004).

Nutritional Transition

Risk Factors for Nutritional Transition

Several risk factors are estimated to be involved with the overweight and underweight burden. The following discussion relates to the effect of these risk factors on underweight and overweight.

Education Level

The risk of underweight was lower for a higher level of education, and the risk of being overweight was higher for a higher level of education compared to people with no education. The women with higher level of education in general belong to well-off family. They are also involved in highly paid job. So they have ready cash to eat away from home, meeting friends and colleagues in fast-food restaurant, thus consuming energy-dense food. At the same time, most of these women are involved in desk-based job, which may also have impact on gaining weight.

In contrast, between 1996 and 2011, the total average annual rate of increase (AARI) of overweight was much higher among women with no education compared to women who completed secondary education or higher educational level (15.43% vs. 4.39%). On the other hand, the average annual rate of reduction (AARR) of underweight was higher among women who completed secondary or have higher educational level compared to the women with no education (6.71% vs. 3.84%). Thus, though the AARR of underweight is higher among the higher educated women, the AARI of overweight is much higher among the women with no education. This indicates a shift of overweight problem over the years among women with no education.

Age Category

A recent study (Hoque et al. 2014) on children and adolescent from countries of Indian subcontinent indicates that whereas only 2% of under 5-year-old children are overweight, 15% of children aged 10–18 years old were overweight in these countries. This may be due to the following biological reason: girls, after 12 years of age, experience pubertal growth spurt. In general, girls of this age in Bangladesh are confined to involve in sports and several physical activities. The study shows that individuals at 50 years old and above had higher risk of overweight and underweight compared to individuals who are 19–34 years old. However, the risk of overweight among individuals at 50 years old and above is higher than the risk of underweight.

Socioeconomic Status

Household socioeconomic status, as represented by household asset ownership, was found to be associated with the nutritional status of family members. Individuals from higher socioeconomic status families had significantly higher rate of overweight burden compared with individuals from lower socioeconomic status families. This may be due to higher food-purchasing capacity of the wealthy household. It can be argued that food-purchasing capacity and food-

consuming behaviors are not always positively associated. Several studies have proved that food purchasing and food intake patterns are related to the household wealth.

Rural-Urban Difference

A large variation in the prevalence of overweight and obesity between rural and urban residence exists in the country. The study findings showed that urban living is associated with overweight as the individuals from urban areas had higher odds of overweight compared with individuals from rural areas. This may be due to the fact that the urban women have higher baseline prevalence of overweight compared to their rural counterpart. The following are the reasons between the association of urban stay and higher overweight prevalence: increased level of sedentary behavior; lack of physical activity due to lack of parks, walkway, and playgrounds; higher use of modern utilities; and consuming more energy-dense food as most of the fast-food restaurants are located in urban areas.

Gender Difference

The higher annual average rate of increase of overweight among the rural and low socioeconomic group, especially among women in the group, is a reflection of the socioeconomic development of Bangladesh. This indicates that the rural women are quickly catching up to their urban counterpart who had higher baseline overweight prevalence. However, this increasing trend of overweight burden among the rural and poor people indicates a rising inequality burden of overweight in the country. Gender inequality exists in the prevalence of underweight and overweight as women were found to be more overweight and less underweight than men. Urban men had lower risk of overweight and higher risk of underweight compared with their female counterpart. This might be due to the tendency of women in Bangladesh to stay at home and to be involved in less physical activity than men.

Emerging Burden of Noncommunicable Disease and Economic Burden

It is obvious that a nutritional transition in Bangladesh is underway as the burden of overweight is increasing and the burden of underweight is decreasing. However, the underweight burden is still very high and thus ensures the existence of a double burden of underweight and overweight. The rate of increase of overweight prevalence was higher than the rate of decrease of underweight prevalence in both urban and rural areas. This increasing trend of an overweight burden also leads to rising burden of noncommunicable diseases attributable to overweight. In 2010, around 30% of the total population in Bangladesh was at young age (10–24 years), and as this young population grows up, there is a possibility that the noncommunicable disease burden will increase. Regarding economic burden, the cost associated with this burden will be immense and will create a significant challenge for the country in terms of financial burden.

Policy Response Addressing the Nutritional Transition

Though both underweight and overweight health burdens coexist in Bangladesh and there is a nutritional transition from an underweight burden to an overweight burden, the overweight burden is a comparatively new issue in Bangladesh as poor nutritional status is still a big public health concern. Most of the policies related to nutritional issues are mainly focused on reducing the undernutrition problem as the country has been facing this burden for a long time. For instance, the National Health Policy (GoB 2011) and National Plan of Action for Nutrition (GoB 1997) both branded and concentrated on undernutrition and identified only undernutrition as an issue, but not overweight. It seems that Bangladesh's health policy still does not recognize the importance of preventive public health interventions to control the emerging disease burden associated with overweight and to address the nutritional transition. This omission may be due to lack of experience and the ability to handle the emerging overweight burden and lack of national policy guidelines to deal with the disease burden and focus on undernutrition issue. However, a vital document "The Country Investment Plan: A Road Map towards Investment in Agriculture, Food Security and Nutrition" identified both under- and overnutrition as important issues. In addition, the current Health, Nutrition and Population Sector Development Program (HNPSDP 2012) identified overweight as an obstacle for economic development of the country. However, the operation plan of executing HNPSDP is inclined to prevent noncommunicable disease-related risk factors more than the overweight burden only.

Conclusion

Future research is needed to get a complete picture of the health and economic burden of underweight and overweight in Bangladesh and to address the nutritional shift. The consequences of the transition from an underweight burden to an overweight burden and the coexistence of both underweight and overweight burden, and the future implication for the health and economic sector of the country need to be analyzed and understood. As the public health burden and concern about overweight is comparatively a new area in Bangladesh, policies addressing this health burden are rare. Policy and research gap analysis is needed to address the nutritional transition in Bangladesh, addressing both the underweight and overweight burden, and to recommend key strategies to curb the increasing burden of overweight. Several sporadic efforts have taken place to curb or control the overweight burden. In addition to the government initiative, several Non-Government Organizations (NGOs) are conducting various programs to address Bangladesh's nutritional problem. However, these NGOs are targeting the undernutrition issues, especially for mothers and children. Such involvement of the NGOs in one specific area of nutrition is understandable as most of the health policies of the country are directed towards controlling the underweight burden.

Policies and Protocols

This chapter describes the double burden of underweight and overweight in Bangladesh and currently undergoing nutritional transition from underweight to overweight in Bangladesh. To address this problem, several policies should be adopted as mentioned below:

- Bangladesh's health policy should recognize the importance of preventive public health interventions to control the emerging disease burden associated with overweight and to address the nutritional transition.
- It is needed to conduct operation research involving the community into policy action through citizen engagement to identify strategies for simultaneously controlling the increasing trend of overweight prevalence among Bangladeshi people while maintaining the decreasing trend of underweight prevalence.
- A policy and research gap analysis is needed to address the nutritional transition in Bangladesh, addressing both the underweight and overweight burden, and to recommend key strategies to curb the increasing burden of overweight.

Dictionary of Terms

- **BMI** – an index of weight for height that is commonly used to classify individual nutritional status
- **Overweight** – BMI $\geq$ 25 kg/m^2
- **Obese** – BMI $\geq$ 30 kg/m^2
- **Underweight** – BMI $\leq$ 18.5 kg/m^2
- **z-scores** – cutoff value of <-2 and $>$ +2 z-scores are commonly used for assessing nutritional status of the children. A z-score cutoff point of <-2SD is classified as low weight-for-height (wasting), low height-for-age (stunting), and low weight-for-age (underweight). The cutoff point of $>$ + 2 SD classified high weight-for-weight as overweight in children

Summary Points

- A clear existence of a double burden of underweight and overweight among both genders, though underweight dominates in both cases, was observed. A quarter of the adult population were underweight at national level, and almost one in seven of the adult population is overweight.
- A rising trend of overweight both in urban and rural areas among the population was observed.
- A higher average annual rate of reduction of overweight was found among the wealthy, highly educated, and urban women, while a higher average annual rate of increase was found among the poor, uneducated, and rural women.

- There are important gender differences in the prevalence of underweight and overweight among the adult population of the country. High socioeconomic status, higher educational attainment, and urban residency increased and reduced the risk of women being overweight or underweight, respectively, compared with men.
- Adults living in urban areas were more likely to be overweight compared with adults living in rural areas. A large variation between rural and urban areas was observed in the prevalence of overweight among children and adults.

80% of its inhabitants are under the age of 50 years. Throughout the years, Mexico has been plunged into poverty and this calamity is expanding overtime. In addition, income inequality has been a constant which keeps the country under economic and health-related hardships. Among other factors, poverty contributes to the onset of malnutrition and intestinal infectious diseases which prevail in the southeast of the country where the majority of poverty and marginalization is concentrated. In 1999, the prevalence of underheight was ~70%, mainly affecting indigenous children. For almost half a century, malnutrition has led to the proliferation of certain diseases such as intestinal amebiasis and ascariasis, positioning them among the twenty most common causes of morbidity in Mexico. In 2015 for example, the incidence rates of both diseases were 211.04 and 39.81 cases for every 100,000 inhabitants, respectively. In a similar trend, intestinal infectious diseases and helminthiasis were positioned within the ten leading causes of death in the southern and central part of the country. From 1998 to 2014, the cysticercosis and ascariasis claimed the most lives with 2575 and 448 cases, respectively. Other medical relevant protozoa include *Cryptosporidium parvum*, which contributes to malnutrition in children, and *Giardia lamblia* whose seroprevalence in Mexico has been determined to be as high as 55.3%. Recommendations by the WHO are to provide antiparasitic drugs, improve the access to drinking water, and implement health education with the purpose of eliminating these neglected diseases. To complete these actions, it is necessary to provide additional investment into the nation's health sector which will foster and promote the well-being of Mexico's children.

Introduction

For almost half a century, intestinal infectious diseases have affected the peasant and indigenous Mexican population. These diseases are some of the main causes of morbidity and mortality over the last few decades. A similar situation has been observed with mild protein-energy malnutrition. Fortunately by 2014, this condition left the top 20 principal causes of morbidity. It is important to mention that in the country there is great disparity of nutritional status. The northern states present the highest prevalence of overweight and obesity, while the southern states present major malnutrition problems. Regions where populations are affected by malnutrition are more prone to have a greater number of cases of intestinal infectious diseases, in comparison with the northern part of Mexico (Monarrez-Espino et al. 2011; Quihui et al. 2006).

Mexico's socioeconomic factors have played an extremely important role in these health disparities. For example, the income inequality that Mexicans perceive is more accentuated in the southern part of the country, in comparison with the northern. Even though, this context does not allow reducing the high mortality rates in regards of infectious intestinal diseases.

In the current chapter we present an overview of the most important intestinal parasitic diseases affecting the Mexican population, including studies of the mortality burden in different regions, i.e., states of Mexico, where data is available. We introduce a perspective about the state of the infections within the social environment where they have developed. In the same way, the work will enable us to view and assess action strategies in order to correct or reduce long-term trends of these diseases in Mexico.

The Scenario of Intestinal Parasitic Disease in Mexico

The results of the National Population Census performed in 2010 revealed that the population of Mexico is predominantly young with 53.4 million inhabitants between the ages of 0–24 years, followed by those 25–49 years and finally those from 50–65 years or more (38. 4 and 20.4 million, respectively) (INEGI 2016). Almost half of the Mexican and Latin-American inhabitants are classified as living in poverty, besides the fact that in these regions there is high income inequality (Hotez et al. 2008).

According to official figures, from 2008 to 2014, the poverty level has increased in Mexico, passing from 44.5% to 46.2%. In regard to social deprivation, the most notable were: social security access (58.5%), followed by food access (23.4%), access to basic housing services (21.2%), educational lagging (18.7%), and access to health services (18.2%) (INEGI 2016).

Additionally, the World Bank pointed out that the slow economic growth and income inequality among Mexico's inhabitants have increased poverty (Walton and

Lopez-Acevedo 2005). For example, in almost half a century, the Gini coefficient, which evaluates the distribution of income within a nation, only improved 18% going from 0.53 (in 1963) to 0.435 (in 2010) (Narro Robles and Zepeda Tena 2012). During 2014, the value of this indicator was of 0.438 (INEGI 2016), revealing that inequality is still valid.

All of these above mentioned factors, along with ethnicity, age, sex, and ecological conditions provide breeding ground for neglected tropical diseases (Hotez et al. 2008). In Mexico, the most frequent tropical diseases are intestinal parasitosis caused by helminths and protozoa. Among helminths, the most prevalent etiological agents are: *Ascaris lumbricoides* (roundworms), *Trichuris trichiura* (whipworms), *Necator americanus*, and *Ancylostoma duodenale* (hookworms). Some of the effects caused by helminthiasis are: anemia, vitamin A deficiency, weakness, malnutrition, and intestinal obstruction (Stephenson et al. 2000; WHO 2011, 2015). During 2002, trichuriasis was the most prevalent in Latin-America, followed by ascariasis and ancylostomiasis with a total of 100, 84, and 50 million people infected. Most of these people were located in Brazil, Mexico, and Guatemala (de Silva et al. 2003). Furthermore, cysticercosis, fasciolasis, and paragonymiasis constitute the most important infections caused by plathyhelminths in Latin-America. In this part of the world, approximately 400,000 persons were affected by cysticercosis (Hotez et al. 2008).

To respond to the upcoming challenges that helminthiasis poses in high-risk populations, the WHO has suggested the prophylactic use of certain drugs such as albendazole, levamisole, mebendazole, and pyrantel (WHO 2002). It has been observed that in cases of ascariasis, children who were treated with the aforementioned drugs improved their nutritional status, gained weight and height, and their skin fold got thicker. In infections caused by hookworms or trichuriasis, treatment is helpful for preventing anemia brought on by iron deficiency; meanwhile in pregnant women it is useful for preventing maternal morbidity (Savioli et al. 2004). It is important to point out that, if a nation invests in the wellbeing of its inhabitants, the health status of people affected by these parasites could improve and this would represent a beneficial impact on both individual incomes and national incomes promoting sustainable wealth (Jamison et al. 2015). Thus, some actions that should be taken in Mexico, in order to fight against neglected diseases, are the establishment of a universal national health service based on family medicine and a reduction in the economic and social inequality gap which still exists in the country (Narro Robles and Zepeda Tena 2012).

Malnutrition

The impact of infection by intestinal parasites on the nutritional status of the host has been extensively documented. Anorexia is one of the negative effects along with weight loss (Stephenson et al. 2000). Furthermore, when a person is malnourished, the immune system deteriorates, becoming increasingly susceptibile to different intestinal infectious agents (Papier et al. 2014). All of this establishes a vicious circle between malnutrition and such types of infectious agents (Rodríguez et al. 2011).

According to official numbers, for more than a decade, mild protein-energy malnutrition has been positioned within the first 20 causes of disease (2000–2013). It should be noted that malnutrition has mainly affected infants between one to 4 years of age. Starting in 2014, mild protein-energy malnutrition was no longer considered an important cause of morbidity given that the country experienced an abrupt transition toward obesity with the number of new cases almost tripling (3.5×10^5) in comparison to the new cases of mild protein-energy malnutrition of the previous year (1.1×10^5). Alarmingly, in 2015, new cases of obesity increased more than 30% in comparison with 2014. In both years the most affected population included adults between the ages of 25–44 years of age (DGE 2014) (Fig. 1).

Surveys of the Mexico's national health have revealed that the nutritional status of the population is polarized. During 2006, the highest prevalence of obesity among

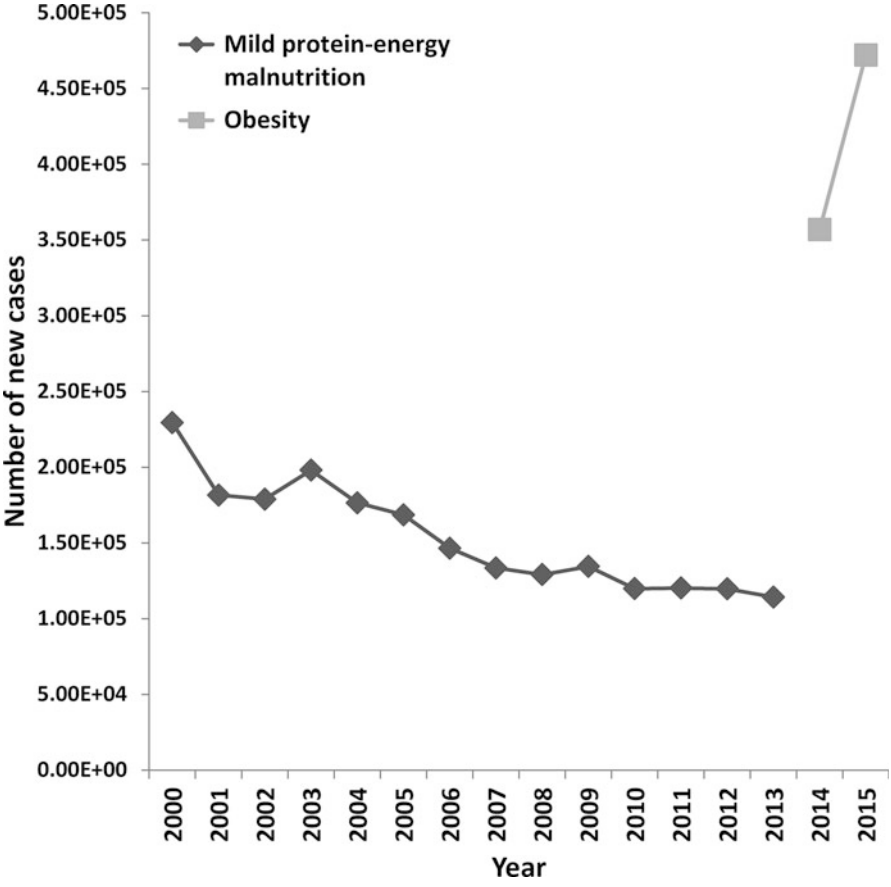

Fig. 1 Mild protein-energy malnutrition (ICD diagnosis code E44.1) and obesity (ICD diagnosis code E66) new cases in Mexico. A timeline shows a decrease in the number of cases of mild protein-energy malnutrition; however, a suddenly onset of obesity appears since 2014 and this trend continues at present

adults was detected in the northern region (34.7%), followed by the southern region (27.3%), and in 2012 the trend was similar in both regions (Barquera et al. 2009; Barquera et al. 2013). In contrast, malnutrition increased in the southern part of the country, mainly among indigenous children. In 1999, prevalence of underheight and underweight were of 69.8 and 49.8%, respectively, whereas in the northern part of the country these were 36.1 and 22.6%, respectively. The northern of Mexico presented the highest prevalence of overweight/obesity among indigenous children (14.2%), in comparison with the southern region (5.6%) (Chavez Zuniga et al. 2003).

Several authors have pointed out that chronic malnutrition has persisted in Mexico for more than 24 years, affecting indigenous children who live in rural zones of the southern part of the country (Rivera-Dommarco and Cuevas-Nasu 2013; Rivera et al. 2003). The focalization of malnutrition has also been pointed out by a study which demonstrated the prevalence of stunting in more than half of 2666 indigenous children younger than 5 years of age (54.1%), living in poverty and marginalization conditions, and under an atmosphere imbued with political conflicts (Sanchez-Perez et al. 2007). Unfortunately the nutritional status of these children has not changed. A recent study performed on children around the age of two, and living in rural and marginalized zones from the central and southern regions of Mexico, revealed that almost half of these children (43.4%) presented stunting associated with retarded speech development (Carrasco Quintero et al. 2016).

Parasitic Diseases in Mexico

The nutritional status of the Mexican population, linked to socioeconomic profile, reveals differential risk between the northern, central, and southern regions of the country, with people living in the southern region being subject to a higher risk of acquiring a neglected disease such as infectious and parasitic diseases covered here. For more than three decades (1984–2015), intestinal infections (ICD diagnosis codes A04, A08-A09, except A08.0); intestinal amebiasis (ICD diagnosis codes A06.0-A06.3, A06.9); helminthiasis caused by trematodes, nematodes, cestodes, and filarial parasites (ICD diagnosis codes B65-B67, B70-B76, B78, B79, B81-B83); and ascariasis (ICD diagnosis code B77) have been positioned within the top 20 causes of transmissible diseases affecting the Mexican population (DGE 2014; Ximenez et al. 2009) (Fig. 2).

Although in Mexico intestinal amebiasis is one the most important parasitic diseases by protozoa, its incidence have diminished the last few years. For example, while 1.6×10^6 new cases were reported in 1998, there were only 2.5×10^5 new cases in 2015. The most affected groups were preschool and grade-school students. The states of Nayarit, Guerrero, and Yucatan (the first two from the central and the last from the southern part of the country) presented incidence rates higher than the national rate (211.04 per 100,000 inhabitants) during 2015: 546.17, 523.52, and 516.15, respectively (Table 1; Fig. 3a). Since 2008, ascariasis has also experienced a similar trend and it has even disappeared from the top 20

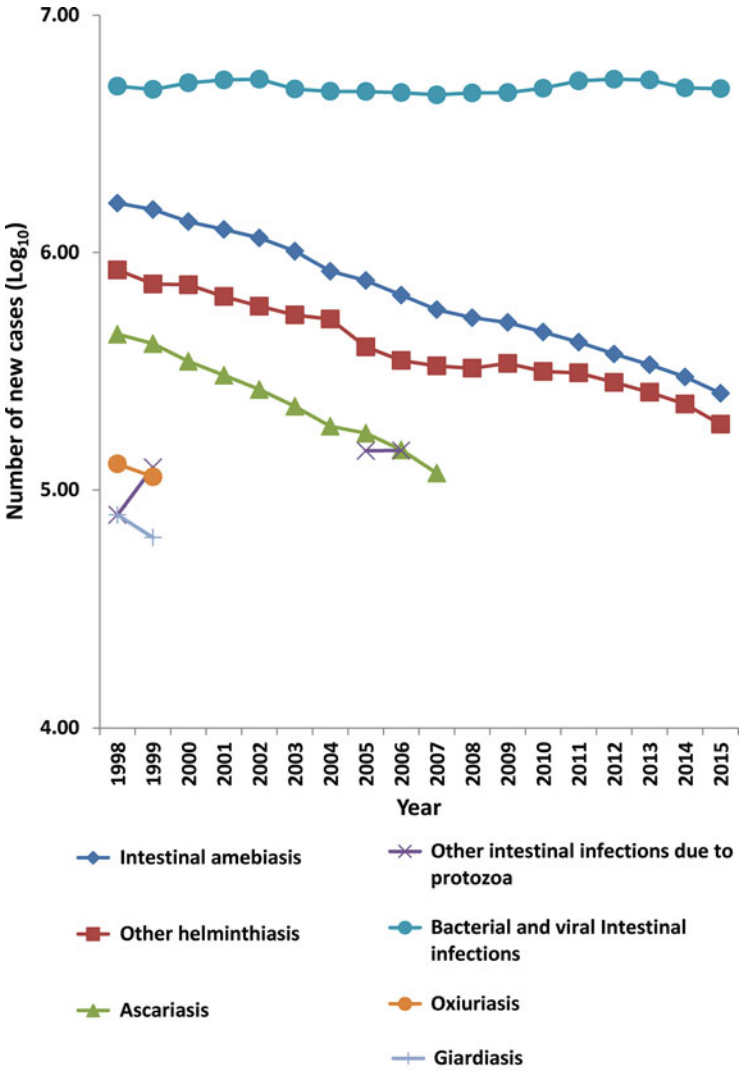

Fig. 2 New cases of parasitic diseases in Mexico (1998–2015) (DGE 2014). A timeline depicts that bacteria and virus are the top etiology agents of intestinal infections; amoebas are the main protozoa affecting the Mexican population, followed by helminths

cases of morbidity in Mexico. This helminthiasis has also affected preschool and grade-school students as the incidence rates which exceeded the national value (39.81) during 2015 were observed mainly in the southern part of the country (DGE 2014) (Table 1; Fig. 3b).

Since 1990, the YLL rate and the DALY rate caused by diarrheal diseases have also shown a parallel decrease in morbidity rates. Nevertheless, these are still concentrated in the southern part of the country. During 2013, the states of Chiapas,

Table 1 Morbimortality of the most prevalent intestinal infectious diseases in Mexico. The incidence rates, and cumulative deaths, caused by the main intestinal infectious diseases in the most affected Mexican states

	Incidence rate (per 100,000 inhabitants; 2015)		Number of deaths (1998–2014)	
State	Intestinal Amebiasis	Ascariasis	Intestinal infectious diseases	Helminthiasis
National rate	211.04	39.81	–	–
Aguascalientes	394.2	7.77	631	61
Campeche	449.84	11.90	307	16
Chiapas	490.82	92.37	9462	245
Colima	362.84	51.97	253	18
Guerrero	523.52	255.2	2585	117
Hidalgo	419.79	71.85	926	117
Mexico	213.64	5.06	8723	224
Mexico city	133.97	4.08	5808	366
Morelos	240.74	10.94	1000	48
Nayarit	546.17	64.47	605	32
Oaxaca	475.41	55.75	5727	187
Puebla	280.47	50.65	4981	455
Quintana Roo	285.05	117.6	444	32
San Luis Potosi	216.56	27.6	1812	104
Sinaloa	314.99	18.50	1007	59
Tabasco	426.7	144.89	996	63
Tamaulipas	129.57	46.03	834	46
Tlaxcala	314.63	4.38	653	42
Veracruz	224.8	93.64	4358	427
Yucatan	516.15	285.54	1751	50
Zacatecas	282.92	6.66	1005	97

Guerrero, and Oaxaca registered YLL rates caused by diarrheal diseases of 494.5, 349.7, and 326.8 respectively, greater than the national rate (172.6) (Gomez-Dantes et al. 2016).

Mortality records caused by this kind of transmissible diseases showed a similar trend. For more than a decade (1998–2014), parasitic infectious diseases caused a total of 310,996 deaths (from a total of 9.1 million during such period) and for this reason they figured among the first 10 causes of mortality in the country, after diseases of the circulatory system, endocrine diseases, nutritional and metabolic diseases, tumors, external causes of morbimortality, diseases of the digestive system and respiratory diseases (INEGI 2016) (Fig. 4).

According to information provided by the National Institute of Statistics and Geography (INEGI by its acronym in Spanish), the largest quantity of deaths due to intestinal infectious diseases were registered in Chiapas, State of Mexico, Mexico City, Oaxaca, and Puebla. On the other hand, deaths caused by helminthiasis were

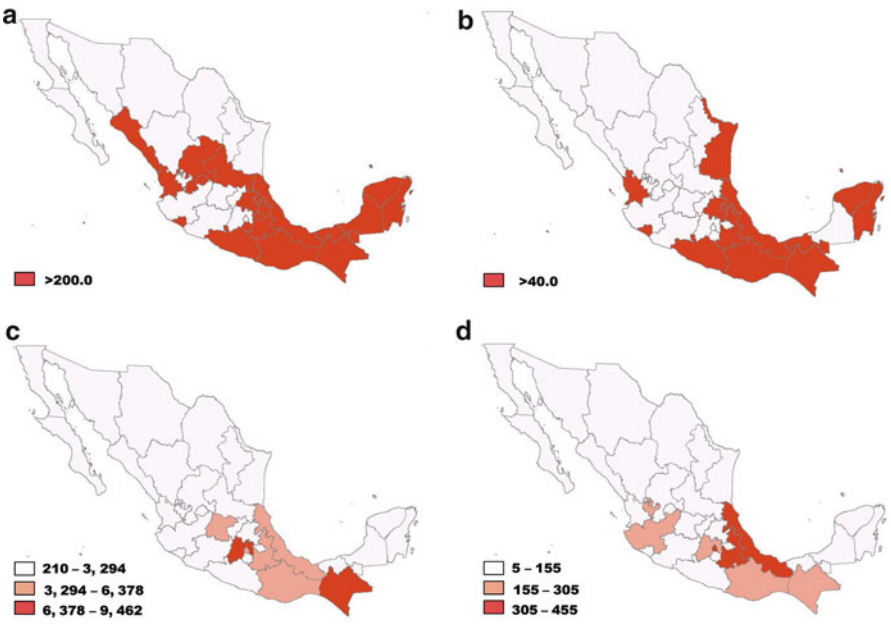

Fig. 3 Distribution of the main intestinal infectious diseases in Mexico. States above national incidence rate (per 100,000 inhabitants) due to: A, intestinal amebiasis; B, Ascariasis. Cumulative deaths (1998–2014) due to: C, intestinal infectious diseases; D, helmithiasis (INEGI 2016) (Maps of figure courtesy Ca. Dr. Jorge Antonio Paz Tenorio, a full-time professor at the Facultad de Ingeniería, Universidad de Ciencias y Artes de Chiapas, using the online free Mapa digital de Mexico software (version 6.1)

observed primarily in Puebla, Veracruz, Mexico City, Chiapas, and Jalisco (Table 1; Figs. 3c, d).

From 1998 to 2014, deaths caused by intestinal infectious illnesses (ICD diagnosis codes A00-A09) and helminthiasis (ICD diagnosis codes B65-B83) added 71, 655, and 3730 cases, respectively and for this reason they were positioned among the top 10 causes of death in Mexico (second and seventh place, respectively). The largest number of deaths caused by both illnesses was registered during 1998 with 6680 and 480 cases, respectively. During 2014, these numbers decreased to 3449 and 137 deaths, respectively (Fig. 5).

In Mexico the access to drugs for use against amoebas has reduced mortality rates caused by this protozoan. Amebiasis are among the top 20 causes of morbidity (Ximenez et al. 2009). Similarly, the reduction of deaths caused by helminths can be attributed to the availability of antihelminthic drugs and to the implementation of other actions suggested by the WHO as: environmental hygiene improvement, access to safe drinking water, and the urge to count on health education (Crompton et al. 2003). For example, during 2006 the Mexican government implemented the "Programa Oportunidades" (Opportunities Program) for disadvantaged and

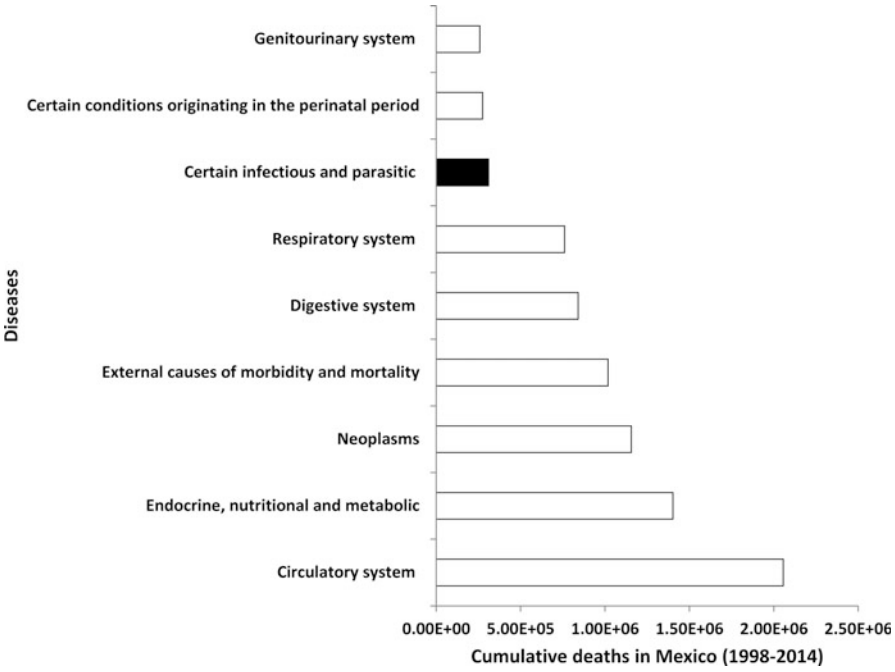

Fig. 4 The main causative agents of death in Mexico, 1998–2014 (INEGI 2016). The infectious and parasitic diseases are within 10 leading causes of death in Mexico. Data show cumulative deaths from 1998–2014

marginalized families. Families received economic support under the condition of family assistance, regular medical checkups, and commitment to take their children to school (Levy 2007). This approach proved to be successful in fighting against parasitic infectious diseases.

A study conducted with the assistance of indigenous students from the northern part of Mexico showed that after an action strategy which lasted 20 weeks and included treatment with oral nitazoxanide, improvement of the physical infrastructure, and implementation of an educational program targeted at children, parents, and school personnel resulted in the reduction of *G. lamblia* from 51.7 to 10.4% and *A. lumbricoides* from 37.5 to 0% (Monarrez-Espino et al. 2011). Another study performed in a rural zone of Colima, Mexico (Mexico's central-west) revealed that from 280 participants, 86 individuals presented infection by *A. lumbricoides*. Adults were the most affected (58%; >18 years of age), followed by children (35%; 2–12 years) and teenagers (7%; >12–18 years). Infection by this parasite may be associated with houses lacking of drainage and dirt floors; nevertheless after the administration of nitazoxanide, prevalence caused by this helminth diminished to 13% (Galvan-Ramirez et al. 2007).

Deaths caused by helminthiasis due to cysticercosis in Mexico ranked first (2575 cases), followed by unspecified intestinal parasitosis and ascariasis (639 and 448 cases, respectively) (Table 2).

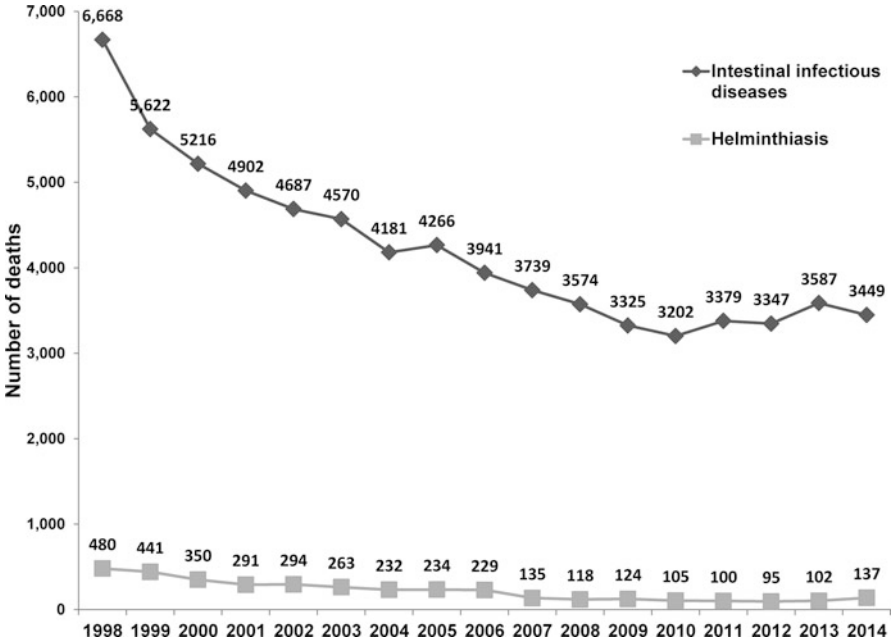

Fig. 5 Deaths by intestinal infectious diseases and helmintiasis in Mexico, 1998–2014 (INEGI 2016). A timeline showing a decrease in the number of deaths due to intestinal infectious diseases and helminthiasis in Mexico

Cysticercosis is caused by the *Taenia solium* cestode (pork tapeworm), a parasite which possesses a biological cycle involving swine and humans. After eggs are consumed through the fecal-oral pathway, the oncosphere hatches out and penetrates the intestine, invading the intestinal wall. Then, it migrates toward the striated muscle, liver, and brain. Once it migrates to these organs it causes severe consequences, such as neurocysticercosis (García et al. 2003).

Fleury et al. (2010) stated that the prevalence of neurocysticercosis reported by the "Instituto Nacional de Neurología y Neurocirugía de Mexico" (National Institute on Neurology and Neurosurgery) did not differ significantly between 1994 and 2000 (2.4% versus 2.5%, respectively). This suggests that, in Mexico, this parasitosis remains of great importance and requires major actions for its eradication.

A study of helminthiasis that was carried out between 1997 and 2000 revealed a greater prevalence of these parasites (53%) in rural communities of Oaxaca (southeast), in comparison with those founded at Sinaloa (northeast), with 33% (Quihui et al. 2006). This trend may be due to the fact that, as it has already been mentioned, in the southern part of the country and in Guatemala it is possible to find a great number of rural zones, primarily inhabited by poor and marginalized indigenous communities and for this reason they present the highest rates of helminthiasis in America (Hotez et al. 2008).

Table 2 Deaths by helminthiasis in Mexico, 1998–2014 (INEGI 2016). Leading causes of death in Mexico, due to helminthiasis

Helminthiasis	Number of deaths
Cysticercosis	2575
Unspecified intestinal parasitosis	639
Ascariasis	448

Trichinosis	3
Trichuriasis	2
Taeniasis	2
Other trematode infections	1
Fascioliasis	1
Necatoriasis	1
Total	3, 730

Parasitic Diseases Associated with Malnutrition

A recent study carried out in the southeast of Mexico with 250 children of less than 5 years of age (belonging to the zoque and tzotzil indigenous groups) revealed a prevalence of intestinal parasites of 38.8%. *Ascaris lumbricoides* was the most common helminth (33.6%). In more than one-third of the participants, the presence of this parasite was associated with malnutrition (Gutierrez-Jimenez et al. 2013). Another survey done with 243 six-year-old children, living in a rural zone of Colima, Mexico (central-east) showed that more than half of the participants exhibited low ferritin levels (60.9%). Infection with *Trichuris trichiura* in these children was associated with both low ferritin levels and stunting (Gutierrez-Rodriguez et al. 2007).

Fasciolasis is another pathogenic helminthiasis but has only caused one decease in Mexico the last 16 years (INEGI 2016). However, we must not forget a report warning us about an endemic zone of this parasitosis in the municipality of Atlixco, Puebla (central Mexico), characterized by certain ecological elements that are suitable for this kind of helminthiasis as: altitude, presence of snails from the *Galba*/*Fossaria* genus, and infected cattle. In this region the prevalence of disease caused by this parasite ranged from 2.9% to 13.3% and was associated with the consumption of raw vegetables and coinfection with protozoa and helminths. Fortunately the treatment with nitazoxanide showed to be effective (Zumaquero-Rios et al. 2013).

Regarding parasitic protozoa, there are several studies documenting the negative impact of these organisms over the nutritional status of certain populations. *Cryptosporidium parvum* and *C. hominis* appear to have contributed to child malnutrition (Valenzuela et al. 2014). In the north of Mexico (i.e., Hermosillo, Sonora), the

prevalence of *C. parvum* in students between 6 and 13 years of age was of 24%. These children displayed a risk of suffering from malnutrition nearly three times higher than noninfected children (Quihui-Cota et al. 2015). Another work conducted among preschoolers from Guadalajara, Mexico (central-western part of the country) identified *C. parvum* as one of the most frequent protozoans (5.1%) and as the etiology agent of acute diarrhea, followed by *Giardia lamblia*, *Blastocystis hominis*, and *Entamoeba histolytica* (1.2, 0.9, and 0.3%, respectively) (Larrosa-Haro et al. 2010).

In regards to *G. lamblia*, a study revealed that in Mexico the seroprevalence of this parasite was 55.3%, showing the highest prevalence (72.9%) among adults (40–59 years) in comparison with younger age groups (5–9 years of age; 34%), and mainly affecting men (Cedillo-Rivera et al. 2009). In Merida, Yucatan (southeast Mexico) *G. lamblia* cysts appeared in the feces of 33/429 children (7.6%), only slightly fewer cases than those infected with *B. hominis* (N = 45). These parasites were the most predominant. This work reported that six *G. lamblia* isolates corresponded to B genotype, which may be associated with persistent diarrhea (Torres-Romero et al. 2014). Another study that involved children from the northern part of the country reported that infection by *G. lamblia* compromises the absorption of vitamin A in the intestine, causing the mobilization of retinol which is stored in the liver for deficit compensation (Astiazaran-Garcia et al. 2010). As a matter of fact, the National Health Survey (2012) revealed that deficit of vitamin A is still considered to be a public health problem among Mexican children, especially in the southern part of the country (20.3%). Factors that reduce levels of vitamin A are: poor consumption of foods enriched with retinol and presence of intestinal parasites such as *G. lamblia* (Villalpando et al. 2015).

Another protozoan infection affecting Mexican children is amebiasis caused by *Entamoeba histolytica*. Fortunately, as it has already been documented, morbimortality by this parasitic disease has decreased over the time. A recent study conducted in a rural locality of Morelos, Mexico (central part of the country) with 309 children, revealed that 23.3% of these children were mainly infected with *B. hominis* and *G. lamblia* (25, 19.4%, respectively), whereas 9.7% were infected with *E. histolytica*/*dispar*. The ones presenting infection by *E. histolytica* did not show apparent health problems or nutritional deficiencies (Rojas et al. 2016).

Conclusions

In Mexico, infectious diseases caused by intestinal parasites such as protozoa and helminths are still a major public health problem. Even though the actions taken for their eradication are not complex, these diseases have remained prevalent for more than three decades. Although morbimortality rates from these diseases reveal a significant decrease over time, they must be still considered as one the most important infectious diseases, particularly in the southeast part of the country. These infectious diseases may cause several negative effects among inhabitants, causing morbidity and impacting the economy of the nation. A number of studies

have demonstrated the benefits of implementing recommendations made by WHO with the purpose of fighting against neglected diseases. Nonetheless, it is necessary to invest in well-being and it is necessary to do it through the application of programs directed to such "red flags." The fact remains that, inequality is still a challenge to overcome, along with other factors such as corruption, which negatively affects life expectancy and access to health services in this country (Idrovo 2005).

Policies and Protocols

Protocol

Measuring the Nutritional Status of the Mexican Population

This chapter addresses the nutritional changes experienced among the Mexican population. With the purpose of evaluating the nutritional status it was necessary to access the ENSANUT survey (ENSANUT 2015). In these terms, weight is determined through a scale (accuracy of 100 g), size is determined through a stadimeter (accuracy of 1 mm), and length is determined through an infantometer (in child under the age of 2 years of age). For children under the age of five, the nutritional assessment was determined through the "Z scoring" value of the anthropometric indices W/A, H/A, and W/H. Its interpretation, based on the scoring or "Z" value, is performed in accordance to the criteria provided by the world health organization (WHO): underweight, stunting, and wasting, when the W/A, H/A, and W/H (respectively) are of less than −2 DE in relation to the median of the reference population. If the "Z" value of the P/T indicator is superior to 2 DE, it is considered as overweight. For children over 5 years of age, we must calculate the Body Mass Index (BMI) in accordance to the International Obesity Task Force. For persons over 20 years of age, the BMI will be interpreted in terms of the WHO: underweight (<18.5 kg m^{-2}), healthy weight (18.5–24.9 kg m^{-2}), overweight (25 to 29.9 kg m^{-2}), and obesity (>30 kg m^{-2}) (Rivera-Dommarco and Cuevas-Nasu 2013).

Analysis for Intestinal Parasites

The current chapter deals with information about the incidence of intestinal worms which mainly affect Mexican children. These parasites are identified, through optical microscopy, using the zinc sulfate flotation technique which allow the identification of protozoa (cysts, trophozoites) and helminthes (eggs, larvae). This requires 15–20 g of fresh feces, conserved in 5–10% of formaldehyde (Garcia et al. 2005). The helminth parasitic load was determined using a quantitative protocol known as the Kato Katz technique. The interpretation is as follows: for *A. lumbricoides* finding <5000 epg is considered light infection, moderate infection includes 5000 to $<50{,}000$ epg, and severe infection are those individuals with $>50{,}000$ epg. Other examples include: *T. trichiura,* light (<1000 epg), moderate (1000 to $<10{,}000$ epg), and severe ($>10{,}000$ epg) while for *N. americanus,* light (<400 epg), moderate (400 to <3000 epg), severe (3000 to $<10{,}000$ epg), and very severe ($>10{,}000$ epg) (WHO 1987).

Policies

Policies to Improve Access to Health and Food in Mexico

In this chapter we described how malnutrition in Mexico is mainly localized in the southeast where a great portion of indigenous people live in conditions of poverty and marginalization. On the other hand, in the north part of the country we may observe overweight and obesity. In 1997, the Mexican government implemented the program called "Progresa" with the purpose of fighting malnutrition. "Progresa" was focused to indigenous children from rural areas. Through the program, their families received fortified foods, health services, and financial support conditioned to regular attendance to medical check-ups and taking their children to school (Rivera et al. 2004). In 2002, the program was extended to all states of the country under the name of "Oportunidades" (Leroy et al. 2008). In 2014, the program changed again its name to "Prospera" with the main goal of fostering productivity, promoting better family income, and obtaining financial and labor inclusion.

Dictionary of Terms

- **Stunting** – Children with low stature with respect to age.
- **Incidence** – Number of new cases of a disease in a period of time.
- **Mild protein-energy malnutrition** – Weight loss below 2 but less than 3 standard deviations with respect to the threshold mean value for a reference population.
- **Morbidity** – Number of persons affected by a disease in a space and determined time.
- **Mortality** – Number of death caused by a disease in a space and determined time.
- **Seroprevalence** – Number of persons with antibodies against a disease, in a space and determined time.
- **Retinol** – Synonymous of A vitamin with biological actions on retina, bone tissue, and skin.

Summary Points

- This chapter focuses on malnutrition and the main intestinal parasites that affect Mexican population.
- The prevalence of the mild protein-energy malnutrition among Mexican population has decreased until 2013; however, the sudden onset of obesity affects this population at present.
- The obesity affects mainly people from northern Mexico, whereas malnutrition is observed among indigenous infantile population from southeast.
- The intestinal amebiasis and helminthiasis are the main intestinal parasites affects Mexican population from center and south of the country.

- The income inequality, poverty, and marginalization are the main factors that favor malnutrition and intestinal parasites in Mexico.
- However, we argue that in effort to fight against malnutrition and intestinal parasites, it is necessary to have a universal national health service as well as reduce the social and economic inequality in Mexico.

Abstract

The act of ensuring freshwater is considered the most essential and basic need for humanity. Although the planet is water-rich in some terms, the freshwater sources available for human consumption and beneficial uses are very limited. Excess population growth, industrial development coupled with improving living standards have caused an unprecedented need for freshwater supplies all over the world. Regions once rich in water resources are struggling to meet the ever increasing demands in recent years. In addition, climate change and unsustainable water resource management practices have led to situation called "drought" in many regions. Water supplies in drought conditions can be addressed by taking two major approaches related to management and technology development. The management approaches include demand mitigation and supply enhancement. Demand mitigation can be done by implementing water conservation practices and by enforcing a mechanism to influence user-responsible behavior through higher water fares and other billing routes. Supply enhancement can be achieved by utilizing the methods available for water reclamation, reuse, and recycle including rain harvesting. This chapter provides a critical insight of the causes for drought and the issues caused by persistent drought conditions followed by discussion of management approaches required to maintain adequate water resources in these regions.

Keywords

Drought · Water scarcity · Water reuse · Recycle · Ground water · Sustainability · Energy · Pollution · Water supplies · Desalination · Aquifer storage · Dams · Rain harvesting · Public education · Outreach

Introduction

Water is an essential natural source which is often considered to be available abundantly and free of cost (Yarlagadda et al. 2011). However, due to various reasons related to population growth and increasing living standards all over the world and climate change, these water sources are dwindling at a faster rate than they can be naturally replenished. Most of the world population still depends on groundwater which is available in finite reserves and other populations along the coastal areas depend on the seawater as a source of water supply.

Water is one of the most abundant resources of the earth which covers three-quarters of the earth's surface. About 97% of this volume is saline, and only 3% is fresh water, suitable for humans, plants, and animals. Of this fraction, nearly 2.5% is blocked in polar ice caps, glaciers, and atmosphere, leaving about 0.5% of water accessible to human needs (Gude and Nirmalakhandan 2009). In addition, many communities around the world face water supply challenges due to increasing demand, persistent drought, resource depletion and impairment of surface and of groundwater, and dependence on single sources of supply. Many

of these communities have access to brackish groundwater and seawater, which make the suitable for desalination. While other approaches such as water reuse and recycling help address the water shortage problem, treatment technologies are not affordable.

Causes for Water Scarcity

Causes of water scarcity are related to drought, overuse, anthropogenic pollution, physical distance, and political and social stress.

Water Scarcity Due to Drought

Drought can be occasional, temporary, and perpetual which can have detrimental effects on the society and local water sources (Iglesias et al. 2007). Occasional droughts can be recovered from excess precipitation. Temporary drought usually occurs on annual basis, which may also be recovered in successive years. Perpetual droughts are related to those areas which decertified over long period of time due to climate change, overuse, and poor management practices. It has been noted that some regions of the world have experienced historical droughts in recent years. For example, the California's drought has increased over the past decades due to climate change and global hydrological patterns (Gude 2016). Australia has experienced so-called millennium drought.

Although considered a water-rich country, United States has some disparities in its water source availability. In addition, populations in many regions have increased between 100% and 400% within the four decades. For example, the population of Texas has doubled in this period, while the populations in Florida, Arizona, and Nevada have increased by 175%, 275% and 450%, respectively (U.S. Census 2010; NRC 2012). The southwest region of the country is arid and drought-prone, while other parts of the country are reasonably well sourced. It is estimated that an additional 60.56 billion m^3 per year of water may be required by 2020 for municipal and light industrial uses in USA (Cohen 2007). In California alone, combined agricultural, urban, and environmental demands already exceed average supplies by 1.23 109 m^3 (326 billion gallons) per year, while 50% of the nation's future population growth is forecast to occur in CA, FL, and TX regions already experiencing water shortages.

One of the highly populated and driest continents in the world is Australia (Australian Government National Water Commission 2005). Its water supply sources are continuously being jeopardized due to climate change patterns of severe droughts followed by forest fires and floods. The continent experienced worst drought for many years since early 2000s (Hall et al. 2011). Similar to California in USA, 10–15 years of low rainfall (El Saliby et al. 2009) known as "millennium drought" (most dry period in more than 100 years) has been the cause for the urgent rise of desalination and water reclamation plants in Australia.

Water Scarcity Due to Overuse

Population growth, urbanization, and economic development in many regions of the world have caused overuse of water (Kumar and Singh 2001). Population growth alone stimulates the need for additional water resources for meeting the basic necessities of water for food production and hygiene and commodities. Some other causes for overuse are related to industrial processing of water due to high living standards which give rise to use of electronic devices and tourism where luxurious use of freshwater is a necessity. In some regions of the world, there is a situation called "Artificial shortage of surface water" which is caused by the excess withdrawals than the actual need (Slavikova et al. 2017). This happens due to poor water demand management. As the excess withdrawal becomes a norm, this leads to a situation where the availability of surface water declines, additional costs may be incurred to provide these excess volumes.

Water Scarcity Due to Anthropogenic Pollution

Environmental pollution due to human activities such as domestic sewage, effluents originating from agricultural, concentrated animal feed (CAF) operations for dairy and meat production, illicit discharge of construction and industrial wastewaters and other pollutants originating from storm water, heavy floods, and recreational activities may reduce availability of acceptable quality raw water for human consumption (Dokulil et al. 2000).

Water Scarcity Due to Physical and Political Barriers

In some cases, water resources may be available in adequate quantities but at a distance that cannot be economically reachable (Molden 2007). This is particularly true for rural communities in underdeveloped countries. This can be named as a physical barrier. This also relates to geographical barriers across the nations that will not permit transport of water. The political barrier relates to those conflicts arising from the political interests between the water-rich and water-scarce regions.

Issues Caused by Water Scarcity and Drought

Lack of access to drinking water and basic sanitation: Water scarcity causes lack of access to clean drinking water required for basic sanitation (water needs for bathing, cooking, and cleaning) and hygiene. This results in use of available impaired waters which causes development of new diseases and other issues public health issues. Many children and infants loose lives due to consumption of unclean water.
Hunger and poverty: Regions facing drought and water scarcity often have limited production of essential crops and meat. This causes hunger and impacts the morality

of the people in these regions. Prosperity and well-being is affected severely leaving populations in poverty. Poverty and the drive for ensuring reliable supplies of food will cause internal and external conflicts.

Education: Poverty and lack of basic sanitation will lead to lack of education. This causes the communities lacking education are not necessarily knowledgeable in managing the local, limited water supplies. They need education to understand the value of water and to manage this precious source in an equitable and beneficial manner.

Water Quality in Drought Areas

Groundwater Quality

Increasing withdrawals of freshwater due to population explosion and industrialization from current dwindling surface water sources have led the populations around the world to depend on the ground water sources for domestic and agricultural uses. These resources are finite and deplete with continued activity called as "mining" for our increasing demands. Fig. 1 shows the regions in the USA where groundwater depletion is highly pronounced. In some regions, though they were originally water-rich, the depletion rates are very high (Konikow 2013). This is usually associated

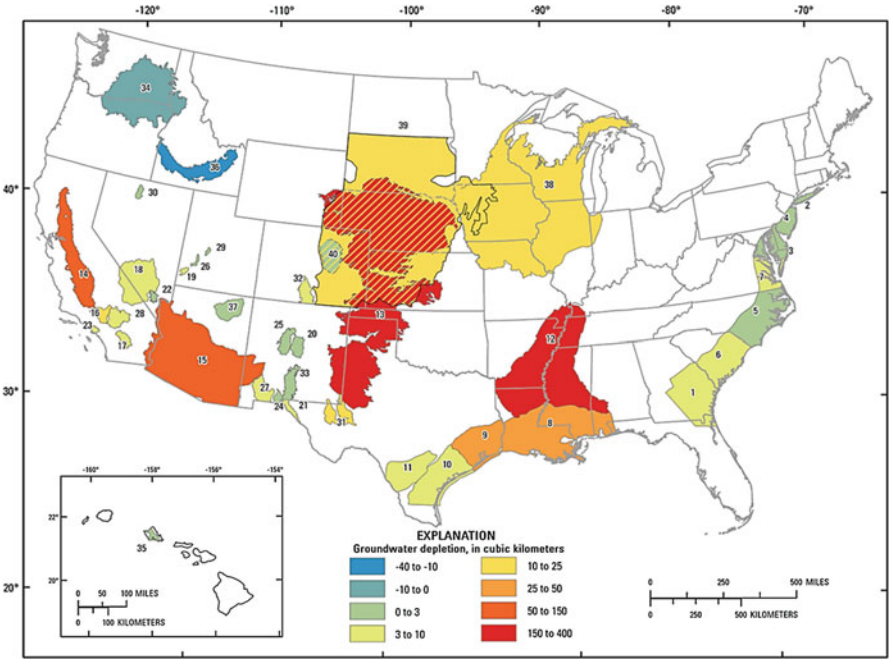

Fig. 1 Groundwater depletion in the United States between 1900 and 2008 (Konikow 2013, USGS)

with increased withdrawals for irrigation as in the case of Mississippi. In some cases, it is compounded by the water needs due to excessive population growth, for example, the water crisis in Central valley of California.

As the quantity declines in many groundwater reserves, quality of the source becomes unsuitable for many purposes when other undesired groundwater chemistry that could take place when soil and water contact. In many parts of the world, ground water is not suitable for direct consumption. They are impaired either due to naturally occurring hazardous substances such as uranium, fluoride, and arsenic (Yarlagadda et al. 2011). In some cases, the impairment is caused by illicit discharges by industrial sectors. Often, these ground waters also contain high dissolved solids, leading to their categorization as brackish waters. Traditional treatment techniques are not adequate to remove the dissolved solids. For instance, two-thirds of the continental United States including New Mexico has large volumes of saline water sources. The total volume of ground water in aquifers in New Mexico is estimated to be 20 billion acre-feet; however, 75% of the groundwater is too saline (10,000–35,000 ppm) for most uses and the remaining 25% of the ground water contains dissolved concentrations of lower than 2000 mg/L.

Brackish Groundwater

Although there are many groundwater sources available in some parts of the world, they are often not suitable for direct use. These sources are highly saline which requires for additional treatment to remove the salts to produce potable water or water suitable for other nonpotable uses. Similar to many parts of the world, some regions of the United States, especially southwestern part, are in critical need of potable water supplies. As mentioned earlier, extreme population growth and industrial development coupled with unsustainable practices have resulted in unmanageable water demands. As shown in Fig. 2a, some of the highly populated cities are located in water-scarce regions. In addition, about 50% of the population is concentrated in coastal regions where access to freshwater is an issue (Fig. 2b). Other regions that are in desperate need for freshwater are the inland communities which are committed to agriculture and irrigation as shown in Fig. 2c. It can be noted that groundwater sources in many of these regions contain high dissolved solids concentrations which render them not suitable for most potable uses including irrigation. Nontraditional technologies such as membrane and thermal desalination processes should be considered to treat these water.

Water Scarcity Around the World

At present, one-third of the world population is lacking access to clean water and by 2025, 1.8 billion people will experience absolute water scarcity, and two-thirds of the global population will be living under water-stressed conditions (Macedonio et al. 2012). Many parts of the world are reaching a critical situation of water scarcity (see Fig. 3). Water scarcity is classified into physical water scarcity and economic water scarcity (Rijsberman 2006). Physical water scarcity means that there are simply no adequate water resources to meet the current needs. The economic water scarcity refers to a situation where the water sources are available in abundance (water resource

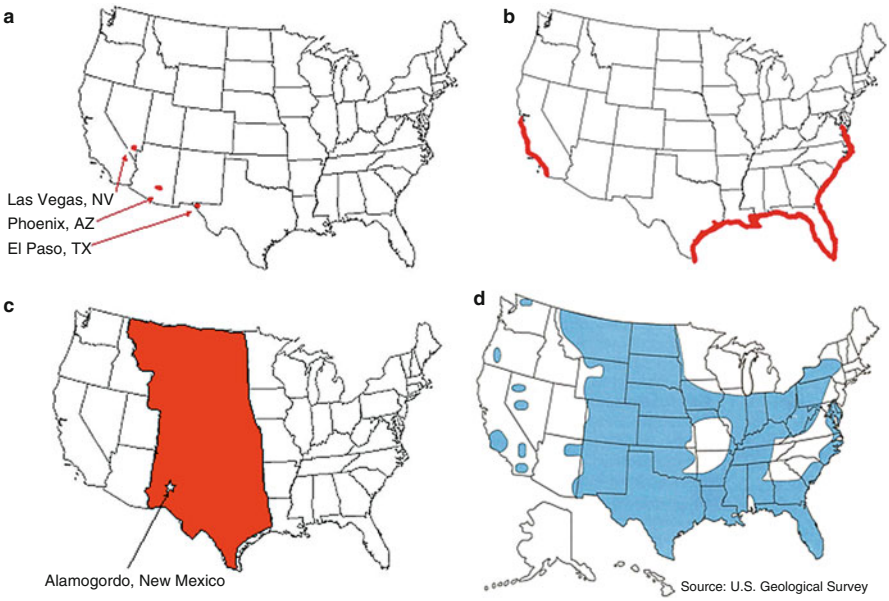

Fig. 2 Water-scarce regions and ground water quality in the USA: (**a**) major water-scarce, populated inland cities in USA, (**b**) highly populated coastal communities, (**c**) water-scarce inland rural communities due to excess irrigation needs, and (**d**) brackish water reserves in the USA

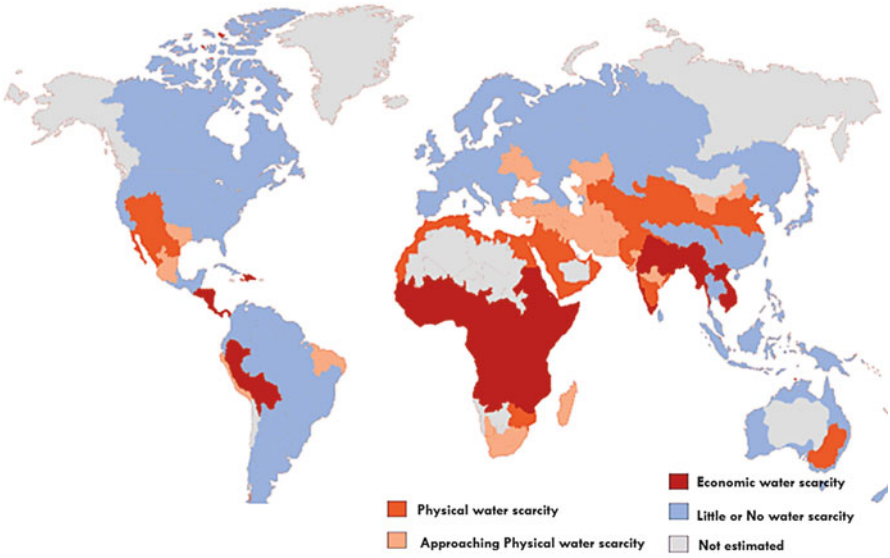

Fig. 3 Different types of water scarcity around the world (Fewresources.org)

availability is higher than the withdrawal, or the resource capacity is underutilized), but the mechanisms to acquire access to these sources have not been established or are influenced by human, institutional, and financial capital limitations. This could be because of the economic issues, polluted water resources, and political and social and climatic issues. In most cases, the economic water scarcity refers to a situation where the affordability to obtain clean water has been jeopardized due to economic issues. Physical water scarcity is currently experienced in southwestern region of the United States which includes California, Arizona, New Mexico and Texas and Mexico, Middle Eastern and North African countries (MENA region) and southeastern European countries, Southern India, Pakistan, Mongolia, Afghanistan, Kazakhstan, Turkmenistan, Uzbekistan, Tajikistan, and western Australia. Economic water scarcity is experienced in central and Latin America including Caribbean region, South and central Africa, North India, some parts of China and some other Asian countries. In some of these countries, desalination supported by renewable energy sources could be implemented as a sustainable option, but many nontechnological barriers need to be overcome.

Water Stress Regions in the World

Over the past century, the worldwide population has tripled, while the water use or water withdrawals increased more than six-fold which suggests increasing water consumption mostly driven by improved living standards and industrialization all over the world. Many regions realize the inadequacy of existing freshwater sources to meet ever growing water demands. In some cases, sufficient surface and ground water sources to even meet current demands for water supplies are not available. This situation is called stress. Fig. 4 shows the water stress regions around the world. It can be noted that the high populated countries with economic development are facing severe stress, while some developed countries such as Australia are facing water stress due to climate change and desertification.

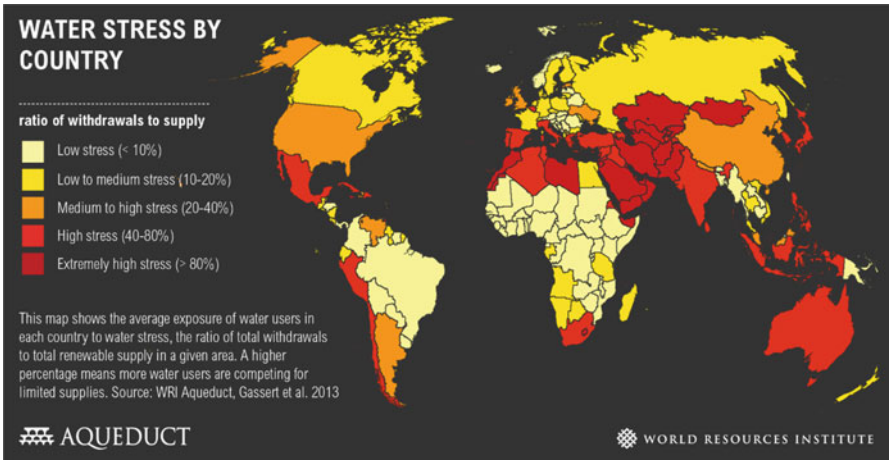

Fig. 4 Water stress levels around the world (wri.org)

Solutions to Water Supply Issues in Drought Areas

Water supply issues in drought areas can be addressed using different approaches. This is a multifaceted problem which requires involvement from users, governing bodies, industrial partners, and research and development and regulatory agencies. Figure 5 shows the approaches that should be considered for a holistic management of the problem. The solution includes mitigation of current demands where possible with proper governance and supply enhancement to meet the demands by management and technological approaches.

Demand Mitigation

Conservation activities such as retrofitting water-saving fixtures in domestic applications, industrial production, and other public amenities where water use is a must. Agricultural sector contributes to most of the water loss followed by power production industry. Water conservation practices in irrigation practices can make significant improvement in this aspect. About 30–75% of the water withdrawals are lost in power production, especially in cooling applications. Water losses due to evaporation can be reduced by considering other novel approaches such dry cooling and among others (Gude 2015a).

Water is often considered abundant natural source available freely in abundance. This is a misperception that many of the communities carry across generations. Water should be realized as a precious and dwindling commodity to ensure its availability for future generations to come. This can only be achieved by enforcing appropriate water pricing dependent on the socioeconomics of a community. This will enable improve user behavior in terms of responsible use and concern for its protection and management. This approach requires active involvement of public,

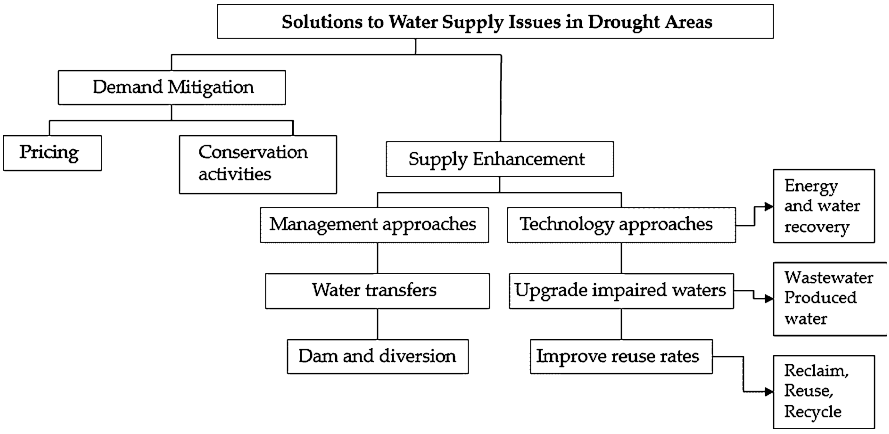

Fig. 5 Solutions to holistic management of water supply issues in drought areas

administrators, and industrial partners. Public education and outreach is a key to achieve success. The main drawback is that the progress can be slow as it depends on the user psychology, preparation levels, and willingness to protect the valuable resource.

Demand mitigation approaches do not solve the supply problem directly, but they can establish a system in which water supply options can become more feasible and affordable.

Supply Enhancement

Water supplies can be enhanced following management and technological approaches. Water management approaches include immediate or near-future construction activities or those intended for long-term sustainability. Short-term and immediate approaches involve water transfer acts across the regions. The main mechanisms in which water supply enhancement can be done is by: intercepting (rain harvesting), diverting (water diversions), storing (dams and reservoirs), and transferring water (transport water among basins or regions). The following paragraphs discuss the

Water transport – Water management can be done by considering transport of water from water-rich region to a water-scarce region if affordable water costs can be achieved through this mean. For example, many countries such as Singapore, USA, and other European countries already practice this approach as a water supply alternative (Gude 2016). International transfer and interstate transfer is possible depending on the situation. The main drawback with this option is that this arrangement may create some political stress and economic dependence on water-rich countries. Construction of dams and water flow diversion can be considered as other feasible approaches when dealing with the surface water sources with seasonal and geographical changes.

Technology development – Technological approaches include innovation in the present technology based on scientific discovery and practical feasibility. Many technologies are available that produce high quality and safe drinking water or water suitable for other beneficial uses. Technological approaches depend on the type of source water as well as the purpose of the end product. Surface and ground water sources with less than 3000 mg/L total dissolved solids (TDS) can be treated with conventional technologies such as coagulation, flocculation, lime-softening, and sedimentation and filtration processes. Membrane technologies can also be used to remove the TDS effectively. Ground waters and seawaters having TDS higher than 3000 mg/L should be treated using membrane or thermal desalination technologies.

Energy efficiency and water recovery – As shown in Fig. 5, energy efficiency and water recovery are the two important factors in determining the feasibility of a desalination technology. Membrane technologies offer superior performance at lower specific energy consumption, while thermal technologies require both thermal and electrical energy. In general, both technologies are energy-intensive and cost-prohibitive. However, the absolute necessity for water makes these technologies viable. In some regions where low-cost thermal energy is available as a result of power generation, thermal

technologies are more feasible. The reason for utilization of thermal technologies is also often associated with high TDS seawater and seasonal fluctuations in temperatures. Energy recovery schemes have offered a less energy-intensive desalination option in both membrane and thermal technologies. Reuse and recycling is the fundamental principle followed in thermal technologies, whereas the advent of energy recovery devices has made the membrane desalination a feasible option despite high capital and maintenance costs. More details on the energy recovery aspect are not within the scope of this chapter and hence not discussed here. However, readers are referred to other publications in this area (Gude 2011, 2015a, b).

Rain harvesting – Some drought regions face water scarcity not because of low precipitation levels, rather due to lack of methods for capturing the excess water during rainy events which is usually drained or lost to the environment. Rain harvesting has been practiced for centuries as a simple, proactive alternative to deal with the dry seasons. Rain harvesting can be done at very small to large-scale applications depending on the water needs. Capturing the rain water itself can be done many ways (Sharma and Smakhtin 2006) which are in situ harvesting, cisterns/tamks/kunds, Khadin system, Nadis/tobas, check dams, and percolation tanks.

In situ rainwater harvesting is practiced all over the world by developing field bunding, contour bunding, ridging, conservation furrows, key line, and contour cultivation as measures. Vegetative barriers to replace or supplement earthen bunds that emerged in 1980s have been tried in a number of countries with mixed results. Constructed microcatchments is another method to capture the rain water in in situ conditions. Cisterns/tankas/kunds that are essentially underground storage tanks used most commonly for centuries and more predominant in the Indian arid zone, Pakistan, Sri Lanka, China, and several other countries, generally constructed for storage of surface runoff.

Run-off water harvesting based farming (khadin farming) for rain water capture and moisture conservation is well suited in deep soil plots surrounded by some sort of natural catchment zone. Nadis/tobas are small to medium sized excavated or embanked village ponds, for harvesting meager precipitation to mitigate the scarcity of drinking water and domestic needs in water scarcity regions. Pond water is available for periods from 2 months to a year after rain, depending upon the catchment characteristics and amount and intensity of rainfall. The nadis range from 1.5 to 12 m in depth, 400 to 700,000 m^3 in capacity and have drainage basins of various shapes and sizes (8 to 2000 ha) (Sharma and Smakhtin 2006).

Series of check dams on natural streams provide for artificial recharge by restricting the surface run off and by making additional water available for percolation. The surface water is impounded during monsoon behind the structure and spread over the entire streambed and thereby increasing the wetted area. The impounded water helps in replenishment of groundwater. Percolation tanks are generally constructed on the small streams or rivulets with adequate catchment for impounding surface runoff. These tanks are used entirely for recharging the aquifer through percolation. In comparison to ponds, percolation tanks conserve water to a greater extent because the filling and recharge occur mostly during the monsoon when the evaporation rate is about the half of potential rate in summer through which ponds contain water.

Some of the above methods can be implemented at small-scale, while the others are more suitable for large-scale water management. Large-scale rain harvesting in drought-prone areas can be realized as a strategic tool for drought mitigation, if it can be implemented through the adoption of relevant policies and investments at different levels such as user, watershed, urban locality, district, state, and a country.

Water reclamation and reuse – Supply enhancement can be achieved by utilizing impaired waters such as treated secondary effluents (wastewater) for water reuse related to nonpotable uses, and other impaired waters used in process cooling and heating applications and produced waters from shale gas production. As the conventional water supplies are diminishing and the need for water reuse is inevitable, water reclamation and reuse allows for securing the longevity of available water resources for more critical needs, while the recycled water can be used for nonpotable uses. The most common nonpotable uses include irrigation, for example, agricultural, horticultural, and green spaces; environmental purposes; and domestic nonpotable uses such as third pipe systems. These uses are often employed to reduce the pressures on other existing water sources or to provide a water source where a suitable one does not already exist.

Water reuse has been practiced for over 5000 years; however, during the last 100 years, efforts have been made in many regions of the world, for the production of high-quality reused water, following strict quality guidelines (Angelakis and Gikas 2014). Wastewater sources for water reuse can be of four types: municipal wastewater, industrial wastewater, agricultural wastewater, and grey water (wastewater from clothes washers, bath tubs, showers, and sinks). Reclaimed water reuse for other potable uses has been very well accepted in many parts of Australia (Dillon 2009). Grey water reuse is widely practiced in United States, Europe, and many other countries in Middle East. Around 75% of wastewater is reused in the Middle Eastern countries. United States has a long history of water reuse beginning in 1912 for watering the lawns in California. USEPA has set the guidelines for the water reuse practice based on the type of use. The quality of the product water for reuse differs for various applications such as urban reuse, agricultural reuse, recreational impoundments, construction uses, cooling uses, groundwater recharge of potable aquifers, and augmentation of surface suppliers (WEF 2006). Kuwait and Qatar take lead in water reuse program with more than 10% of reclaimed water out of total water supply (Madwar and Tarazi 2003).

Water reuse implementation – Water reclamation and reuse programs have been widely adopted across the world in view of the increasing demands for water supplies. However, the contribution from this approach still remains to be unsubstantial (Miller 2006). Including water reuse option in the water supply and management portfolio helps to realize the true value of the contribution from this approach. It can be instrumental in water policy development and its implementation, which may lead to long-term sustainability (especially, availability) of these resources. However, including water reuse in the overall water supply and management portfolio can create many challenges rising from water governance, health risks, regulatory aspects, and public perception. Other requirements would be the need for developing innovative technologies, technology transfer, and novel applications and public education. Novel technologies are essential to remove the emerging contaminants such as endocrine disrupting chemicals and pharmaceutical and

personal care products. In some regions, groundwater recharge or aquifer storage is considered a long-term sustainability approach.

Options for water reuse implementation – Several options can be considered to make the water reuse and recycle programs to be effective (see Fig. 6). These options are education and outreach, incentives, removing barriers, and mandates and regulations (GE 2015).

Education and Outreach may include programs that promote certification programs and recognition awards. Programs to disseminate the scientific information and general benefits and essential facts about the water reuse by education and outreach efforts. Educating the users on water withdrawal trends, consumption, discharge, and reuse data can help create interest in water reuse implementation.

An incentive program including direct subsidies, reductions in payments to the government, payments for water reuse, adjusting pricing mechanisms, regulatory relief for recycled water users, government procurement of water recycling/reuse equipment, and structuring of water rights to reduce the use of potable water can be beneficial in supporting the water reuse implementation.

Regulatory reliefs may include modification of local regulations depending on the application especially in terms of water quality standards, revising plumbing codes to allow dual piping, and monitoring permitting and inspection requirements for recycled water.

Creating mandatory requirements should consider utility planning and management to develop plans for recycled water, restricting potable water to human or food-related uses, and requiring the use of recycled water for agriculture and other nonpotable uses and requiring water recovery systems.

Role of desalination technologies – Finally, combining water reuse and desalination mechanisms may help achieve supply enhancement (Gude et al. 2010).

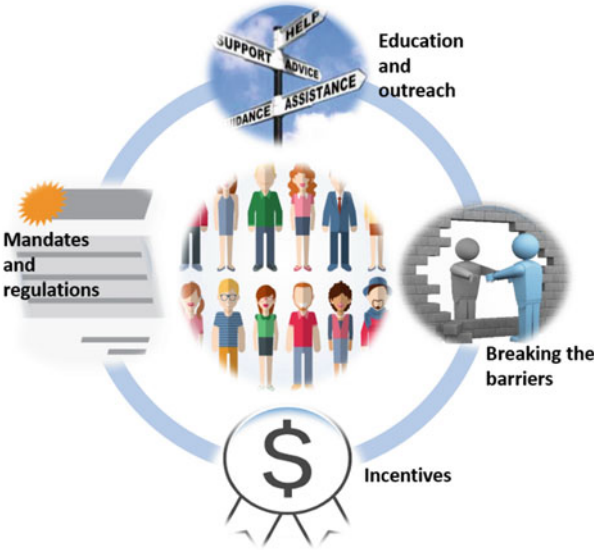

Fig. 6 Options for water reuse implementation

Technologies available for these two approaches make it possible to convert wastewater into high-quality water that suits various industrial applications because these technologies share similar characteristics. Feed source for both is an impaired water source whether it is seawater or produced water. The technology that is used most widely for water reuse or desalination is based on membranes for several reasons. Desalination by reverse-osmosis membranes combined with the use of conventional pretreatment units or modern pretreatment technologies are now well-established methods of wastewater desalination techniques (Madwar and Tarazi 2003). Microbial retention is a major concern in water reclamation which can be achieved by microfiltration (MF) and ultrafiltration (UF) (Côté et al. 2004). MF and UF are employed as preferred pretreatment processes for nanofiltration (NF) or reverse osmosis (RO), i.e., the quaternary treatment step which can produce drinking or ultrapure process water quality. This dual membrane treatment concept plays now a major role in water reclamation schemes that are aimed at advanced levels of purification. Applications include several aquifer recharge projects (one even for indirect potable reuse) and dual water systems in households and industrial process water, or for mixed urban and agricultural uses. Water production costs to treat the effluent from the conventional activated sludge followed by membrane bioreactors through RO process have been compared with the seawater process. The total life cycle costs for the produced water from secondary effluent (RO) are two times cheaper than the traditional desalination process from seawater (SWRO). The advantages of the reclaimed process over the traditional seawater process are the following: no pretreatment required, higher recovery with higher flux rates at lower operating pressures (energy savings) and longer membrane life.

Affordability of Desalination as Water Supply Alternative

Energy requirements for desalination have fallen significantly in recent years. Although the energy budget for domestic desalination units appears to be reasonable, many communities around the world cannot afford these energy demands and associated costs. Figure 7 depicts the desalinated water affordability around the world. The vertical axis presents the cost per capita of desalinated water to all at all times. The horizontal axis depicts the ability to pay for water and it increases from left to right.

Four basic quadrants can be identified. The bottom right quadrant depicts situations where the costs of supplying water in a sustainable manner are low and countries' ability to pay is high. These situations are limited largely to rich humid regions, particularly in Western Europe and North America. In these countries, the main cost may pertain to assuring adequate water quality and pollution prevention. The top right quadrant pertains to regions where the per capita cost of clean water supply is high, but as these regions are rich these costs are still only a small share of the total gross national product (GNP) per capita. Thus, countries in this quadrant, such as the arid but rich Gulf oil states, can afford the high cost of clean water supply even when this includes large-scale seawater desalination. These countries may enjoy the desalinated water, despite their extreme first-order scarcity due to availability of ample nonrenewable energy sources and inexhaustible seawater sources. The bottom left area

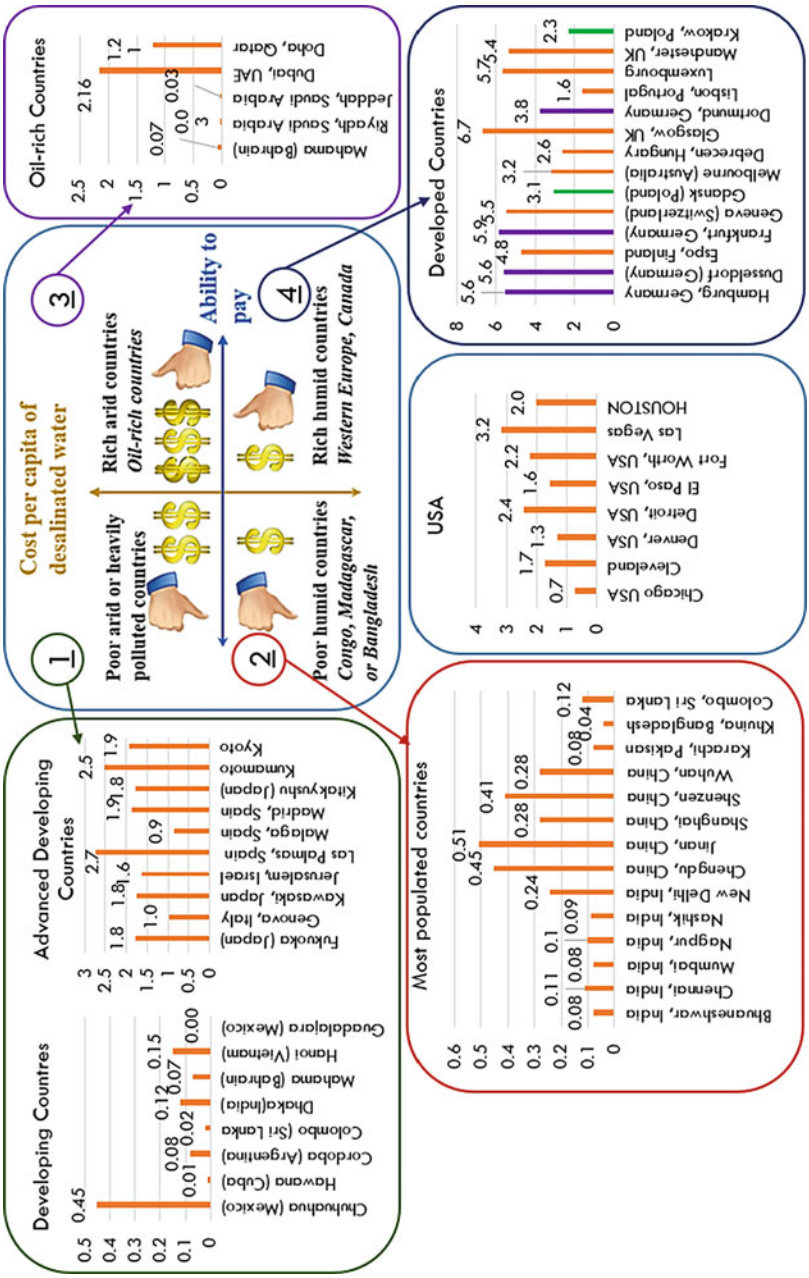

Fig. 7 Desalination affordability around the world (adapted from Gude 2016)

depicts poor regions with ample water resources. In these regions, the cost of desalinated water supply may be low, but as the GNP is also low even these comparatively low costs may become a significant burden. These countries do not suffer from first-order scarcity. Because of second-order scarcity and particularly low financial capacity, desalination may not be an attractive alternative. Examples of such countries would include Congo, Madagascar, or Bangladesh. The worst situation, however, is depicted by the upper left quadrant. This is the situation where the per capita cost of sustainable clean water to all people at all times would require high cost per capita and in which such costs would be a large share of the per capita GNP. Thus, regions in this situation may find that the costs of sustainable clean water are unaffordable for their citizens and especially through desalination technologies. The countries most prone to this situation are, naturally, poor countries in arid or semi-arid regions. Such countries may have had relatively high adaptive capacity, as demonstrated by traditional societal institutions and infrastructures, and yet may not have the financial resources to cope with rapid increases in population or pollution due to a weak economic base. Desalination alternative may not be meaningful for many low income countries due to very low GNP where other meaningful indicators could make more sense (Feitelson and Chenoweth 2002).

Protocol

Determining the Water Supply Options

This chapter described various alternatives and pathways for expanding freshwater supplies for drought conditions. It is important to consider demand reduction alternatives prior to considering the supply enhancement schemes. Water reuse and recycle programs reduce the stress on water sources, while the residual demands can be met with desalination alternative which should be considered a final resort.

Policies

Local Governmental Policy for Water Reuse Implementation

This chapter included four major approaches that local governments should consider to encourage water reuse and recycling alternatives. These include:

- Education and outreach (making public aware of water supply issues and need for reuse)
- Breaking the barriers (providing funding and technological support to implement)
- Incentive program (such as tax reliefs and carbon credits for water reuse)
- Regulatory reliefs (related to water quality for reuse options)
- Mandates and regulations (strictly enforcing water reuse as mandatory for new developments).

Dictionary of Terms

- **Desalination** – Is a process that removes dissolved salts and minerals from saline waters. Saline waters include brackish groundwater and seawater.
- **Brackish water** – Is water that has higher concentrations of salt than in freshwater, but not as much as seawater.
- **Microfiltration** – Is a type of physical filtration process where a contaminated fluid is passed through a special pore-sized membrane to separate microorganisms and suspended particles from process liquid.
- **Nanofiltration** – Is a relatively recent membrane filtration process used most often with low total dissolved solids water such as surface water and fresh groundwater, with the purpose of softening (polyvalent cation removal) and removal of disinfection by-product precursors such as natural organic matter and synthetic.
- **Reverse osmosis** – A process by which a solvent passes through a porous membrane in the direction opposite to that for natural osmosis when subjected to a hydrostatic pressure greater than the osmotic pressure.

Summary Points

- By 2050, the world's population will have grown from 7 to 9 billion. This enormous upsurge means the need for water will increase by over 50%, if we continue our consumption at the current rate. Many places in the world just do not have enough water. This is partly due to climate change, but especially due to increasing urbanization.
- Increasing demands for freshwater supplies can be met by management approaches based on the elements of demand mitigation and supply enhancement.
- Public education about the value of water and adverse effects of water impairment and water scarcity will help implement some of the management strategies for demand mitigation.
- Water reclamation, recycle, and reuse should be considered as a primary alternative to demand mitigation. Suitable technologies should be developed for this approach.
- Supply enhancement can be achieved by developing novel technologies. Technology advancement for treating high saline ground and surface waters should be considered for efficient utilization of these sources
- Improving water conservation practices can be the first step in demand mitigation. Sustainable water management practices should be explained to the farmers and other industrial users to reduce the water withdrawals and consumption.
- Improving sewage system as well as supporting clean water initiatives will help both ensure healthy surface waters which in turn can serve as safe reserves and sources for freshwater supplies.
- Governance and financing the clean water ad environment initiatives can help implement a long-term sustainable freshwater supply system in drought influenced regions.

Abstract

Providing clean water for human consumption has become a major challenge at local, regional, national, and global levels due to excess population growth. The direct domestic water demand and the indirect industrial, agricultural, and environmental water needs to sustain this growth is expected to place serious strains on the currently available water resources. Water reuse and desalination technologies can provide a solution to this issue if implemented in a sustainable manner. Provision of clean water inevitably requires energy, which is currently being

provided essentially by nonrenewable fossil fuels which is not a sustainable approach. This chapter discusses various options available for enhancing water supply in drought regions. Water reuse and desalination technologies have been discussed in detail. Energy needs and integration of renewable energy sources, energy recovery and process integration concepts have been discussed. Future research directions to develop energy-efficient water supply technologies are provided.

Introduction

Freshwater is an essential commodity for continued existence of human kind. Recent statistics show that currently 2.3 billion (~35 % of current world population) people live in water stressed areas and among them 1.7 billion (~25% of current world population) live in water scarce areas (Misra and Kupitz 2004; Greenlee et al. 2009). The situation is going to worsen further in the coming years. It has been estimated based on the current demographic trajectory; the human population will surpass 10 billion by the year 2030 (Ehrlich and Ehrlich 1993; McFalls 1991). Since 1990, the global rate of water withdrawal from surface and groundwater sources has increased six-fold, while the world population increased only three-fold. Water withdrawal rates are projected to at least double in the next two decades. Renewable water resources are on the decline in many countries due to increased population and rapid industrialization. Traditional fresh water resources such as lakes, rivers, and groundwater are overused or misused; as a result, these resources are either diminishing or becoming saline. As countries continue to develop and cities expand, few new water resources are available to support daily fresh water needs. Some areas of the world have a very low renewable energy sources (Greenlee et al. 2009), for instance, total annual renewable water resources 5500 m^3 per capita in Africa, about 3500 m^3 per capita in Asia, and as low as 636 m^3 per capita in the Arab world. The increased use of the fixed water resource in response to rising demands is not only reducing water availability, but also jeopardizing water quality (Hamoda 2004). While water conservation and reclamation/recycling practices provide partial solution to the water scarcity, appropriate technological solutions are considered to augment water resources through nonconventional sources (Hamad and Abdul-Karim 2005). Many of these technologies are based on desalination principle, separation of salts and/or other ions from seawater or brackish ground waters. As discussed in the previous chapter, water supply issues can be addressed by demand mitigation and supply enhancement. Demand mitigation can be implemented by water reclamation and reuse, and supply enhancement can be achieved through desalination processes which will be discussed in this chapter.

Water Reuse Technologies

Various chemical and microbial contaminants should be removed to make the wastewater sources suitable for potable or nonpotable uses. Advanced treatment using chemical and physical separation mechanisms is often considered as a treatment scheme. Numerous treatment options, including engineered and natural treatment processes, are available to achieve this goal. Selection of a suitable treatment scheme depends on the specifics of water quality objectives intended for specific uses (Miller 2006). Advanced treatment processes are also capable of removing emerging pathogens or contaminants such as endocrine disrupting chemicals and pharmaceutical and personal care products (Fast et al. 2017).

Natural systems are considered in treatment schemes where the water quality objective is a potable water reuse. These involve "natural barriers" such as soil aquifer treatment, wetlands, and other land application for soil infiltration to provide natural treatment of organic and nutrient compounds and microbial contaminants (Gude et al. 2013; Martinez-Guerra et al. 2015). This is achieved by providing a retention time suitable for natural attenuation of contaminants followed by blending with the water sources. Application of natural systems is subject to climate and hydrogeological conditions. These systems are not the preferred method currently due to lack of standardized guidelines for design and operation.

Engineered solutions are designed by taking the advantages of chemical, physical, and characteristics of the contaminants in the water (Gude 2015a). Conventional sand filtration is commonly used to remove the suspended solids, but membrane filtration processes such as microfiltration and ultrafiltration have become a more common practice in recent years. Chemical coagulation, precipitation, neutralization, oxidation, hydrolysis, and other reactions are considered for organic contaminant removal. Trace organics including volatile contaminants can be removed using granulated organic carbon (GAC) filters and ion exchange columns. Nutrients and other microbial contaminants can be removed using natural systems such as wetlands, soil application, and air-stripping and reverse osmosis processes. Disinfection is performed using chlorination, and/or ozonation, and/or ultraviolet exposure (UV), depending on the specific objective of the water reuse application. Table 1 shows the different membrane technologies and their specific characteristics in water treatment and desalination applications (Baker 2000; Tsuru 2001; WEF 2006). Microfiltration and ultrafiltration are used in lieu of conventional sand filtration process due to higher efficiency and smaller footprint. Nanofiltration can be used to remove some specific contaminants at a molecular weight cutoff with much lower specific energy consumption compared to reverse osmosis. Salts and other dissolved and micro- or trace contaminants can be removed using reverse osmosis membrane filtration.

Some examples of water reuse applications in the United States are shown in Table 2. It can be noted that lime coagulation, clarification, and media filtration are used in plants constructed in 1960s through 1990s. Membrane filters have become more dominant in the plants constructed after 1990s, mainly due to development of highly efficient membrane materials with lower energy consumption. Soil aquifer

Table 1 General characteristics of membrane technologies for water treatment and desalination (Adham et al. 1996)

Membrane type	Particle capture size	Typical contaminants removed	Typical operation pressure ranges	Key applications
Microfiltration	0.1–10 μm	Suspended solids, bacteria, protozoa	0.1–2 bar (1–30 psi)	Water treatment plants, pretreatment in desalination plants, the preparation of sterile water for industries, such as pharmaceuticals
Ultrafiltration	ca. 0.003–0.1 μm	Colloids, proteins, polysaccharides, most bacteria, viruses (partially)	1–5 bar (cross-flow) 0.2–0.3 bar (dead-end and submerged) (3–80 psi)	Drinking water treatment, the pretreatment process in desalination, and membrane bioreactors
Nanofiltration	ca. 0.001 μm	Viruses, natural organic matter, multivalent ions (including hardness in water)	5–20 bar (70–220 psi)	Treatment of fresh, process, and wastewaters
Reverse osmosis	ca. 0.001 μm	Almost all impurities, including monovalent ions	10–100 bar (800–1200 psi)	Treatment of fresh, process and wastewaters, desalination of sea water

treatment is also used often in plants where the intended end use is the recharge of local water supply aquifers.

Desalination Technologies

Desalination is a process that separates dissolved solids (mostly salts) from a saline water source to produce fresh water driven by an evaporative process (thermal desalination) or a mechanical filtration (membrane separation) process. Thermal desalination is based on the principle of evaporation of freshwater in the form pure water vapors from the saline water and condensation of the same on a cold surface to produce nearly pure water free of dissolved solids. The membrane processes employ a physical barrier (membrane) which allows the water molecules to permeate through to produce permeate with considerably low concentration of dissolved solids. Thermal processes require large quantities of heat energy to evaporate the pure water and the membrane processes require high-quality electrical energy to apply the mechanical pressure on the membrane to cause separation.

Table 2 Examples of water reuse plants and their operating schemes in the United States (National Research Council 2012)

Location	Type of indirect reuse	Project size MGD (10^3 m^3/day)	First installation Year	Current status	Treatment technologies

Thermal desalination technologies include solar distillation (SD) such as solar stills and active and passive solar desalination systems, multieffect evaporation/distillation (MED), multistage flash distillation (MSF), thermal vapor compression (TVC), and mechanical vapor compression (MVC). Membrane processes include electrodialysis (ED) and reverse osmosis (RO). Other processes that involve a combination of the two principles in a single unit or in sequential steps to produce pure or potable water include membrane distillation (MD) and reverse osmosis combined with MSF or MED processes (Gude 2015b).

Desalination has become an important source of freshwater supply and has taken place for a long time, predominantly by means of thermal processes (over the past 60 years) such as multistage flash distillation (MSF) or multieffect distillation (MED), followed by membrane processes developing over the past 40 years (Hamad and Abdul-Karim 2005; Gleick 2006). Desalination of all types is both cost- and energy-intensive (Pettersen et al. 1996). The process typically requires the conveyance of the water to the desalination plant, pretreatment of the intake water, separation of salts, disposal of the concentrate (brine), and process maintenance (Shannon et al. 2008). The energy requirements for desalination vary in the range of 3.5–25 kWh/m^3 depending on the source of water, desalination method, and capacity. Membrane technologies represent the lower end of the scale with specific energy consumption in the range 3–9 kWh/m^3, while thermal technologies are on the higher end of the scale with specific energy consumption in the range 10–25 kWh/m^3. For membrane technologies, the energy requirements vary with feed water concentration as it is the direct relation between the osmotic pressure and the dissolved salt concentration. This is the reason that reverse osmosis or nanofiltration units are able to remove the salts from low salt concentration waters with specific energy consumption as low as 0.5–3 kWh/m^3 of freshwater (NRC 2008).

Membrane Desalination Technologies

With increasing energy costs and availability of improved membranes properties, it has been recognized long ago that membrane-based desalination plants will provide cost-effective and energy saving solution for freshwater supply. Membrane processes are widely used for desalination due to their simplicity in operation, relatively lower capital and operating costs, and lower energy requirements. The dominance of membrane technologies in seawater, brackish water and surface water desalination has already shown its presence in many areas of the world. For example; in the United States, the share of membrane technology-based desalination among existing desalination plants is 75%. The share of MSF, a predominant thermal process, has decreased by 10%, whereas about a similar percentage of increase has been noted for RO, a leading membrane technology for desalination in Middle Eastern countries (Mehdizadeh 2006).

Membrane processes offer several advantages for desalination applications. The advantages of the membrane processes can be listed as (1) low energy consumption, (2) moderate costs (lower capital and operating costs), (3) easier operation and

maintenance, (4) compact and modular units, flexibility in capacity expansion, short construction periods, (5) lower start up and delivery times, (6) advances in RO membranes and technology, (7) decoupling of power and desalination plants (due to water demand growth factor of 11% over 4% for power), (8) possible hybridization of three or more processes, (9) ambient temperature process, and (10) lower environmental impacts. Apart from the above, the membrane technologies have wide range of applicability, such as desalting, disinfection by-product (DBP) control, disinfection (pathogen removal), clarification, and removal of inorganic and synthetic organic chemicals which make the use of membrane processes universal (Jacangelo et al. 1997; Mohsen and Al-Jayyousi 1999; Duin et al. 2000; Glucina et al. 2000; Darwish et al. 2003; Judd and Jefferson 2003; Cath et al. 2005; Mehdizadeh 2006; NRC 2008; Bayod-Rujula and Martinez-Gracia 2009).

The disadvantages of membrane technologies are, in general, RO is not generally favored for seawater desalination due to high salinity (45,000 ppm of TDS in the Persian Gulf), high temperatures (40 °C in the Persian Gulf), high silt density, high bacteria activity, and pollution. However, reverse osmosis is being considered recently for seawater desalination as a first option. The most important disadvantage of membrane systems is the problem of fouling. Pretreatment is very important for RO systems. However, there has been a recent inclination towards using RO in seawater desalination, both for new plants and in connection with present MSF plants, due to a reduction in energy requirements and lower operation costs (Mehdizadeh 2006).

Predominant membrane technologies for desalination are namely reverse osmosis (RO) (seawater and brackish water), electrodialysis (ED) (brackish water), and membrane distillation (MD) (seawater and brackish water). Reverse osmosis and electrodialysis processes are well established worldwide. Membrane distillation is an emerging technology with great potential for large-scale applications. General characteristics of these membrane technologies are presented in Table 1 (Tsuru 2001; WEF 2006; Baker 2000).

Reverse osmosis (RO): Reverse osmosis process is a nonphase change operation where a semi-permeable membrane (allowing water to pass through but not the salts) is used to separate the freshwater from the saline feed water. An external pressure is applied to exceed the osmotic pressure of the feed water to allow the freshwater to pass through the membrane (Gude 2015b). The amount of energy required for mechanical pumping to create the external pressure depends on the feed water salt concentration. This process does not require heating or phase-change of the feed water. A typical RO plant consists of four major components: feed water pretreatment, high-pressure pumping, membrane separation, and permeate posttreatment (Ayyash et al. 1994). The pretreatment step involves removal of large suspended solids, bacteria, and colloidal matter that may cause damage to the membrane operations. A typical pretreatment includes chlorination, coagulation, acid addition, multimedia filtration, micron cartridge filtration, and dechlorination (Al-Sheikh 1997; Durham and Walton 1999). Additionally, the fouling problems should be avoided by using cleaning solutions (Amjad 1997). The type of pretreatment mainly depends on the feed water characteristics, membrane type and

configuration, recovery ratio, and product water quality (Gude 2011). Post-treatment of the permeate (fresh water) is done by re-carbonation and blending with feed water (Gude 2011).

Reverse osmosis and nanofiltration processes require severe pretreatment of the feed water to avoid membrane fouling associated maintenance and replacement issues including the costs. Chemical coagulation followed by conventional sand filtration or membrane filtration can be used for the pretreatment. Table 3 shows a comparison of the conventional vs. membrane filtration technologies. In several aspects, conventional filtration works similar to the membrane filtration. Conventional filtration requires lower capital costs but with larger footprint and less reliable microbial separation. Membrane filtration is expensive when compared with conventional filtration but provides higher quality effluent.

Electrodialysis (ED): The operating principle of this method is based on the migration of ionic salts towards their respective counter charge electrodes. Selective membranes that allow passage of either anions or cations in an alternating fashion result in concentrate and product streams. The anions can pass through the anion-selective membrane, but are not able to pass by the cation-selective membrane, which blocks their path and traps the anions in the brine stream (Strathmann 1993). Similarly, cations move in the opposite direction through the cation-selective membrane under a negative charge and are trapped by the anion-selective membrane.

A typical ED system includes a membrane stack with a number of cell pairs, each consisting of a cation transfer membrane, a demineralized flow spacer, an anion transfer membrane, and a concentrate flow spacer. Compartments for the electrodes are at opposite ends of the stack. The electrodes need regular flushing to reduce fouling or scaling (Gude 2015b). Recycling the concentrate stream and discharging concentrate to waste or blowdown is common and called feed-and-bleed mode. This is necessary because of the fact that there are sharp differences in flow rates between the product and brine streams. Diluate flow is about 10 times the flow of the brine stream; this difference in flows creates pressure imbalances, requiring concentrate recycle (Gude 2015b). An ED unit can remove about 50% to 94% of dissolved solids from a feed water, up to 12,000 mg/L TDS. Voltage input, and process configuration (number of stacks or stages), raw water quality, and membrane selection determine the salt removal efficiency of the process.

TDS removal is generally limited by economics. The cost of ED increases as the feed water TDS increases. Electrodialysis reversal (EDR) is similar to ED, but the polarity of the electrodes is regularly reversed, thereby freeing accumulated ions on the membrane surface. This process minimizes the effect of inorganic scaling and fouling by converting product streams into waste streams. This process requires increases membrane life and does not require chemical addition and improves membrane and electrode cleaning.

Membrane distillation (MD): Membrane distillation process can be described as a hybrid process since it combines thermal evaporation and membrane separation principles in a single process unit. The feed water (saline water) is heated by an

Table 3 Comparison between conventional pretreatment and membrane pretreatment (Rosberg 1997; Wolf et al. 2005; WEF 2006; Vedavyasan 2007)

Parameter	Conventional treatment	MF	UF
Membrane pore size	NA (media effective size 350–2000 μm and smallest particle removed 8–12 μm)	0.03 to 10 μm	0.002 to 0.1 μm
Feed pressure (psi)	64		82
Chemicals required		Coagulant or powder activated carbon	
10 log removal	1 to 2	1 to 2	> 5.8
Membrane fouling index	1.5–3.0	0.4–0.7	0.12–0.2
Salt density index	5 to 6	2	< 1
System recovery (%)	40	55	55
Energy requirements	Less than MF/UF due to gravity flow	Higher than conventional (requires pumping water through the membranes)	
Capital costs	Competitive with MF/UF	Slightly higher than conventional pretreatment	
Chemical costs	High due to coagulant and process chemicals	Chemical use is low dependent on raw water quality	
Foot print	Larger foot print	Significantly smaller foot print (30–50% of conventional filters)	
Membranes used		*Memcor, Zeeweed*	*Norit/X flow, Aquasource, Zeeweed-UF Pall and Koch*
Applications	Traditional surface water treatment and wastewater treatment	Reduce turbidity, remove suspended particles, algae, and bacteria	Removal of contaminants that effect color, high-weight dissolved organic compounds, bacteria, and some viruses
Other applications			Recycling of backwash from sand filters, recycling of industrial and municipal waste water
RO capital cost	Higher than MF/UF since RO operates at lower flux	Higher flux with lower capital costs (due to lower SDI values, RO can be operated at 20% higher flux reducing capital costs)	
RO operating costs	High (due to higher potential of membrane fouling resulting in higher operating pressures and frequent cleaning of membranes)	Lower operating costs due to less fouling potential and longer membrane life (membrane cleaning is reduced by 10-100% reducing system downtime and prolonged membrane life)	

external heat source often derived from solar energy or process waste heat and is passed through the hot side of the unit to allow for the water vapors to raise and diffuse through the membrane barrier and condense in the permeate flow on the cold side of the unit (Camacho et al. 2013). Because the hot (saline water feed) and cold (permeate or freshwater) streams are separated by a membrane barrier, a very low temperature differential of 10 °C is sufficient to produce freshwater through this process. The membrane applied in this process should be porous enough allow the water vapor to pass through but not allowing the liquid and preferably should not be wetted by the process liquids. There are four main configurations of the MD process: (1) direct contact membrane distillation (DCMD), air gap membrane distillation (AGMD), vacuum membrane distillation (VMD), and sweep gas membrane distillation (SGMD) (Yarlagadda et al. 2009). In DCMD, the membrane is in direct contact with the liquid phases, while in AGMD, an air gap is introduced between the membrane and condensation surface to improve the energy efficiency. In VMD, the permeate side is maintained at a lower pressure by mechanical pumping to increase the permeate flux, while in the SGMD, a stripping or carrier gas is used to collect the vapor produced. Among these methods, DCMD operates at a reasonable efficiency and a higher permeate rate. MD systems can be operated standalone using solar energy (Qtaishat and Banat 2013; Saffarini et al. 2012). The permeate flux is very low for the AGMD. VMD can produce higher permeate but at the expense of higher energy requirements and is suitable for feed waters with volatile contaminants (Yarlagadda et al. 2011).

As of June 2011, there were 15,988 desalination plants worldwide which combined produce a total of 65.2 million m^3 of freshwater equivalent to 17.5 billion US gallons in over 150 countries supporting 300 million people (Gude 2016a). Out of these desalination plants, reverse osmosis with about 60% share currently dominates the other desalination technologies (Gude 2016b) and this trend is expected to continue into the future followed by well-established MSF technology (26.8%) and MED technology (8%) with the remaining 5% contributed by electrodialysis and other hybrid technologies. Sixty percent of the desalination plants process seawater to produce freshwater followed by brackish water (21.5%), river water (8.3%), wastewater recovery/reuse (5.7%), and other water sources (4.5%). Energy requirements for desalination technologies vary significantly in quantity and quality (Gude 2016a).

Thermal Desalination Technologies

Multistage flash distillation (MSF): MSF distillation involves flash evaporation where seawater is evaporated by reducing the pressure in successive effects (stages). The energy economy is achieved by successive regenerative heating where the seawater flashing in each flash chamber (effect or stage) rejects heat to the feed water, thereby heating the incoming seawater (Gude 2015b; El-Nashar 2001). Seawater prior to the introduction in the first stage is heated by external heat sources, such as low pressure steam, form power plants or an extraction steam from a steam

turbine plant. This heated seawater then enters the flash evaporation chambers with falling operating pressures in the successive stages; 15 and 30 stages in modern large-scale MSF plants are common to achieve optimum energy recovery (Khawaji et al. 2008). The operating temperatures vary between 90 °C and 120 °C (also known as top brine temperatures), which depends on the quality of heat source available in the first stage.

Multieffect evaporation/distillation (MED): Similar to MSF process, MED process operates in a number of effects to increase the energy efficiency and has higher thermodynamic efficiency when compared with an MSF process (Al-Shammiri and Safar 1999). However, in contrast to MSF process, the preheated seawater is sprayed onto the tubes in the first evaporation chamber which are heated by external heat source derived from a power plant steam (Ophir and Lokiec 2005). These are operated in a dual purpose power plant scheme. The freshwater vapor evaporated in the first evaporation chamber is allowed to pass through a condenser which serves as evaporating surface in the next effect. The remaining brine from the first evaporation chamber is passed through the next effect where it is sprayed on the evaporating tubes at lower temperatures and lower pressures. This process continues in the successive effects as long as suitable temperature gradient is available for freshwater evaporation. The energy or steam economy is proportional to the number of effects. The total number of effects is limited by the total temperature range available and the minimum allowable temperature difference between successive effects (Michels 1993). Typical number of effects in MED process varies between 4 and 21, which again depends on the heat source temperature and the top brine temperature in the first effect. The top brine temperatures are usually around 90 °C for MED processes, but a lower top brine temperature of 70 °C is also possible which are called low-temperature MED (LTMED) (Ophir et al. 1994). Although thermodynamically efficient, this process requires large heat transfer areas. The heat transfer areas for LTMED are considerably higher than MED process often varying between 25% and 40%.

Solar distillation (SD): Solar distillation refers to solar stills and active or passive solar desalination systems that are supported either by direct solar energy or indirect solar energy (Gude et al. 2010). Indirect solar energy means that the solar energy harvested in the solar collectors (flat panel collectors, parabolic trough collectors, etc.) is supplied to the desalination unit. These applications depend on the type of solar energy harvesting technology and a suitable desalination mechanism. The solar stills are the simplest and cheapest direct solar harvesting desalination units. These units utilize the direct solar energy to evaporate the freshwater from salt water leaving behind the concentrated brines. Solar stills incorporate the evaporating and condensing units into a single chamber. Often, the glass roof of the unit serves as the condensing surface which rejects the latent heat to the ambient.

The energy efficiency of typical solar stills varies between 30% and 40% (Tiwari et al. 2003). The stills with an external condensing surface maintained in shade or at lower temperatures showed higher energy efficiencies up to 70%. The energy efficiency and the distillate product can be improved by adding multiple effects in the same unit. The energy efficiency is calculated as the ratio of the amount of the

distillate produced to the amount of solar energy received by the solar still unit. Other indirect solar desalination systems include multieffect distillation or evaporation system, low temperature multieffect desalination, humidification-dehumidification, and membrane distillation systems (Sampathkumar et al. 2010; Kalogirou 1997).

Energy Requirements for Desalination Processes

Energy requirements for desalination vary from process to process (Gude et al. 2010; Gude 2011). Thermal desalination processes require both thermal and electrical energy for evaporation, process hydraulic flow, and transport of the feed and product water. Membrane desalination processes require electrical energy to supply the mechanical energy for membrane separation and pumping in and distribution out of the plant. Figure 2 shows the specific energy consumption for thermal and membrane desalination processes in terms of kJ of energy required for producing one unit of freshwater in kilogram (Mehdizadeh 2006). It can be noticed that MSF process has the highest specific energy consumption, while the seawater reverse osmosis (SWRO) process has the lowest specific energy consumption. For this reason along with its inherent simplicity, the SWRO process is the preferred desalination method for both brackish and seawater desalination around the world. Table 4 shows the equivalent electrical energy requirements for the desalination processes expressed in kWh/m^3 of freshwater production (Mehdizadeh 2006). From this table, it can be inferred that membrane processes require higher electrical energy for freshwater production for both with and without energy recovery options. It should also be noted that electrical energy is a prime (highest form) quality energy that could probably be used for other high value beneficial uses. At the same time, for thermal processes, the availability of steam is important whether it is produced for desalination solely or in conjunction with power production.

Renewable Energy Powered Desalination

The potential renewable energy-desalination technology combinations are shown in Fig. 1. The renewable energy sources (RES) should be integrated with the relevant desalination technology that has the best capability to utilize the energy in the most effective manner (Gude 2015b). Some renewable energy source-dependent desalination technologies must be placed on the same site (co-location) and some do not have this requirement. Accordingly, the following thermal desalination-renewable energy combinations require colocation (located on same site):

(a) Wind–shaft–MVC
(b) Solar thermal–TVC
(c) Solar thermal–MSF
(d) Solar thermal–MED

Table 4 Equivalent electrical energy consumption for desalination processes (Data taken from Gude 2016b)

Process	Steam energy kWh/m^3	Electrical energy kWh/m^3	Equivalent electrical energy kWh/m^3	Equivalent CO_2 emissions kg CO_2/m^3
MSF	7.5–11	2.5–3.5	10–14.5	0.09
MED	4–7	2	6–9	0.04
VC	–	7–15	7–15	0.051
SWRO	–	4–6 (with ER) 7–13 (without ER)	4–6 (with ER) 7–13 (without ER)	0.032
BWRO	–	0.5–2.5	0.5–2.5	
ED	–	0.7–2.5	0.7–2.5	0.038

(e) Solar thermal–SD
(f) Geothermal–TVC)
(g) Geothermal–MSF or MED

The other electricity-driven combinations that do not require co-location are (a) wind–MVC, (b) wind–RO, (c) solar PV–RO, (d) solar PV–MVC, (e) geothermal–MVC, and (f) geothermal–RO. More details on this topic can be found in Gude (2015b).

Energy Recovery and Integrated Concepts

Thermal desalination technologies are generally considered energy-intensive and therefore cost-prohibitive. However, these technologies are more acceptable in regions where thermal energy sources can be accessed at low cost especially in oil-rich regions of Middle Eastern countries. Low-temperature thermal desalination processes are considered energy-efficient (Gude and Nirmalakhandan 2008), which can also utilize waste heat sources such as reject heat from the domestic air-conditioning units, and heat harvested by solar collectors and photovoltaic thermal collectors (Gude et al. 2011a, b, 2012). Often thermal desalination technologies are co-located with power plants, the waste steam from the condenser is utilized as a heat source for MSF or MED processes. In thermal desalination technologies, energy recovery and recycling is done through successive stages. However, energy source utilization must be maximized. As shown in Fig. 2, it can be noted that state-of-the-art power plants have a high energy efficiency of 35–40%, whereas a cogeneration plant can achieve an energy efficiency of 75–80%. If the beneficial uses can be extended through heating and cooling applications in a configuration called "Poly generation," energy efficiencies as high as 90% can be reached.

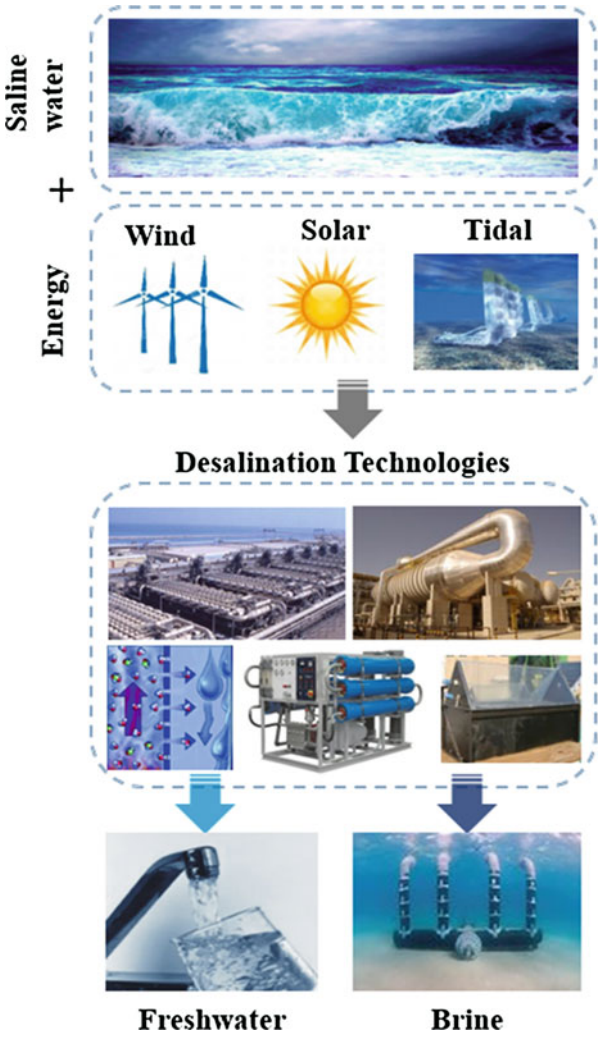

Fig. 1 Renewable energy applications for desalination (Adapted from Gude 2015b)

Membrane desalination technologies are also considered energy-intensive because they utilize electrical energy which is a high-quality energy. Energy recovery in membrane processes is a widely studied concept. Various types of energy recovery devices have been developed over the past few decades to minimize the specific energy consumption in membrane processes. Because minimum theoretical energy consumption cannot be achieved due to other constraints such as membrane scaling and biofouling, water recovery in multiple pass configurations can help reduce the specific energy consumption as well. For more information on this topic, the readers are suggested to refer to the contribution by Gude (2011).

Other Considerations for Desalination

The major drawback with desalination technologies is one of the end products which is highly concentrated with salts called "brine" or "concentrate." Disposal and management of brine streams is an ongoing issue for these facilities. Coastal desalination plants have the privilege of considering ocean discharge for brine disposal. However, inland desalination plants are faced with the dilemma of options that are usually not so environmentally friendly. Evaporation, deep well injection, discharge to sewers, land application, and valuable chemical recovery through further processing are the available options, all of which are again energy- and cost-intensive. Environmental permits are another major hurdles that these facilities need to consider. Concentrate disposal into surface waters or sewers increases salt concentrations of existing water supplies, whereas an impermeable barrier is required for evaporation and land application options.

Protocol

Desalination technology selection

This chapter described various alternatives for desalination and water reuse. Membrane technologies are more suitable for water reuse applications to recover potable water from wastewater effluents, while desalination technologies should be used for high saline ground water or seawater as water supply sources. Water reuse and recycle programs should be given priority before considering desalination alternative for water supply enhancement. Energy recovery and integrated configurations along with enhanced water recovery should be implemented in desalination.

Policies

Governmental policy for water reuse and desalination

This chapter described various membrane and thermal desalination technologies. As desalination processes are energy-intensive, the following should be considered.

- Priority should be given to renewable energy driven desalination configurations
- Mandatory regulations and incentive programs should be implemented.
- Environmental impacts of desalination plants should be thoroughly evaluated.

Dictionary of Terms

- **Feed water** – Supply water that is fed into the RO system to be treated
- **Permeate** – A portion of the feed water that passes through a series of membranes and is returned as purified water
- **Concentrate** – A portion of the feed water that is rejected by the membrane and contains the solution of impurities that have been filtered out of the permeate
- **Water flux** – The rate of permeate production typically expressed as the rate of water flow per unit area of membrane (e.g., gallons per square foot per day)
- **Recovery rate** – The ratio of permeate flow to feed water flow, which indicates the overall water efficiency of the system
- **Reclaimed water** – Municipal wastewater that has been treated to meet specific water quality criteria with the intent of being used for beneficial purposes. The term *recycled water* is synonymous with reclaimed water.
- **Water reclamation** – The act of treating municipal wastewater to make it acceptable for beneficial reuse.
- **Water reuse** – The use of treated wastewater (reclaimed water) for a beneficial purpose. Synonymous with the term *wastewater reuse*.

- **Potable reuse** – Augmentation of a drinking water supply with reclaimed water.
- **Nonpotable reuse** – All water reuse applications that do not involve potable reuse (e.g., industrial applications, and irrigation).

Summary Points

- Supply enhancement can be done by considering water reuse technologies such as advanced chemical and membrane treatment processes or desalination technologies.
- Because desalination technologies are energy-intensive, it is important to reduce their nonrenewable energy input by integrating solar and wind energy sources.
- Future research efforts in desalination technology development should focus on development of energy-efficient and high recovery process configurations including membrane materials with high rejection capacities and water recovery.
- Membrane technologies such as forward osmosis and nanocomposite membranes show the potential for wide application. Forward osmosis is a desired process to recover water from impaired sources such as wastewaters and other oil-/gas-produced waters. Capacitive deionization process still shows promise for future applications especially for energy savings.
- Hybrid and trigeneration configurations including membrane/thermal and physico-chemical processes should be considered for enhancing the water recovery and supply process benefits.

Abstract

Obesity is an important medical and social problem due to its severity and increasingly high prevalence, which has led to a significant increase in the number of bariatric surgeries.

Bariatric surgeries are the most efficacious treatment for obesity, leading to a recognized improvement in health and quality of life and heightened patient survival, but they may result in several complications. Protein-calorie malnutrition is a serious major complication, particularly in its severe form. Few evidence-based studies have been found in the literature, and the most relevant ones helped guide the choice of strategies and procedures.

Introduction

Obesity is a significant medical and social problem due to its severity and high and increasing prevalence.

The severity of obesity, especially in its visceral form, is related to increasing risk of several diseases and metabolic and physical disorders, such as those associated with metabolic syndrome: systemic arterial hypertension, dyslipidemia, type 2 diabetes mellitus, increase in total cholesterol, decrease in HDL-c levels, and abdominal circumference. Other disorders may also develop, such as cardiovascular diseases (acute myocardial infarction, cerebrovascular accidents, and venous stasis),

pulmonary dysfunction, degenerative arthropathies, gastroesophageal reflux disease, nonalcoholic fatty liver disease, cholelithiasis, abdominal hernias, higher risk of some malignancies, female sexual dysfunction, worsening of psychological disorders, and social discrimination.

Obesity is an epidemic condition with a worldwide exponentially increasing incidence over the last few years. At least 2.8 million people in the world die each year from overweight or obesity complications (Masters et al. 2013). The proportion of obese male adults in England increased from 13.2% in 1993 to 26% in 2013 and from 16.4% to 23.8% among females in the same period (Lifestyles Statistics Team, Health, and Social Care Information Centre 2015). http://www.hscic.gov.uk/pubs/sopad15.

Bariatric surgery is considered to be the most efficacious treatment for severe obesity because of its good results regarding the resolution of comorbidities and the consequent improvement in health (Buchwald et al. 2004) and quality of life for most patients (Karlsson et al. 2007), in addition to increasing survival (Sjöström 2013). However, it is not free from complications. Nutritional deficiencies are the most important long-term complications of bariatric surgery (Tack and Deloose 2014). Severe protein-calorie malnutrition (SPCM) is not common after bariatric surgery but is a complication of an often difficult solution, besides being potentially lethal (Wade et al. 2010).

Although the definitions of protein-calorie malnutrition (PCM) are not uniform, this condition may be described as "protein, energy and micronutrient deficiency, depending on the inability of the body to satisfy the protein and energy fuel requirements through diet" (Torún 2009).

Severe PCM is characterized by a marked protein loss resulting in a generalized muscle and fat loss and signs and symptoms such as diarrhea; sparse, fine, and dry hair; fine and dry skin; weakness; apathy; and a substantial reduction in physical capacity.

This chapter focuses on SPCM after bariatric surgery, its causes, diagnosis, and medical treatment. Published studies on PCM, especially in its severe form, are relatively scarce, most of which are retrospective and almost always do not define the type and severity of malnutrition.

Surgical treatment is indicated for patients with a body mass index (BMI) equal or greater than 40 kg/m^2 or above 35 kg/m^2 when associated with comorbidities that do not respond to conservative treatment. There has been an increasing demand for bariatric surgery given the positive results regarding both weight loss and improvement in comorbidities. Those results have surpassed those of conservative treatment in various prospective and randomized trials (Karlsson et al. 2007; Ikramuddin et al. 2013; Sjöström 2013). Since the late 1990s, there has been a marked increase in the number of bariatric surgeries performed, from approximately 10,000 in 1998–100,000 in 2003 (Buchwald et al. 2004) and from 145,301in 2003-340,768 in 2011 (Buchwald and Oien 2013).

To better understand PCM after bariatric surgery, it is important to bear in mind the anatomical basis and the main physiological consequences of the surgical techniques currently in use.

Bariatric Surgeries

The surgical techniques can be performed by means of laparoscopy or laparotomy and are classified as follows, according to their objective:

Restrictive: based on the reduction of gastric capacity, resulting in early satiety and a marked decrease in food intake. The number of vertical banded gastroplasty and laparoscopic adjustable gastric banding (LAGB) has fallen, whereas that of vertical gastrectomy, also called sleeve gastrectomy (SG) (Fig. 1a), has increased.

Malabsorptive: based on the exclusion of an ample small bowel segment from the food transit, resulting in a marked reduction of food absorption capacity. Jejunoileal and jejunocolic bypasses are currently proscribed due to their high rates of long-term nutritional and metabolic complications.

Mixed: they involve both gastric restriction and intestinal malabsorption and may have a predominant component – restrictive (Roux-en-Y gastric bypass (RYGB) or malabsorptive (biliopancreatic diversion (BPD) and its variant duodenal switch (BPD/DS)). The small bowel segment between the anastomosis of the alimentary limb (AL) with the biliopancreatic limb (BPL) and the ileocecal valve is called common limb or common channel (CC). It corresponds to the portion of the small bowel where the food starts to come in contact with the bile and the digestive enzymes from the pancreatic juice.

RYGB (Fig. 1b) is the universally more accepted procedure for the surgical treatment for obesity and involves vertical gastroplasty (restrictive component) and Roux-en-Y gastrojejunal bypass (malabsorptive component). The weight loss is usually within the 30–40% range, and the loss of excess weight is within the 60–75% range, for 1 and 2 years (Pajecki et al. 2007). RYGB and SG induce alterations in hormonal secretion

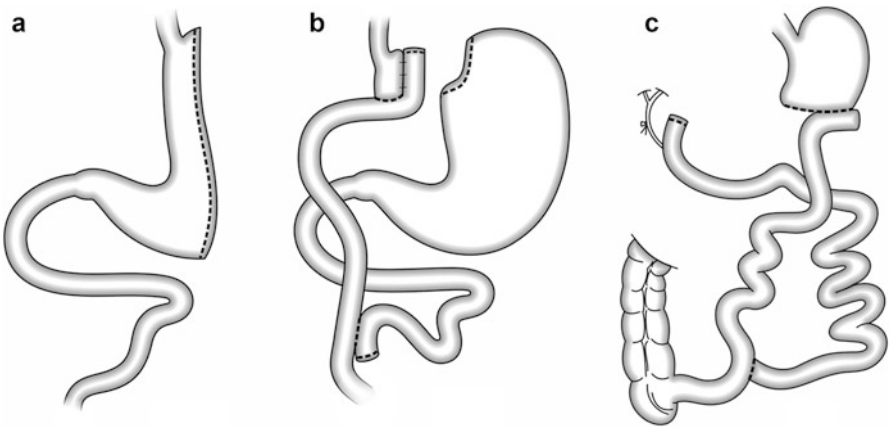

Fig. 1 Bariatric surgeries. (**a**) Sleeve gastrectomy. (**b**) Roux-en-Y gastric bypass. (**c**) Biliopancreatic diversion

such as increase in glucagon-like peptide and peptide YY and a decrease in ghrelin levels, leading to satiety and a favorable effect on glycemic levels.

With the distal Roux-en-Y gastric bypass (DRYGB), a modification of standard RYGB is made by increasing the malabsorptive component through the elongation of the AL or the BPL, alone or combined, with a consequent shortening of the CC, thus effecting a reduction of the absorptive area of the bowel.

The biliopancreatic diversion (BPD) based on the Scopinaro technique (Fig. 1c) consists of a distal gastrectomy with a Roux-en-Y gastroileal anastomosis. The biliopancreatic diversion based on the Marceau-Hess technique, also called duodenal switch (BPD/DS), is a modification of Scopinaro's technique. It consists of SG and duodenoileal anastomosis, while preserving the pylorus, with the ileum anastomosed to the duodenum at 200 cm from the ileocecal valve and enteroenterostomy located at 100 cm from the ileocecal valve. The DRYGB scheme is shown in Fig. 2 and the BPD/DS in Fig. 3.

With the biliopancreatic diversions, the partial resection of the stomach effects the restriction, which is greater with the BPD/DS than the BPD, and the intestinal bypass causes malabsorption, especially of fats and carbohydrates. The weight loss is usually within 35–40% range and the loss of excess weight within 75–80% range, about 1–2 years after surgery. A surgery inducing loss of more than 50% excess weight is considered valid (Pajecki et al. 2007), a result not always achieved by using purely restrictive operations. The BPD with or without DS, due to the restriction of food intake and mainly to the malabsorption of both macro- and micronutrients, requires close monitoring. Biliopancreatic diversions cause a marked and lasting weight loss, but malabsorption, especially of fats, can also cause side effects that limit its use, such as increased frequency of daily evacuations of fetid feces and flatus. Besides that, various nutritional deficiencies and metabolic changes can occur leading to higher mortality as compared to alternative procedures. RYGB involves a

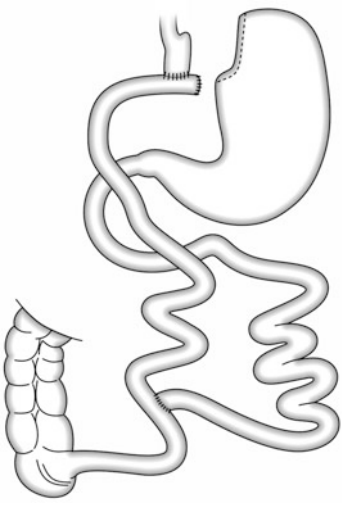

Fig. 2 Distal Roux-en-Y gastric bypass

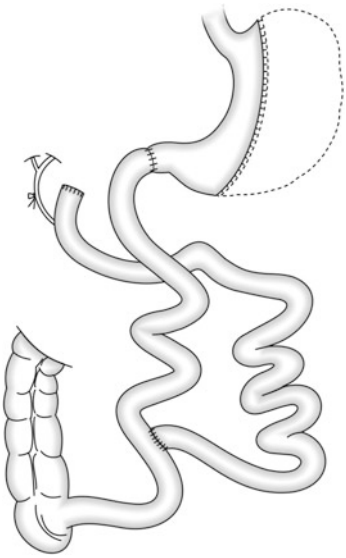

Fig. 3 Biliopancreatic diversion with duodenal switch

greater risk of nutritional deficiencies than purely restrictive surgeries but a lower risk than biliopancreatic diversions (Søvik et al. 2013; Suarez Llanos et al. 2015).

Buchwald and Oien (2013) studied the relative distribution of 340,768 metabolic/bariatric procedures conducted in 42 nations or national groupings in 2011. They observed that the more frequently used surgeries were RYGB (46.6%), SG (27.8%), adjustable gastric banding (17.8%), and BPD/DS (2.2%), with a marked increase in SG. Welbourn et al. (2017) described demographic data from the report of IFSO Global Registry including 54,490 patients from 31 countries operated in the 3 years 2013–2015. Gastric bypass was the most prevalent operation (49.4%), followed by sleeve gastrectomy (40.7%) and gastric banding (5.5%) (Welbourn et al. 2017, 1). Scott et al. (2017, 2935) used the Premier database that collects data from community and teaching hospitals and large health systems in the USA and found that the proportion of SG went up from 39% to 63%, while that of RYGB decreased from 44% to 30% and gastric banding from 13% to 2% over the period 2012–2015.

The postoperative mortality rate of bariatric procedures is of 0.1–2%, and a non-negligible number of patients suffer from acute or late surgical or clinical complications (Karlsson et al. 2007).

Protein-Calorie Malnutrition

Many patients seeking bariatric surgery already have nutritional deficiencies, including hypoproteinemia and lean mass depletion, resulting from bad eating habits and previous restrictive diets (Ernst et al. 2009; Kulovitz et al. 2014). Thus, attention should be paid to the patient's nutritional status before and after performing a bariatric surgery (Lopez et al. 2007; Santarpia et al. 2014; Dietch et al. 2015).

Malnutrition may occur as a consequence of the restrictive and/or malabsorptive effects of the bariatric surgery itself and also results from other causes: reduction in nutrient intake, due to decreased tolerance to protein-rich foods, besides mechanical problems resulting from benign processes (peptic or caustic stenosis) or malignant ones (tumor-induced stenosis), in the upper digestive tract, or yet surgical sequels; reduction in intestinal absorption, due to Crohn's disease, AIDS, and celiac disease, among others; and increase in metabolic demands, resulting from severe infections, burns, cancer, trauma, or neurological injuries (Enomoto et al. 2013).

The decrease in protein levels after various bariatric procedures may occur in the early postoperative period as a result of several conditions occurring at this phase, such as increased metabolic stress and accelerated protein catabolism, besides anorexic state and decreased tolerance to protein-rich foods.

Restrictive surgeries may lead to a reduction in protein intake, although usually without any clinical or laboratory repercussion. Vomiting contributes to the development of malnutrition. If postoperative vomiting is intense and persistent, nutritional deficiency may occur, especially regarding vitamins and minerals. The nonacceptance of, or non-compliance with the diet directions, and the intolerance to protein-rich foods, also not rare after RYGB, may lead to insufficient protein intake and so aggravate malnutrition. This occurs between 3 and 6 months after surgery but almost always resolves after 1 year (Bock 2003; Moize et al. 2003). Postoperative nutritional support should be provided by encouraging patients to ingest at least 60 g protein per day, even if this should require supplementation with formulas with high-protein content (Schollenberger et al. 2016). Protein malnutrition after SG or LAGB is rare.

Protein-calorie malnutrition after RYGB may result from several causes, such as stenosis of the gastrojejunal anastomosis, psychiatric disorders, intestinal bacterial overgrowth, diarrhea due to bile salts, chronic dumping, and some early complications, such as dehiscence of the anastomosis and/or a digestive fistula (Akusoba et al. 2016). With the mixed procedures, the measurement of the total length of the small bowel is essential to prevent the inadvertent constructing of too short a CC.

The investigation of diarrhea caused by RYGB entails several exams, among which a radiologic study of the intestinal transit, qualitative and quantitative examination of fecal fat, and tests of bacterial overgrowth. While the cause is being investigated and the clinical and laboratory data available are being analyzed, nutritional support may be provided, as well as experimental treatment with antibiotics, probiotics, or pancreatic enzymes (Machado et al. 2008; Chen et al. 2016). Diarrhea secondary to bacterial overgrowth in the small bowel ($>10^5$–10^6 microorganisms/mL) may be the result of the reduction in gastric acidity and/or stasis in the afferent loop. Weight loss induced by diet or bariatric surgery may modify the gut microbiota composition (Damms-Machado et al. 2015).

The standard test for diagnosing intestinal bacteria overgrowth is the microbial investigation of jejune aspirates. Quantitative culture of small bowel bacteria would be indicated for diagnosis confirmation, but this is a laborious test. The diagnostic hypothesis can be tested out by the expired hydrogen assay after glucose or lactulose ingestion (Machado et al. 2008), however keeping in mind some recent queries

about this exam, reported in the literature (Ishida et al. 2014). The prophylactic use of probiotics has shown promising results (Chen et al. 2016).

Patients submitted to RYGB are at low risk of protein malnutrition. PCM is detected in less than 5% of patients with a Roux loop of 150 cm or less (Faintuch et al. 2004; Isom et al. 2014) and in 13% of patients with a Roux limb >150 cm (Isom et al. 2014). With techniques using a significant malabsorptive component such as BPD, BPD/DS, and DRYGB, there is a greater chance of diarrhea and a drop in albumin content, depending on the length of the absorptive bowel to be maintained (Scopinaro 2006, Ciovica et al. 2008; Currò et al. 2015). Often diarrhea demanding careful control may lead to severe protein-energy malnutrition (Buchwald and Oien 2013). With the technical standardization of the length of common loops being about 50–100 cm, the incidence of various degrees of PCM is of about 40%, especially in the first 2 years after operation (Sethi et al. 2016). Hypoalbuminemia in itself tends to cause a worsening of diarrhea and aggravation of PCM, due to edema of the intestinal loops and the consequent reduction in the absorptive area.

The severity of PCM can be measured by the assessment of the patient's nutritional status based on their clinical history, anthropometric measurements, and on laboratory tests.

Significant short-term weight loss indicates nutritional risk. In non-bariatric hospitalized patients, the interpretation of values related to weight loss and time of evolution can be made according to the classification proposed by Blackburn et al. (1977) (Table 1). It is common knowledge that patients who underwent RYGB have usual postoperative weight loss rate of about 13% at 3 months, 23% at 6 months, and 30–40% within 1 and 2 years (Pajecki et al. 2007). Much greater losses than these indicate risk of malnutrition.

Severe malnutrition relates not only to low BMI but also to the percentage of short-term weight loss. The speed of malnutrition installation and low BMI are associated with the risk of patient's death.

Nutritional history and physical presentation are usually sufficient for the diagnosis of SPCM, which should be confirmed, evaluated, and monitored by means of laboratory tests. Besides confirming the clinical diagnosis of PCM and making possible the monitoring of nutritional interventions, laboratory tests can detect subclinical nutritional deficiencies.

Care about hydration is important, and protein intake should be 60–80 g per day after RYGB or 1.1–1.5 g/kg of ideal body weight (BMI = 25 and 90–120 g per day after BPD/DS (Slater et al. 2004; Dagan et al. 2017). Supplementation with vitamins and minerals is essential for a daily routine nutrition after mixed bariatric surgeries, especially those with the predominance of the malabsorptive component, by

Table 1 Malnutrition risk according to the percentage of unintentional weight loss in relation to the elapsed time for non-bariatric hospitalized patients

Elapsed time	Significant weight loss	Severe weight loss
1 week	1–2%	>2%
1 month	5%	>5%
3 months	7.5%	>7.5%
6 months	10%	>10%

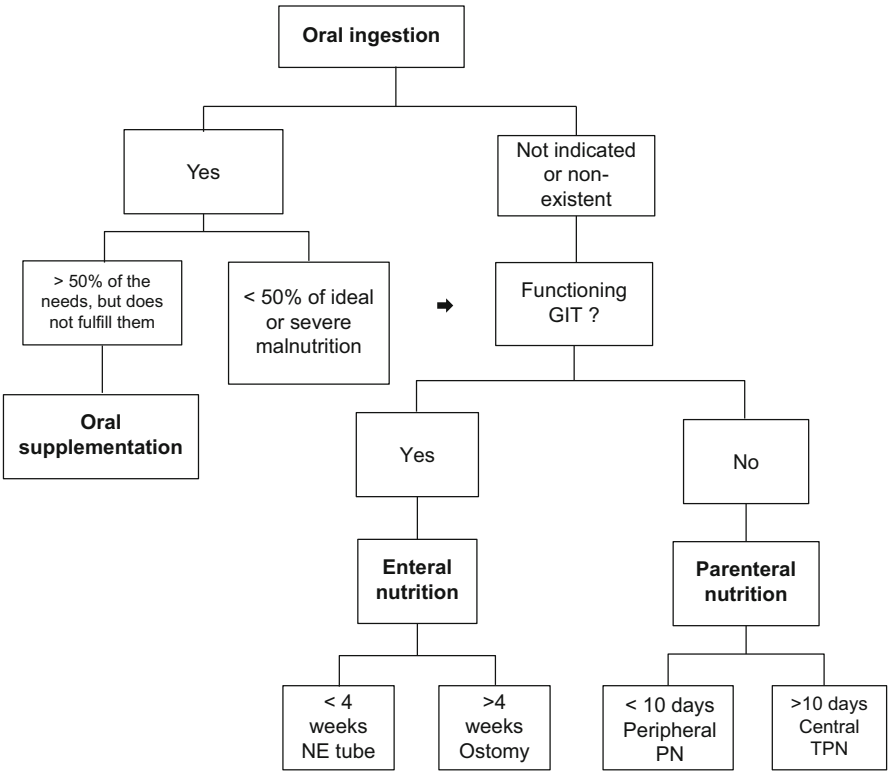
administration of commercial products containing those micronutrients in adequate quantity. The prescription may be calcium (500 mg two to three times/day or more), vitamin D3 (cholecalciferol) (2000–3000 U/day or more; titration should be done to reach normal concentrations of 30 ng/ml), and vitamin B12 (250–350 mcg/day or 1000 mcg/week sublingual or 3000 mcg intramuscular every 6 months). Vitamin B1 (thiamin), folic acid (400 mcg/day), fat-soluble vitamins, zinc, copper, and vitamin C should also be routinely recommended (Dagan et al. 2017). There may be changes in this prescription according to clinical laboratory evaluation of each patient. The diet of those patients, who frequently have inadequate intake of macronutrients and micronutrients, should receive special attention (Campos et al. 2008). Patient follow-up and clinical laboratory assessment at short intervals are necessary for an early diagnosis and correction of nutritional deficiencies (Bavaresco et al. 2010; Thibault et al. 2016). In addition to hypoproteinemia and possibly associated anemia, deficiency of other nutrients should be searched, among them vitamin B12; folate; vitamins A, B1, and D; calcium; copper; iron; zinc; and selenium, especially in critically ill patients (Donadelli et al. 2011; Rosa et al. 2011; Choban et al. 2013; Salgado et al. 2014; Kwon et al. 2014; Santarpia et al. 2014; Smelt et al. 2016).

Medical Treatment

Mild and moderate uncomplicated malnutrition can be treated at an outpatient service since hospitalization increases the risk of infections and also anorexia. Critically ill patients should be hospitalized, and their treatment for existent diarrhea may involve administration of pancreatic enzymes and antibiotics, as well as protein-calorie nutritional support by oral, enteral, or parenteral route, each alone or in combination. Nutritional therapy for malnourished patients after bariatric surgery may be guided by flowcharts (Flowchart 1), which should be modified with adequate adaptations to the conditions of each patient. The choice of route to be followed for the supplying of nutrients is based on several parameters, including the feasibility of the route, the sufficiency of supply for energy needs, and the evolution of clinical and laboratory conditions of the patient.

Nutritional therapy by oral route progresses from a fractionated clear liquid diet for the first days up to foods of reasonable consistency. Vitamin and mineral supplements should be administered routinely, and attention should be paid to protein intake (Lopez et al. 2007).

When the digestive tract can be used but the patient with PCM is unable to ingest an appropriate quantity of nutrients for 7–14 days, enteral nutrition therapy is indicated (Isom et al. 2014). When the patient's physical condition after bariatric surgery is precarious or when the recovery period has been predicted to be long enough to permit a revision surgery without posing a high risk, gastrostomy at the remnant stomach should be considered for enteral nutrition. It should persist until satisfactory results are achieved. The administration of enteral diet through gastrostomy or a nasoenteric tube should start with small volumes and gradually increase to prevent refeeding syndrome (Akusoba et al. 2016). The enteral diet, also



Flowchart 1 Flowchart of nutritional therapy for the malnourished patient. *GIT* gastrointestinal tract, *EN* enteral nutrition, *PN* parenteral nutrition, *TPN* total parenteral nutrition

containing appropriate quantities of vitamins and minerals, should be slowly and continuously administered, in order to optimize the absorption process, preferably by using an infusion pump, which would also facilitate appropriate monitoring. Whole nutrients may aggravate malabsorption with an unfavorable course of nutritional status, with oligomer diets being then indicated.

Parenteral nutrition is indicated after bariatric surgery when severe complications follow, leading to intestinal insufficiency or failure which may occasionally become chronic (Abdal Raheem et al. 2014). Few studies are found in the literature regarding the indication of prolonged parenteral nutrition after bariatric surgery. Abdal Raheem et al. (2014) reported on six patients who became dependent on parenteral nutrition after bariatric surgery, with four of them suffering from short bowel syndrome. The response of patients to nutritional therapy should be monitored mainly if hypoalbuminemia occurs. A shorter half-life protein such as prealbumin followed over time may be a useful parameter for monitoring the response of the patient to nutritional therapy (Koch and Finelli 2010).

With nutrition therapy, it is interesting to consider the BMI. Protein supply recommendations are $\geq$1.9 g/Kg for class I and II obesity (BMI 30–40(Kg/m^2)

and ≥2.5 g/Kg of ideal body weight for class III obesity (BMI ≥40 Kg/m^2) (Choban and Dickerson 2005). Moizé et al. (2013) recommended a supply of calorie of 25–30 Kcal/kg weight/day and of protein about 1.2 g/Kg weight/day. No consensus was observed to exist as to which correction factors should be used to establish the total energy requirements for enteral or parenteral feeding, since malnourished patients are at risk for suffering complications related to refeeding syndrome. On the other hand, A.S.P.E.N. guidelines recommend starting with a hypocaloric, high-protein feeding for the critically ill, obese patients, with normal renal and hepatic function, aiming at preventing overfeeding and hyperglycemia and achieving a net protein anabolism (Choban et al. 2013; Isom et al. 2014).

The best method for measuring energy needs is the indirect calorimetry. When this is not possible, the measurement of energy requirements for the critically ill, adult, obese patients may be done by estimation of the resting metabolic rate (RMR) by using predictive equations involving some variables according to the patient's characteristics (Mifflin et al. 1990; Ireton-Jones and Jones 2002; Choban et al. 2013; Isom et al. 2014; Beebe and Crowley 2015) (Table 2). Based on the physiological and anatomical effects of bariatric surgery, Isom et al. (2014) suggest that recent guidelines for critically ill, obese patients can be applied to all patients undergoing bariatric surgery.

The most frequently used equations to estimate energy expenditure by obese patients are shown in Table 2. The choice of predictive equations should be based on patient's clinical status (Mifflin et al. 1990; Breen and Ireton-Jones 2004; Isom et al. 2014).

The A.S.P.E.N. Clinical Guidelines for Nutrition Support of Hospitalized Adult Patients with Obesity recommend the use of the Penn State University 2010 equation (PSU) for critically ill, ventilated, obese patients ≤60 years of age and the PSU modified equation for patients >60 years of age (Isom et al. 2014). If the PSU equation cannot be used or patients are not ventilator-dependent, the use of the Mifflin-St. Jeor (MSJ) equation should be recommended (Mifflin et al. 1990; Choban et al. 2013; Isom et al. 2014). For those equations, the actual body weight should be used. The calculated resting metabolic rate (RMR) should be multiplied by the appropriate activity and stress factors, such as sex (male = 1, female = 0), trauma (present = 1, absent = 0), and burn (present = 1, absent = 0) (Ireton-Jones and Jones 2002; Choban et al. 2013; Isom et al. 2014; Beebe and Crowley 2015).

For critically ill patients, the A.S.P.E.N. guidelines recommend starting with hypocaloric, high-protein feedings providing ≤14 Kcal/Kg of the actual body weight. The protein requirements for this type of feeding are 1.2 g/Kg of actual weight and 2–2.5 g/Kg of ideal body weight (Isom et al. 2014). In the trauma intensive care unit, class I or class II obese patients receiving hypocaloric, high-protein enteral feedings need a minimum of 1.9 g/Kg ideal body weight/d to achieve nitrogen equilibrium. For the class III obesity patients, a minimum of 2.5 g/Kg ideal body weight/day or more are necessary (Choban and Dickerson 2005).

Laboratory monitoring of malnourished patients after bariatric surgeries should be done to search for good results. Nutrition supervision is of great value, as malnutrition and vitamin and micro- and macronutrient deficiencies may lead to

Table 2 Predictive equations of energy requirements for adult obese patients

PSU 2010 (≤60 years)	RMR (Kg/day) = MSJ (0.96) + Tmax (167) +VE (31) − 6212
PSU (modified) (>60 years)	RMR (Kg/day) = MSJ (0.71) + Tmax (85) + VE (64) + 3085
MSJ (men)	RMR = (10 × Weight [Kg]) + [6.25 × Height ([cm)] − (5 × Age) + 5
MSJ (women)	RMR = [10 × Weight (Kg)] + [6.25 × Height (cm)] − (5 × Age) – 161
Ireton-Jones (mechanical ventilation)	EE(v) = 1925 – 10(Age) + 5 [(eight [Kg]) + 281(S) + 292(T) + 851(B)
Ireton-Jones (spontaneous breathing)	EE (s) = 629 – 11(Age) + 25 [Weight (Kg)] – 609(O)

PSU (Penn State University), *MSJ* (Mifflin-St Jeor), *RMR* (resting metabolic rate), *Tmax* (maximum temperature in the past 24 h), *VE* [minute ventilation (L/min)], *EE* (energy expenditure), *v* (mechanically ventilated), *s* (spontaneous breathing), *S* [sex (male = 1, female = 0)], *T* (trauma), *B* [burn (present = 1, absent = 0)], *O* [obesity (present = 1, absent = 00)]

deleterious consequences (Handzlik-Orlik et al. 2015). Isom et al. (2014) and Handzlik-Orlik et al. (2015) suggest that vitamins B1, B12, and D, calcium, folic acid, and iron should be monitored before bariatric surgery and at 3, 6, and 12 months and yearly after; vitamin A before and yearly after bariatric surgery, and vitamin K, zinc, and copper yearly after the surgery. The measurement of the micronutrients may be done at shorter intervals or at any moment if necessary, mainly for malnourished patients.

Revision surgery is frequently indicated in cases of SPCM. If anatomic causes occasionally continue after bariatric surgery, malnutrition may persist or be reestablished, even after a favorable response to conservative treatment has occurred. According to Akusoba et al. 2016, it is of interest to perform revision surgery after a significant improvement of a SPCM. It is also crucial to perform this procedure at an opportune time without over insisting on protein replacement therapy when the latter proves to be inefficient, and a delay might be dangerous. Potentially fatal protein-calorie malnutrition can occur after gastric bypass or after biliopancreatic diversions (Wade et al. 2010), and revision procedures can be an obligation (Buchwald 2015).

Policies and Protocols

Policy

Obesity is one of the current problems of public health, especially in the industrialized and developing countries. Due to its frequent comorbidities, obesity exerts a substantial negative impact on the quality of life and causes reduction in the patient's life expectancy, besides being a significant economic burden to society because of the lower service income of the obese and higher public health

expenditure. In this chapter, we reported that bariatric surgery is the most effective method of treating severe obesity, but it only solves the problem of the relatively few patients selected. The governmental acts of obesity care have been directed almost exclusively to the treatment of the already obese. However, in order to fully tackle the problem, several issues should be addressed, such as acknowledging that the medical treatment of patients with severe obesity results in limited and transient weight loss, with almost constant failures, surgical treatment is not free from complications, and public hospitals are unable to meet the full demand for bariatric surgery. Based on the importance of those facts, it is essential that governments should optimize their actions aiming at the prophylaxis of obesity through building awareness of the problem and providing guidance to the population at various levels, besides implementing resources of care conductive to a healthy lifestyle.

Protocol

Obesity is characterized by BMI values higher than 30 Kg/m^2. In this chapter, we reported that the BMI is the best indicator for measuring obesity and its prevalence. However, it is important to have in mind that visceral and subcutaneous adipose tissues are morphologically and functionally different, including metabolic differences. The preponderant accumulation of visceral fat over peripheral fat is expressed in the increase in waist circumference, defining the so-called visceral or central obesity. Central obesity, more common in men than women, is more often associated with metabolic syndrome and, consequently, poses higher cardiovascular risk. People with BMI higher than 30 kg/m^2, however, may have normal body fat and increased muscle mass, such as athletes, and people with normal BMI may have excess visceral fat and reduced muscle mass, thus facing higher risk of cardiovascular diseases. These data illustrate the risk of taking the BMI alone as a reference for the definition of obesity and its severity. Waist circumference and body composition measurements are important auxiliary indicators to identify the severity of obesity. The evaluation of body composition depends on the use of a special device for measuring the bioelectric impedance, while that of abdominal circumference is simpler and faster to be done, using only a tape measure.

For adult men, a short waist circumference is considered to be less than 94 cm long, a long circumference from 94 to 102 cm, and a very long over 102 cm. For adult women, a short waist circumference is considered to be less than 80 cm, a long one from 80 to 88 cm, and a very long more than 88 cm. Several anatomical references have been reported for the measurement of abdominal circumference. One method that seems most reliable is the tape measure, positioned at the midpoint between the lower edge of the last ribs and the upper pole of the iliac crest, after normal inspiration. For a more reliable assessment of obesity and its prevalence, a simple measurement of the abdominal circumference, associated with BMI, should be considered.

Dictionary of Terms

- ***Obesity*** – a chronic metabolic disease of multifactorial causes, with genetic and environmental determinants, characterized by excess body fat associated with weight gain in relation to height. Obesity is defined as BMI values equal or higher than 30 kg/m^2.
- ***Body Mass Index*** (BMI) – is considered the best indicator for measuring obesity and overweight and their prevalence and is calculated by dividing the body weight (in kilograms) by the square of height (in meters). The normal BMI values are between 18.5 and 24.9 kg/m^2. It is important to keep in mind the additional value of the measurements of abdominal circumference and body composition.
- ***Bariatric*** – the word was coined in the 1960s, from the Greek BAROS, "weight," and a derivative of IATRÓS, used with the meaning of "medical practice." The word bariatric refers to the branch of medicine that encompasses the analysis and treatment of obesity. This would include studying the causes of obesity, its symptoms, physical conditions, and commonly associated treatments, as well as other aspects of the disease.
- ***Intestinal bacterial overgrowth*** – is the excessive growth in the number of bacteria that inhabit the stomach, duodenum, jejunum, and proximal ileum and/or alteration in the type of bacteria. Diagnosis of intestinal bacterial overgrowth can be accepted as the concentration of $\geq 10^5$ bacteria/mL in the proximal jejune aspiration.
- ***Refeeding syndrome*** – a potentially fatal condition that occurs within the first few days after initiation of enteral or parenteral nutrition therapy, in which there is acidosis, increased intravascular volume, hyperinsulinemia, hypoglycemia, and severe disorder of electrolytes, body fluids, and micronutrients, besides metabolic abnormalities. Patients commonly have low levels of serum phosphate, potassium, and magnesium.
- ***Metabolic syndrome*** – is characterized by a genetic and/or acquired decrease in insulin sensitivity, notably in the muscles, liver, and adipose tissue, which leads to elevated glycemic levels.

The III Adult Treatment Panel of the National Cholesterol Education Program proposed a simple scheme for the routine diagnosing of metabolic syndrome, according to which diagnosis can be established if there are at least three of the following five risk factors (American Association 2002):

- Increased abdominal circumference ($\geq$102 cm in men and $\geq$88 cm in women)
- Increased triglycerides ($\geq$150 mg/dl)
- Reduction of HDL cholesterol ($<$40 mg/dl in men and $<$50 mg/dl in women)
- Increased blood pressure ($>$130/85 mmHg or under treatment for hypertension)
- Increased glucose ($\geq$100 mg/dl)

Summary Points

- This chapter focuses on severe protein-calorie malnutrition (SPCM) after bariatric surgery, its causes, diagnosis, and medical treatment.
- A literature review was conducted to identify studies reporting the causes, severity, and medical management of protein-calorie malnutition (PCM), as well as the results of treatment. Little information is available about evidence-based studies, especially on the severe form of malnutrition.
- Protein-calorie malnutrition may be described as protein, energy, and micronutrient deficiency, depending on the inability of the body to satisfy the protein and energy fuel requirements through diet (Torún 2009).
- According to the World Health Organization, the diagnosis of SPCM can be made for BMI <16 kg/m^2, but there are error factors associated with body weight. Although the disproportion between the body mass distribution and the hydric balance is cited as an error factor, the changes in the body weight may reflect an insufficient energetic or protein absorption.
- Severe protein-calorie malnutrition is a marked protein and energy deficiency resulting in a generalized loss of muscle mass, decline in nutritional status, weakness, apathy, and a significant reduction in physical capacity with the risk of death.
- The severity of PCM can be established by the assessment of nutritional status based on the clinical history of the patients, on their anthropometric measurements, and on laboratory tests.
- The relation of the percent weight loss to the time of malnutrition development is of great value for assessing PCM risk.
- Speed of installation of malnutrition and low BMI are associated with the risk of patient death.
- Medical therapy for PCM after bariatric surgery does not differ much from that used for PCM caused by other factors than bariatric surgery and emphasizes nutritional support.
- Surgical revision for SPCM after bariatric surgery is indicated when there is a failure of medical treatment or a prevailing anatomical cause, such as anastomosis stenosis refractory to endoscopic dilatation.

Case Report

A 51-year-old obese woman, with a BMI of 50 Kg/m^2, underwent RYGB surgery and 1.5 months later presented vasomotor symptoms suggestive of early dumping syndrome such as tachycardia and intensive sweating and also nausea. To avoid those symptoms, she started restricting food intake, skipping meals, and eating small quantities. Six months after the surgery, the conditions evolved with diarrhea mounting up to ten daily liquid evacuations. However, she did not look for medical assistance for over 2 years after surgery, when she eventually was referred to hospital with complaints of fatigue, difficulty in walking, hair loss, edema, and diarrhea.

Table 3 Nutrition oral and parenteral therapy

Days after hospital admission	Oral	Parenteral			Parenteral + Oral Kcal/day
	Low CH, low fat Kcal/day	Protein (20%) g (Kcal/day)	Carbohydrates (50%) g (Kcal/day)	Lipids (20%) g (Kcal/day)	
10–13	600	45 (180)	135 (459)	30 (57)	1116
14–16	600	70 (280)	150 (510)	38 (72)	1182
17–20	600	85 (340)	180 (612)	42 (80)	1292
21–30	600	85 (340)	210 (714)	48 (91)	1405

CH Carbohydrates

On physical examination, she showed signs of severe protein-calorie malnutrition, including generalized depressive edema, pleural effusion, bruises, and thin and brittle hair. BMI was 24 Kg/m^2. Laboratory data showed hypoalbuminemia (1.7 g/dL), macrocytic anemia, lowered red blood cells count (2,35 10^6 U/L), hemoglobin (8 g/dL), hematocrit (24%), a medium corpuscular volume slightly increased (102), and lowered copper content (44.2 ug%). Sudan test was positive. Reduced oral food intake and mainly diarrhea after RYGB were hypothesized as the main causes of SPCM. Due to the severity of the clinical picture, intestinal transit time and breath test to exclude bacterial overgrowth syndrome were not done at that moment.

Nutrition support was started immediately through enteral nutrition associated with oral diet. A standard enteral nutrition of 200 mL in 24 h was initiated, as well as a sucrose-free and low-fat oral diet, split into six meals per day. The enteral nutrition was continuously administered through a nasoenteric tube with an infusion pump. On the second hospitalization day, the patient had diarrhea with liquid and loose stools, abdominal distension, and flatulence. Then, the enteral diet was discontinued, and the oral diet was maintained and slowly increased. The maximum volume tolerated by the patient was 1200 mL/day, corresponding to about 1200 kcal/day. The stools were still watery and loose, and the daily episodes were around 7 to 8.

Since the patient was not showing any improvement in nutritional status, parenteral nutrition was initiated on the tenth hospitalization day through central venous access. Calorie and protein contents of parenteral and oral nutrition are summarized in Table 3.

Parenteral nutrition was provided for 27 days, and oral diet was maintained in small quantities. After this period, enteral nutrition was restarted, 600 mL/day being administered with continuous infusion. During the parenteral and oral nutrition period, the patient's edema gradually decreased, the bruises disappeared, and the hair started growing again. The patient also had an improvement on the diarrhea. The evacuations decreased to two to three episodes a day, and the stool consistency became thicker. With the decreasing of the edema and the improvement in the nutritional status, the enteral nutrition was gradually increased to 1350 kcal/day. The oral diet was maintained and provided around 600 kcal/day. The hair was thicker, and the stools were no longer loose. The laboratory tests showed normal results for serum albumin (4.1 g/dL), hemoglobin (13 g/dL), hematocrit (38%), red blood cells (4 10^6 U/L), and medium corpuscular volume (94) and a significant increase in copper (60.4 ug%). As the patient showed clinical and nutritional

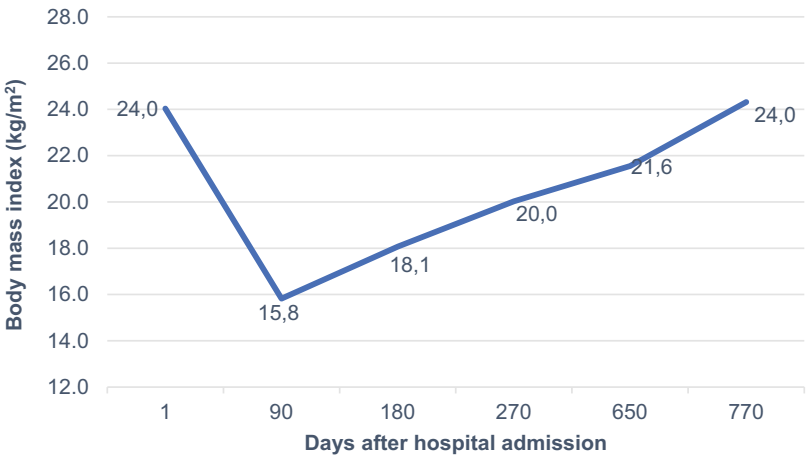


Fig. 4 Body mass index evolution

improvement and increased oral intake, the enteral nutrition was gradually reduced and discontinued at the time of the patient's discharge, after 90 days of hospitalization. The patient was instructed to maintain the oral diet at home, low in sucrose and fat, split in six meals a day.

She continues taking multivitamin and minerals supplementation and being attended at the outpatient bariatric service. Along 2 years after discharge, the patient has had discrete increases of the BMI. After 770 days following discharge, she eats seven meals a day and takes oral protein supplement mixed with fruit twice a day. She does not exhibit clinical signs of protein-calorie malnutrition, her BMI is about 24 Kg/m^2, and her corporal weight is 60 Kg. The most recent laboratory tests revealed normal serum albumin (4.0 g/dL), red blood cells (3.52 10^6 U/L), hemoglobin (11.5 g/dL), and hematocrit (36%). Figure 4 represents the changes in the BMI, 24 Kg/m^2 on admission reduced to 15.8 Kg/m^2 on discharge, probably due partially to the decrease in edema, and increased to 24 Kg/m^2 after 25 months, probably due the increase in corporal muscular mass and fat.

Although the BMI presented normal value on hospital admission (24 Kg/m^2), there are mistake factors associated with body weight. The patient presented edema, but although the disproportion between the body mass distribution and the hydric balance is cited as an error factor, the body weight changes reflect an insufficient energetic or protein intake. There was an important reduction in the preoperative BMI (52%), greater than that expected for patients undergoing RYGB, for whom the weight loss has been referred between 30% and 40% within 1–2 years after the surgical procedure.

The purpose of presenting this case was to emphasize the occurrence of serious malnutrition and anemia due to reduction in food ingestion and mainly to diarrhea in a patient submitted to RYGB and the successful result of treatment just through nutritional support and correction of the dietary mistakes. The patient recovered the normality of her nutritional status, shown by clinical and laboratory results. The question remains whether the long hospital stay could

have been reduced with the administration of pancreatic enzymes and/or antibiotics. The diarrhea episodes were reduced, but the patient still presents a frequency of around three to four daily evacuations of softened stools, and malnutrition and anemia may return if there is non-compliance with the scheduled nutrition recommendations. The occasional recurrence of diarrhea and malnutrition would require a better investigation of the various hypothetical causes of diarrhea, among them intestinal bacterial overgrowth, low digestive action of pancreatic enzymes, and short bowel syndrome. Based on the diagnosis, the proper treatment should be done, including revision surgery.

Abstract

Despite India's progress in launching and scaling up programs aimed at achieving optimal child nutrition over the last decade, India fell short of the 2015 Millennium Development Goals. This chapter reviews existing national level programs that address child nutrition, details their performance, and recommends changes that can enhance their impact on child nutrition. Specifically, we identify challenges and opportunities in the implementation and operation of national level programs, which currently function in silos and lack a cohesive coordinating strategy. This chapter also documents the palpable interest in advancing maternal and child health through national policy, advocacy, and social engagement that pervades India.

Introduction

In 2017, India continues to be at the epicenter of the child undernutrition epidemic. The intransigent nature of child undernutrition in India poses a vexing issue for public health experts, politicians, economists, and philanthropists, alike. Over the past decade, the proportion of stunted children only decreased by 10% (48–38%). Meanwhile, the proportion of children suffering from wasting increased by 1% (19.8–21.0%). Evidently, gaps persist in the knowledge-base and implementation know-how, which are preventing national-level programs from being more impactful in addressing the crisis. This chapter details existing national-level programs and policies aimed at addressing child undernutrition in India.

We organize this discussion of policies around the 2013 evidence-based framework on child malnutrition, which draws attention to the multifactorial causes of child malnutrition and the importance of identifying potential entry points for interventions (Fig. 1) (Black et al. 2013). According to this model, optimal child nutritional status can be achieved by three interdependent pathways improving (1) adequate dietary intake, (2) feeding and caregiving practices, and (3) overall health status (Black et al. 2013). A robust enabling environment at a national level that can support and sustain public health interventions and programs underlies the promise to affect change (Gillespie et al. 2013). This enabling environment can lead to nutrition-sensitive and nutrition-specific public health programs that can improve nutrition through the three aforementioned pathways. Nutrition-sensitive interventions address underlying determinants of malnutrition (Ruel and Alderman 2013), whereas nutrition-specific address immediate-determinants of malnutrition (Bhutta et al. 2013). Therefore, this framework facilitates a comprehensive discussion of child nutrition in India ranging from public policy to personal practice. Figure 1 lists major existing nutrition-sensitive and specific programs in India (bold).

National Policies and Programs

Creating an Enabling Environment

India is uniquely positioned to invest in its maternal and child health due to the capital generated by its booming economy. Led by commendable advocacy efforts of stakeholders, which include human-rights activists, economists, and academicians, nutrition has gained prominence in India's national agenda over the last decade (Swaminathan 2009). A more notable example of this advocacy is the Supreme Court case filed by activists to recognize the right to food as a legal right which was litigated for almost 10 years (2001–2011) (Mander 2012). Eventually, the Indian Supreme Court justices not only ruled in favor of the petition but also mandated enforcement of programs that provide food to underprivileged populations as their legal rights.

Despite these achievements, Indian government's commitment to address nutrition ranks 30th out of 45 nations with severe or alarming undernutrition status (Institute of Development Studies, UK Aid and Irish Aid 2015). This nutrition index considers 12 indicators based on legal decisions, public policies, and public expenditure. A closer look at this index reveals that significant areas of improvement for India at a governance level include developing multisector policy coordination and establishment of time-bound nutrition targets. To accentuate this point, consider Fig. 2 that provides an overview of national programs for addressing child undernutrition. The eight programs described in this figure and detailed below are run by a total of seven different departments from seven different ministries. This lack of horizontal integration leads to redundancy and competing agendas, which may lead to confusion and suboptimal implementation of policies.

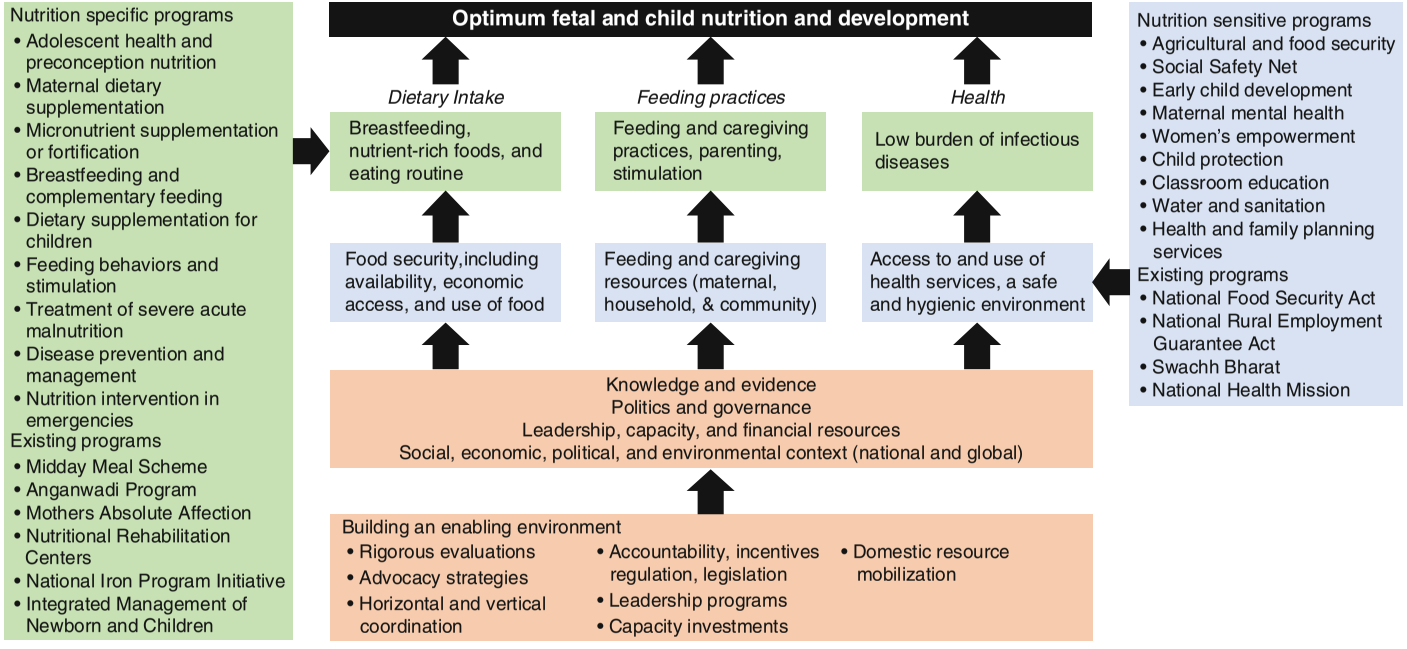

Fig. 1 Framework for optimum child nutrition and development. Modified version of the framework for achieving optimal child nutrition proposed by Black et al. (2013) in a series of articles for child nutrition in the Lancet. Key adaptions in this figure include categorization of existing programs in India at their respective level of action (Reprinted from Black et al. (2013), with permission from Elsevier)

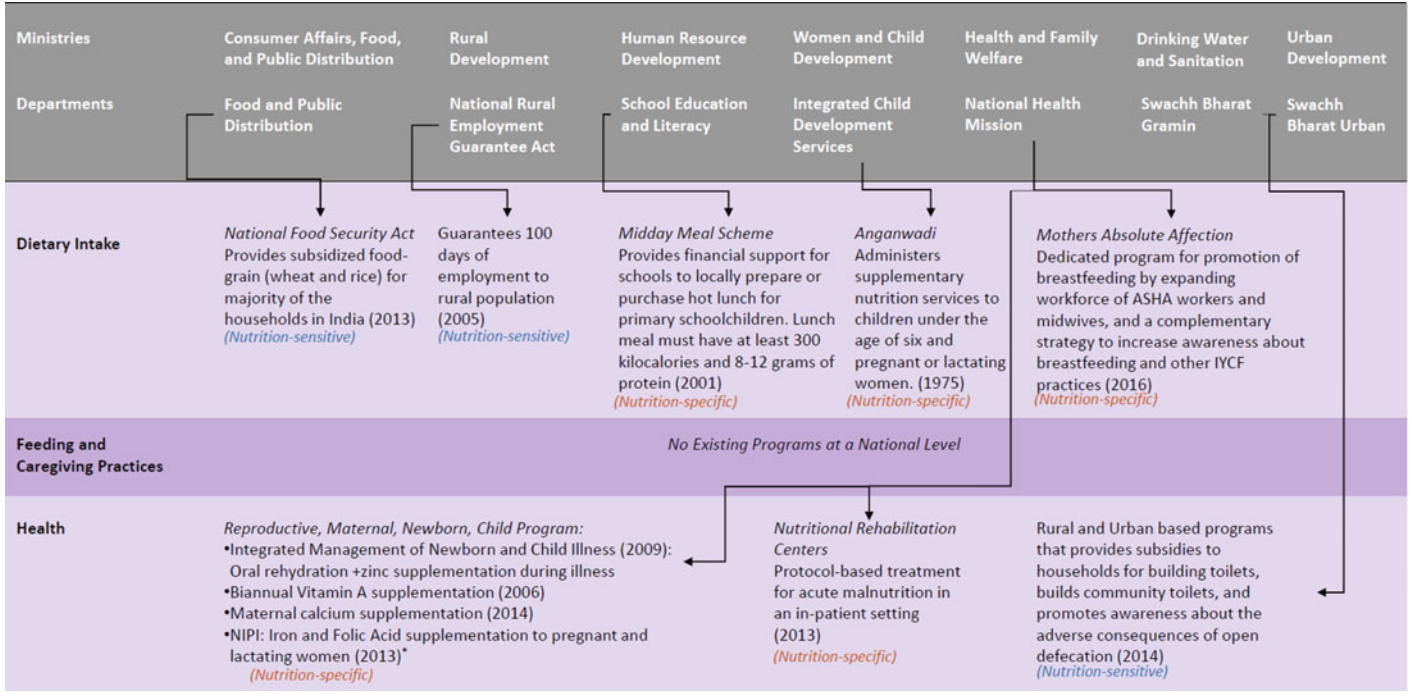

Fig. 2 An overview of national programs in India addressing child nutrition. Existing Indian government programs to support at-scale coverage of evidence-based interventions. The programs are organized based on the pathways (Fig. 1) through which they affect child undernutrition (Credit: Unpublished work by authors, Key: NIPI = National Iron Plus Initiative. ASHA = Accredited Social Health Activists)

Improving Infant and Young Child Feeding Practices: Breastfeeding and Complementary Feeding

Background: National level data from the 2005 National Family Health Survey spurred a nationwide effort to promote Infant and Young Child Feeding practices. According to these results, although the majority (87%) of mothers reported breastfeeding their child in the first year of life, less than a quarter reported early initiation of breastfeeding and less than half reported exclusive breastfeeding for children under the age of 6 months (Menon et al. 2015). Based on the most recent data available from 13 states for which the 2014–2015 National Family Health Survey data have been released, the proportion of children who were breastfed within 1 h of birth and those who were exclusively breastfed has increased by 13.4% (range: −5.1 to 30.9) and 18.4% (range: −6.3 to 43.2), respectively. Conversely, the proportion of children with timely initiation of complementary foods has decreased. In 2005, roughly two out of every three children received solid, semi-solid, or soft food between 6 to 8 months and, while 2014–2015 data are available for only 11 states, it suggests an average decrease of 9.7% (range: −23.8 to 4.9) (Menon et al. 2015). This decline is concerning particularly when considering evidence from randomized controlled trials suggesting that timely initiation of complementary feeding is more effective in preventing stunting than breastfeeding (Jones et al. 2003).

Anganwadi centers: Named after the Hindi word for court shelter, Anganwadi centers are the primary platform for delivery of the Integrated Child Development Services (ICDS). There are more than 1 million Anganwadi centers across India, and their workers are employed by the Ministry of Women and Child Development to administer supplementary nutrition services to children under the age of six and pregnant or lactating women (Bredenkamp et al. 2006; Saxena 2016). Additionally, Anganwadi workers provide nonformal preschool education, health education, immunization, health check-up, and referral services. Initially, these centers started as a program for households that are below the poverty line; however, legislative amendments in 2014 have expanded the eligibility to all children under the age of six.

The full impact of ICDS on child undernutrition is blunted by poor quality and coverage of nutrition-specific programs. In 2011–2012, only 39% of all eligible children had ever received a take-home food ration or prepared hot meals and only 14% of children had received it in the previous month (Kandpal 2011; Desai and Vanneman 2015). Interviews of Anganwadi workers suggests that they are overburdened with the task of deploying multiple programs from different departments and onerous documentation takes away from time that could be used providing services (Programme Evaluation Organisation: Planning Comission 2011). Because allocation of resources and funding to Anganwadi centers is contingent upon documentation, gaps in the effective functioning of these centers have emerged and persisted over time, particularly in high-demand regions (Programme Evaluation Organisation: Planning Comission 2011).

Considering the prominent role played by Anganwadi centers in combating child undernutrition in India, it is important to focus on overcoming process-related challenges by strengthening the workforce at a local level and leveraging technology to mitigate the burden of administrative responsibilities. The newly established

Mothers Absolute Affection program aims to increase local workforce for maternal and child nutrition, specifically for promoting infant and young child feeding practices. More details on this program are described below. The impact of this program's initiative towards meeting the nutrition needs of its community and its coverage of Anganwadi-based programs remains to be seen.

Mothers absolute affection (MAA): MAA is an intensive nationwide effort that was implemented in August 2016 to enhance breastfeeding and other infant and young child feeding practices (Ministry of Health and Family Welfare and Mission 2016). MAA proposes to strengthen the workforce of Accredited Social Health Activists (ASHA: *Hindi word for hope*) and Auxiliary Nurse Midwives at a community level and train them to provide lactation support services to young mothers. The program has dedicated funding to generate awareness about the importance of breastfeeding through mass-media activities that include TV commercials, radio spots, and print media. Additionally, ASHA workers are tasked to conduct regular meetings with mothers from their community to promote breastfeeding practices and reinforce this message during their home visits as part of the checkup for newborns. The MAA program proposes to recruit and train additional ASHA and auxiliary nurse midwives to saturate the villages by August 2017.

A review of the operational guidelines released by National Health Mission raises many concerns. First, the program is centered on breastfeeding practices, and no specific plan is proposed for promoting other Infant and Young Child Feeding practices. Considering that complementary feeding practices and dietary diversity have decreased in the past 10 years, a lack of focus on these indicators is troublesome. Second, the program is not grounded on a cohesive implementation framework. Although there is a concerted effort to consider program activities at a macro-, meso-, and microlevel, a lack of framework impairs the ability to define the implementation processes and evaluate performance in a time-sensitive manner. The dynamic ability to generate feedback during the implementation stage and initiate corrective actions at the regional level is very important in India's socio-culturally diverse context. Lastly, the MAA program is primarily operated by the National Health Mission and misses the mark on horizontal integration with ICDS services and the Anganwadi program. The MAA program largely depends on developing new interactions and contact-points with reproductive-aged women and does not leverage existing partnerships developed by Anganwadi workers.

These limitations notwithstanding, the MAA program has tremendous potential to improve maternal and child nutrition based on its scope and the resources allocated for the program. The program's reach and impact could be enhanced by employing a more dynamic implementation framework, increasing collaboration with ICDS services, and integrating evidence-based interventions in its platform.

Promoting Dietary Diversity

Background: Diversity in mother and child's diet is an important determinant for child undernutrition (Bhutta et al. 2008, 2013). A review of national level data from the past 30 years suggests that dietary diversity has steadily declined in India, as has

overall dietary intake. This decrease is observed in both rural (2150 calories/person/day in 1993–1994 vs. 2020 in 2009–2010) and urban regions (2071 vs. 1946) in India (National Sample Survey Organisation 2012). Dietary diversity, as measured by the proportion of the population consuming at least four food groups (milk, vegetables, fruit, and pulses), has decreased over the same time period as well (Gaiha et al. 2013; Desai and Vanneman 2015). Remarkably, the proportion of women of reproductive age and children with low hemoglobin levels (< 10 mg/dl) has also increased over time (Desai and Vanneman 2015).

National Food Security Act: This new legislation, passed in 2013, strengthens the existing Public Distribution System (PDS) and expands the proportion of the country's households that can benefit from it. As a result, the PDS is now the largest safety net program in the world. It provides five kilograms of cereals per person per month at the subsidized rate of 1 to 3 rupees per kilogram to two-thirds of the country's population (Mishra 2013). However, this reform might be a double-edged sword. Recent scholarship based on data from 2011 to 2012 suggests that families receiving food through PDS predominantly used the subsidized cereals and had reduced dietary diversity (Desai and Vanneman 2015). After accounting for potential confounders, investigators found that on a national average, in comparison to nonbeneficiaries, beneficiaries consumed less milk (780 ml per capita) and less pulses (30 g per capita) on a monthly basis. The assumption that by providing substantial subsidies for cereal, families would use saved capital to consume diverse foods may be inaccurate. Considering the cereal-centric composition of India's staple diet, reduced consumption of milk and vegetables, secondary to a program aimed at enhancing food security, is concerning because dietary diversity is a crucial determinant of children's nutritional status. A higher proportion of children under the age of five from households that utilized Public Distribution System (40.2%) were underweight in comparison to children from households that did not take advantage of the program (33.4%). Adjusting for potential confounders reduced the difference between the two groups (39.4 vs. 37.4), but did not eliminate or reverse it (Desai and Vanneman 2015). Taken together with the evidence for the importance of a micronutrient-rich and diverse diet, there is an urgent need to amend this well-intentioned program to promote consumption of milk, fruits, and pulses.

National Rural Employment Guarantee Act (NREGA): This national employment program is another form of social safety net and guarantees rural households 100 days of unskilled manual work per year (Ministry of Law and Justice 2005). This program is implemented by local governments at the village level, and the costs are covered by the state and national governments. By 2014, 9 years after its inception, NREGA had been implemented across all 673 districts in India; 50 million households participated in the program that year, 48% of whom were women; and the program has generated a total amount of 46 billion US dollars (Ministry of Rural Development 2015). A cross-sectional study of 540 households from Rajasthan, one of the first states to implement NREGA, suggests that female participation is inversely associated with acute forms of child malnutrition but not with chronic forms (Nair et al. 2013). However, other states have not implemented this program to its fullest potential. According to a recent analyses of the program,

20 out of the 31 states in India have suboptimal implementation and can maximize their rural employment gains by increasing engagement of low caste populations and women (Singh 2016). In comparison to efficient states, inefficient states had 133% less involvement of women and 75% less involvement of low caste populations (Singh 2016). Thus, the promise of this program for socioeconomic empowerment remains unfulfilled and concerted efforts to engage women and low caste people in this program, especially in historically poor states, should be prioritized. One possible solution for this challenge is to expand the scope of job opportunities to include apprenticeships for women with female health workers supporting Anganwadi, MAA, and National Health Mission program activities.

Midday meal scheme: Based on a 2001 Supreme Court decision in 2001, the national government funds provision of cooked meals consisting of at least 300 kcal and 8–12 g of protein to children at school. These meals are prepared locally either by the schools themselves or in collaboration with (NGOs) (Khera 2006; Chutani 2012). As of 2015, more than 136 million primary-school going children in India receive meals because of this program (Kumar 2016). A review of survey-based studies have found that there is a rise in attendance and enrollment rates, especially among girls and low caste people after the implementation of this program (Khera 2006). Receipt of Midday meals is associated with a reduced gap between recommended dietary allowance and actual daily intake of children of 30% for total calories, 10% for iron, and almost entirely for protein (Afridi 2010). Another study of children living in drought-prone regions of Andhra Pradesh found that Midday Meals blunted the adversarial effect of drought on children's nutritional status (Singh et al. 2014a). Midday Meal Scheme has also faced substantial controversy due to reports of unsanitary cooking conditions resulting in illness among children across the country. In one such episode in Bihar, 22 children died after consuming meals cooked with adulterated oil (Singh 2013; Pain 2014). The governing body responsible for Midday Meal Scheme has endeavored to set cooking standards and has established an expert committee for ensuring quality and proper sanitation (Kumar 2016). Unfortunately, calls for fortification of food grains were dismissed during the most recent committee meeting for this program (Kumar 2016).

National iron program initiative: The Indian government launched this program as part of their comprehensive strategy to address iron deficiency anemia in the subcontinent. The most recent national-level estimates of anemia and iron deficiency are based on 2005–2006 National Family Health Survey data which revealed that roughly 70% of children under the age of five were anemic and that the prevalence of anemia among mother and child had increased since 1998–1999 (Deb 2015). Under this program, different recommendations are proposed for providing iron and folic acid supplementation for five different groups: children aged 6–59 months, children aged 5–10 years, adolescents aged 10–19 years, pregnant or lactating women, and nonpregnant, nonlactating women in reproductive age (20–49 years). However, there are no explicit guidelines for coordination with other nutrition-specific programs (i.e., Anganwadi, MAA), and there is a paucity of evidence for the effectiveness or coverage of such micronutrient supplementation efforts. As of 2015, almost all states had reported providing supplements to lactating and pregnant mothers, but

only a few states provide supplements to children aged 6 months to 5 years (Assam, West Bengal, Uttarakhand, and Odisha) and even less provide supplements to children aged 5–10 years old (Assam and Odisha) (Deb 2015).

Biannual vitamin A supplementation program: Initially started as a prophylaxis program against nutritional blindness in 1970, the present-day national program for Vitamin A supplementation has undergone significant changes. In 2006, based on a workshop on micronutrients, the Indian Ministry of Health and Family Welfare instituted a policy for bi-annual vitamin A supplementation (Ministry of Health and Family Welfare, Department of Family Welfare and Child Health Division 2006). The program is implemented using the Government's ASHA workers, and in 2011, 62 million children (~66%) received two doses in 1 year. There are no publicly available evaluations of this program's coverage and effectiveness at a local or national level.

Promoting Water and Sanitation Hygiene

Background: The tremendous burden of poor sanitation and hygiene in India is highlighted by two remarkable statistics: (1) a third of worldwide population lacks access to proper sanitation and lives in India and (2) roughly two-thirds of rural Indian population defecate in the open, which highlights the tremendous burden of poor sanitation and hygiene in India (UNICEF and WHO 2012).

Swachh Bharat Program: The current government program to improve sanitation facilities across the rural regions of the country, officially launched on 2 October, 2014 (Mahatma Gandhi's 145th birth anniversary), revamps existing programs dating back to the 1986 (Hueso et al. 2013). In 1986, to reduce open defecation, the Indian government launched a top-down program to provide families with subsidies towards building a toilet. The program invested 6 billion rupees and constructed over 9 million latrines in rural areas but did not produce much change in the sanitary practices as only 22% of rural households reported access to a toilet in 2001 (Department of Drinking Water and Sanitation and Ministry of Rural Development 2012). In response, India launched a rigorous campaign in the 2000s that aimed at enhancing knowledge and awareness of the importance of proper sanitation among rural households (Hueso et al. 2013). However, this effort also fell short of its expectation and the rural sanitation coverage in 2011 improved only by 9% points (Chandramouli 2012).

The current iteration, the Swachh Bharat Program, is informed by lessons learned from these previous experiences and employs a subsidy-based and public-private partnership approach that is supplemented by a massive campaign for generating demand through Information, Education, and Communication tools (Ministry of Urban Development 2014; Ministry of Drinking Water and Sanitation 2016; National Sample Survey Organisation and Ministry of Statistics and Programme Implementation 2016). The goal of Swachh Bharat Program is to eradicate open defecation within 5 years, by October 2, 2019, which marks the 150th birth anniversary of Mahatma Gandhi.

It is unclear whether previous attempts to reduce open defecation by building more toilets resulted in a decreased incidence of diarrhea in children and a subsequent improvement in their nutritional status. Two separate cluster randomized controlled trials to evaluate the effect of Total Sanitation Campaign revealed that although the Government program was associated with an increase in individual household latrines, there were no discernible improvements observed for child health outcomes (Clasen et al. 2014; Patil et al. 2014). A possible reason for this disconnect between improved toilet facilities and health outcomes within the Indian context is the role of hygiene behavior and environmental presence of pathogens (Dutta et al. 2016). A trial to improve nutritional status of school-aged children by providing iron-fortified lunches reported an increase in total body iron but did not improve hemoglobin levels, possibly due to presence of soil-transmitted helminths (Osei et al. 2010). Therefore, the momentum towards improving sanitation facilities at a household level following Swachh Bharat Mission guidelines must be complemented with a systematic effort to help improve individual hygiene for caregivers and children. The scope and reach of MAA program focused on improving infant and young child feeding practices must be explored as a possibility to deliver messages for safe hygiene practices.

Nutrition During Illness and Management of Acute Malnutrition

National Health Mission (NHM): Similar to other nutrition-related programs discussed earlier in this chapter, NHM is an expansion and intensification of an existing program called National Rural Health Mission (NRHM) (Ministry of Health and Family Welfare 2012). NRHM was originally formed in 2005 to address the rural health needs of 18 states, where public health indicators were weak (National Rural Health Mission 2005). In 2013, NRHM was expanded to all 29 states and covered urban regions as well (Ministry of Health and Family Welfare 2012). Several successful maternal and child health programs that were started under NRHM or as experiments in other states were coalesced to form a comprehensive Reproductive, Maternal, Newborn, Child, and Adolescent health strategy grounded in the lifecycle framework for health (Black et al. 2008; Ministry of Health and Family Welfare 2012). Overall, there are more than 20 different child-health-related programs and interventions. We briefly describe selected activities that affect nutritional status of the child before presenting a detailed analysis of Nutritional Rehabilitation Centers, NHM's primary program to combat acute malnutrition (Fig. 2).

Surveillance and supplementation: Leveraging the workforce of nearly 1 million ASHA workers and more than 200,000 auxiliary nurse midwives, NHM aims to track all pregnancies in rural and underserved urban areas using its web-based Maternal and Child Tracking system and promote antenatal checkups. NHM has provisions for free institutional delivery and newborn care for 1 year at public institutions, along with an implementation of an evidence-based newborn care package such as vitamin K injections, support for Kangaroo Mother Care, and administration of antibiotics to prevent neonatal sepsis. Additionally, ASHA workers

conduct scheduled home-based newborn care visits within the first 6 months to identify early danger signs. Auxiliary nurse midwives throughout the country provide oral swallowable calcium tablets to pregnant women and ask them to take it daily (1 g calcium/day) from 14 weeks of pregnancy to 6 months postpartum (National Health Mission 2014). At the time of initiation in second trimester, 12 strips with 15 tablets each are provided by the auxiliary nurse midwives and supplemented during third trimester, at the time of zero dose of polio for the infant, and at the time of diphtheria, pertussis, and tetanus vaccination for the infant. ASHA and Anganwadi workers are tasked with the responsibility of performing house visits to check adherence to twice-daily regimen.

Treatment of acute illness: NHM developed Integrated Management of Newborn and Childhood Illness guidelines to provide field training for ASHA workers in indentifying acute cases of childhood diarrhea and treat them with WHO formulated Oral Rehydration Solution packets and zinc tablets. ASHA workers also collaborate with Anganwadi workers to conduct household visits during peak infectious disease season (July–August) to identify cases of childhood diarrhea and provide oral rehydration and zinc therapy. According to government's estimates, 200 million families were reached and 3.6 million children received ORS-zinc therapy in 2014 (Department of Health and Family Welfare 2015). No independent, peer-reviewed national-level assessment of this intervention has been reported. However, an assessment of adherence to national guidelines for zinc supplementation (10 mg/day for ages 2–6 months and 20 mg/day for ages 7–59 months for 14 days) among districts in the state of Uttar Pradesh revealed that less than half (47.8%) of the children prescribed the treatment were able to complete it within 14 days (Lamberti et al. 2015).

To provide protocol-based treatment for severe acute malnutrition, NHM has established a total of 891 Nutritional Rehabilitation Centers (NRC). Anganwadi workers are primarily responsible for monitoring growth of the children in rural settings and referring them to the NRC program if they are severely underweight as per weight-for-height standardized score or mid-upper arm circumference measurements (National Health Mission 2011). After referral, NRC staff evaluate the child for severe acute malnutrition based on a list of criteria that includes the presence of bilateral pitting edema with any of the following complications: anorexia, fever, persistent vomiting, severe dehydration, hypoglycemia, anemia, or any other indication based on the clinician expertise. Once admitted, guidelines from WHO and Indian academy of Pediatrics are followed until the child is more than −1 standardized deviation for weight/height. WHO recommended F-75 and F-100 diets are prepared by cooks using locally available products; however, recipes are not standardized or published in the operating guidelines for NRCs (National Rural Health Mission 2011). If the child does not meet the threshold within 2 weeks, they are discharged with instructions for preparing nutrition-dense foods. Anganwadi workers are tasked with the responsibility to provide home-based care and monitor nutritional intake of these children postdischarge. ASHA workers are responsible for facilitating four follow-up visits to NRC at 15-day intervals (National Rural Health Mission 2011).

Evaluation and limitations: A handful of regional assessments of NRCs have reported mixed results (Aguayo et al. 2013; Singh et al. 2014b, 2016). Overall, there are reports of modest weight-gain during hospitalization: an average of 9.3 and 12.1 g/kg/day in two separate studies (Singh et al. 2014b, 2016). Less than half of the children who were hospitalized met the threshold for improvement prior to discharge and less than 20% completed all four visits postdischarge (Aguayo et al. 2013; Singh et al. 2014b, 2016). However, there is consensus that NRCs help reduce mortality among children experiencing severe acute malnutrition (Aguayo et al. 2013; Singh et al. 2014b, 2016). The number of NRCs needs to dramatically increase, especially in tribal and historically underserved regions, to effectively care for approximately 6 million children in India who suffer from severe acute malnutrition. In the meanwhile, improvements in the current NRC model can fill some coverage gaps.

Programmatically, there are three major inadequacies in the current NRC program. First, the reliance on Anganwadi workers, who are supported by a different administrative branch and are already overburdened with an outstanding number of responsibilities, to identify and refer children possibly experiencing acute malnutrition creates the possibility of missed or improper identification. Indeed, majority (up to 75%) of the children referred to NRC do not qualify for hospitalization (Prasad et al. 2012). These children are sent back with instructions for preparing nutrition-rich food at home and sometimes, though not always, with treatment for any underlying illness. This experience, especially if it recurs, could breach the relationship between the family and Anganwadi workers, which could lead to decreased attendance in the Anganwadi. Second, the criteria for discharging children after 14 days of stay at the NRC result in almost half of the children returning home with suboptimal nutritional status (Dasgupta et al. 2014; Singh et al. 2014b, 2016). Currently, Anganwadi workers are responsible for conducting home visits to monitor nutritional intake, and ASHA workers facilitate follow-up visits with NRCs (National Health Mission 2011). This generates coverage gaps and may be the cause for the substantial attrition observed in follow-up. Third, there is a need for community-based program that treats moderate acute malnutrition or uncomplicated severe acute malnutrition. Currently, families of children who do not qualify for hospitalization at NRCs or are discharged from NRCs without recovery receive training to prepare nutrition-rich foods, and Anganwadi workers are responsible for monitoring their progress. However, ASHA workers are better-suited to perform home visits, while Anganwadi workers are more effective at their own centers. Management of community-based program can be achieved by pairing Anganwadi workers with ASHA workers such that WHO recommended nutrition-rich foods and fluids can be provided to children either at-home by ASHA workers or at the Anganwadi centers by Anganwadi workers their staff. Development of a community-based program can also alleviate concerns about improper referral by Anganwadi workers to NRCs and can shift the task of preparing nutrition-dense food from families to NHS or ICDS programs. A handful of states have implemented experimental programs for community-based management of acute malnutrition with the support of Médecins Sans Frontières (Bihar), Department for International Development – United Kingdom (Madhya Pradesh and Odisha), and UNICEF (Andhra Pradesh) (Dasgupta et al. 2014;

Dasgupta et al. 2015). These programs show promise for the management of mild-to-moderate acute malnutrition by implementing ready-to-use therapeutic food. There is strategic involvement from India's public policymakers and the existing workforce of Anganwadi and ASHA workers, which is being leveraged to support these state-led experiments (Feeney and Lee 2012). However, the heterogeneity in the implementation of each of these experiments limits the potential for scaling-up similar programs across the country (Dasgupta et al. 2015).

Summary

See Table 1.

The Way Forward

The lack of horizontal integration across different programs (Fig. 2) limits accountability and impairs the full promise of each individual program. An example of a harmonious coordination between these programs to affect change would include co-opting increased workforce from NREGA to develop local centers for preparing and delivering nutrition-rich meals to different programs: Midday Meals, Anganwadi, Hospital, and Community-Based NRCs, etc. Such an approach, employing rural Indian women for nonlabor work, has the potential to empower women by increasing their self-esteem and equipping them with a skillset to seek additional economic opportunities.

The field of implementation science offers an opportunity to enhance horizontal integration across different programs and can facilitate equitable coverage of services. For example, grounding the MAA program on an implementation framework such as Practical, Robust Implementation, and Sustainability Model (PRISM) can promote adaptability of the program at a local level, identify agents of change that can support the initial implementation, and define processes that can help sustain it over time (Feldstein and Glasgow 2008). Under this framework, local stakeholders can be engaged prior to implementation and help identify members from within the community that can help implementation of the program. This grassroots approach can generate buy-in from the community and enhance its uptake. Additionally, this process can also help identify parallel activities within the community, which can be paired with the implementation of MAA program. Moreover, this approach also provides a predefined framework for program evaluators to assess the impact of the program consistently across different settings.

In addition to improved governance of existing programs, equitable coverage of services for tribal and low-caste people must be prioritized. While discrimination based on caste is outlawed in India, low caste members of Indian society still experience it on a daily basis (Haq 2013; Thomas et al. 2013). In a study of 565 villages studied across 11 states, 33% of villages have public health workers who

Table 1 Impact of selected national-level programs on the coverage of evidence-based interventions and recommendations for improving child nutrition in India

Topic	Program	Coverage	Recommendation
Management of Severe Acute Malnutrition	Nutritional rehabilitation centers (NRCs)	1. Close to a thousand nutritional rehabilitation centers across the country 2. Overall reduction in mortality among children with severe acute malnutrition, but low cure rate (<50%), and poor follow-up (<20%).	1. Expansion of NRCs to increase coverage, especially in tribal and historically underserved regions 2. Establishing standards for preparing nutrition-dense foods using local products
	Swachh Bharat program (Gramin and urban) (***Nutrition-sensitive***)	1. Approximately 27 and 25 million more toilets built in rural and urban regions, respectively 2. Impact of the Swachh Bharat program on child growth is unclear, but studies based on previous versions of similar programs showed an improvement in toilet use but were unable to find improvements in child growth or health status	1. More evaluation of the impact of Swachh Bharat program is needed to assess its impact on incidence of infectious diseases and growth failure 2. Programs to promote healthy water and sanitation hygiene can enhance the potential health benefits of increasing toilet use throughout the country
Preventive zinc supplementation	Integrated Management of Newborn and Child Illness	1. Approximately, 3.6 million children received ORS-zinc therapy in 2014 2. A single-state study assessed adherence of national guidelines to zinc supplementation and found 47.8% of children completed treatment	1. Additional evaluation of preventive zinc supplementation is needed 2. Coordination with the ramp-up of community-based management of acute malnutrition
Promotion of breastfeeding	Mothers absolute affection	1. Too early to report program-based findings because it was launched in august 2016 2. Based on data from 2014 to 2015 NFHS, less than 50% of infants from high-priority regions received breastmilk within the first hour 3. Overall, breastfeeding practices increased from 2004 to 2005 while complementary feeding decreased	1. Enhancing emphasis on timely initiation of complementary feeding and dietary diversity in light of a declining trend in the last 10 years 2. Adopt a defined implementation strategy to identify pitfalls in a timely manner allowing for modification at a local level 3. Integrate ICDS and Anganwadi programs in a more defined and specific manner

(*continued*)

Table 1 (continued)

Topic	Program	Coverage	Recommendation
Appropriate complementary feeding	Anganwadi program	1. Recipients of services have improved nutritional status but coverage is poor, especially in high-demand regions. 2. In 2011–2012, less than half of the eligible children had ever received take-home food ration	1. Capacity building to increase coverage of services and lessen administrative burden of Anganwadi workers 2. Partnering with ASHA workers to deliver nutritional services at home
	Midday meal scheme (***Nutrition-sensitive***)	1. Evidence suggesting the effectiveness of the program in closing the nutritional gap, particularly for protein 2. Multiple reports of poor sanitary conditions leading to serious illness and deaths among children	1. Establish safety and sanitation standards for preparing meals (already in place) 2. Incorporate micronutrient-fortified food products in school lunches 3. Promote healthy handwashing and safety hygiene to children
Management of Mild acute malnutrition	No National-Level Programs	1. Five states have implemented experimental programs in collaboration with international health organization and support from Indian government	1. Standardization of protocol to allow for a scale-up of similar programs across other states
Periconceptual folic acid supplementation or fortification	National Iron Program Initiative (includes folic acid)	1. Since the program's launch in 2013, no national-level estimates of anemia has been reported 2. As of 2015, most states provide supplements to pregnant and lactating mothers but only a handful are providing supplements to children	1. Coordination with MAA program, midday meal scheme, and Anganwadi programs can help improve the coverage of this intervention
Maternal balanced energy protein supplementation	No National-Level Programs		
	National Food Security act (***Nutrition-sensitive)***	1. 30 states and union territories are providing subsidized food, 2 states (Chandigarh and Puducherry) are providing direct cash transfers 2. Likely to reduce dietary diversity because beneficiaries over-depend on subsidized cereal	1. Subsidize other food groups (milk, fruits, pulses) 2. Explore partnership opportunities with local dairy and farms

(*continued*)

Table 1 (continued)

Topic	Program	Coverage	Recommendation
	National Rural Employment Guarantee act (***Nutrition-sensitive)***	1. Some evidence for link between female participation and reduces odds of acute child malnutrition 2. Inefficient implementation in several states, not equitable participation from women and low caste people	1. Expand the types of job available to include support staff for Anganwadi and ASHA workers 2. Prioritize employment for women and low caste people in inefficient states
Maternal multiple micronutrient supplementation	No National-Level Programs	1. Several different programs provide micronutrient supplementation (iron, folic acid, Iodine, calcium) during peripartum period	1. A unifying strategy for providing multiple micronutrients can enhance efficiency and coverage
Vitamin A supplementation	Bi-annual vitamin A supplementation program	1. Number of children receiving two doses per year increased from 25% in 2005 to 66% in 2011 2. 62 million children received two doses in 2011	1. Evaluation of the program's impact on night blindness and child mortality/morbidity is needed
Maternal calcium supplementation	Calcium supplementation during pregnancy and lactation	1. 2014 guidelines dictate complete coverage of twice daily oral chewable tablets that are provided by auxillary nurse midwives 2. Surveillance by ASHA and Anganwadi workers to assess compliance with supplementation regimen	1. Pair the program with other existing programs for providing maternal micronutrient supplementation to facilitate a comprehensive strategy 2. Evaluation of the program's impact and implementation process is needed

This table provides a summary of the national-level programs, their impact on the coverage of evidence-based interventions, and finally, recommendations for enhancing their impact (Credit: Unpublished work by authors)

refuse to enter homes of Scheduled Caste people, 25% forbid Scheduled Caste from buying milk, 48.4% do not allow Scheduled Caste access to water supplies, 73% do not allow Scheduled Caste to enter homes of other castes, and in 37.8% of the villages, children of Scheduled Caste families are made to sit separately in government schools (Thomas et al. 2013). A recent study of pregnant women from rural western India found that in comparison to General Caste, women of Other Backward Castes were twice as likely to report experiencing discrimination and women of

Scheduled Castes or Tribes were four times as likely (Khubchandani et al. 2017). Thus, there is a need for a systematic approach to address maternal and child health in low-caste and historically underserved populations.

Conclusions

India has made tremendous progress over the last decade in launching and scaling-up programs aimed at achieving optimal child nutrition by improving dietary intake and health status of children. Although India fell short of the Millennium Development Goals, there is a renewed interest in advancing maternal and child health through advocacy and social engagement. It is important for India to act now and institute support for ongoing successful programs. In addition, India should endeavor to improve the implementation and governance of programs, which lack horizontal integration with other similar projects. An example of a step towards this goal is the MAA program, which aims to improve coordination between the existing workforce and programs focused on maternal and child health. As India sets its agenda towards meeting the Sustainable Development Goals, it is important to have a clear strategy for addressing the social determinants of health and implementing policies focused on health equity. Both of which will be crucial in helping to close the gap in child malnutrition.

In this decade of nutrition, India could be a beacon of light for the rest of the world with concerted efforts to reduce the huge burden of undernutrition and micronutrient deficiencies. To do this, there must be a massive investment in addressing social determinants, especially issues of women's empowerment and huge inequities in access and opportunity. The initiatives undertaken in health must be expanded to address food insecurity, gender, religious, ethnic, and caste disparities as well as targeting interventions and safety nets to reach those who need it most. There is the political will at hand and even resources to address this issue within our life time.

Policies

The eight national-level programs covered in this chapter are run by a total of seven different departments from seven different ministries. This lack of horizontal integration leads to redundancy and competing agendas, which leads to confusion, loss of accountability, and suboptimal implementation of policies. Therefore, in our review of these programs and their impact on child nutrition, we identify potential areas of opportunities for enhancing the performance of each program. Broadly, our recommendations fall within these categories:

- **Expanding effective programs to reach rural, tribal, and historically underserved populations**: Nutritional rehabilitation centers have shown promising results, but their coverage is limited and prohibitive for families leaving in geographically remote regions.

- **Increasing evaluation and oversight of programs to allow community-specific adaptation**: National Rural Employment Guarantee Act is well received but has failed to engage women and low-caste workers in states, especially those with higher burden of child undernutrition.
- **Coordinating activities across different programs to leverage existing resources and infrastructure**: Anganwadi program holds promise for delivering nutrition-specific intervention at scale if its activities are coordinated with MAA program.

In addition to the recommendations for individual programs, our chapter also highlights the importance for governmental leadership to define a comprehensive strategy that is grounded in implementation science and thus can prespecify opportunities for adaptation, intervention, and evaluation of each of these programs.

Dictionary of Terms

- **Child nutrition**: Science of nutrients and nutrition of children necessary for proper health and growth
- **India**: A country located in South Asia
- **Health policy**: A set of decisions and plans that dictate action of and related to health and healthcare
- **National programs**: A set of activities decided by central government of a country (India) that is applied throughout the country
- **Nutrition framework**: A conceptual model to understand the factors that affect nutrition
- **Governance**: The process through which health policy is translated into national programs
- Implementation science: A study of methods and results of implementing conceptual ideas and interventions into real-world settings
- **Advocacy**: The act of coalescing support and providing recommendations on behalf of a particular cause or health policy
- **Rural-urban disparities**: Differential circumstances experienced by people living in rural areas in comparison to urban areas
- **Social determinants of Health**: Nonmedical factors, such as where people are born, live, and work, as well as who they interact with, that affect their health

Summary Points

- Buoyed by support from general population, public health experts, politicians, and economists, India has enacted or augmented several national level programs to address child undernutrition in the last decade.

- However, most of these programs are run by different departments and lack coordination with each other limiting accountability and impairing the full promise of each individual programs.
- In 2011–2012, only 39% of all eligible children had ever received a take-home food ration or prepared hot meals and only 14% of children had received it in the previous month from Anganwadi workers.
- Interviews of Anganwadi workers suggest that they are over-burdened with the task to deploy multiple programs from different departments and have to spend disproportionate time towards documentation at the expense of providing services.
- The central assumption of National Food Security Act that by providing substantial subsidies for cereal, families would use saved capital to consume diverse foods may be inaccurate based on food-consumption data.
- Considering the cereal-centric composition of India's staple diet, reduced consumption of milk and vegetables, secondary to a program aimed at enhancing food security is concerning because dietary diversity is a crucial determinant of children's nutritional status
- According to a recent analyses of the NREGA program, 20 out of the 31 states in India have suboptimal implementation and can maximize their rural employment gains by increasing engagement of low caste population and women. In comparison to efficient states, inefficient states had 133% and 75% less involvement of women and low caste people, respectively.
- The momentum towards improving sanitation facilities at a household level following Swachh Bharat Mission guidelines must be complemented with a systematic effort to help improve individual hygiene for caregivers and children.
- The NRC program relies on already overburdened Anganwadi workers for case identification which can lead to missed or improper identification.
- The NRC program's limit of at most 14 days of hospitalization leads to almost of half of its children returning home with suboptimal nutritional status.
- There is an urgent need to complement NRC with home or community-based nutritional rehabilitation program.
- The field of implementation science offers an opportunity to enhance horizontal integration across different programs and can facilitate equitable coverage of services.

Improving Infant and Young Child Nutrition in a Highly Stunted Rural Community: A Practical Case Study from Guatemala

123

Boris Martinez, David Flood, Katia Cnop, Andrea Guzman, and Peter Rohloff

Contents

Abstract

Stunting is a major public health concern because of its association with child mortality and morbidity and later adult economic and health. Despite Guatemala's important contributions on child nutrition research, the indigenous Maya population in Guatemala has one of the highest stunting rates in the world. This chapter contextualizes the global problem of child stunting with a close

look to Guatemala's historical nutrition research and policy, followed by a description of a comprehensive nutrition programming model for highly stunted communities developed by the nongovernmental healthcare organization Wuqu' Kawoq | Maya Health Alliance and a single-community case study of the model implementation. The model includes both preventative and curative evidence-based interventions to target food security, environmental factors, access to health services, and caregiver education and empowerment. Frontline workers with cultural and linguistic competency deliver individualized education and nutrition assessments. Over a 2-year implementation of the approach in a Maya community, the overall prevalence of stunting under 5 declined 20% and the prevalence of severe stunting 35%. In this and other similar settings, holistic, primary care approaches to malnutrition can have significant impact on child health.

Introduction

More than 150 million children younger than 5 years of age worldwide suffer from chronic malnutrition, or stunting (UNICEF 2016). Stunting results from a complex interplay of social, economic, environmental, and biological factors that lead to restricted linear growth (Reinhardt and Fanzo 2014). Stunting not only is a risk factor for early childhood morbidity and mortality (Black et al. 2013) but also confers deleterious long-term effects on cognitive development, adult health, and economic productivity (Hoddinott et al. 2008; Adair et al. 2013; Sawaya et al. 2003). Although the global prevalence of stunting has been declining since 1990, rates remain high in many low-and middle-income countries (LMIC) (Stevens et al. 2016;

UNICEF 2016). While less than 50% of all children under 5 years of age live in LMICs, 98% of the world's stunted children live in these countries (Black et al. 2013; WHO 2016).

This chapter focuses on child nutrition in Guatemala, a Central American LMIC with a population of 16 million people. With a prevalence of stunting of 46% in children under 5 years of age, Guatemala has the highest stunting rate in the Western Hemisphere (MSPAS 2017; USAID 2016). Additionally, national-level data tend to obscure the disproportional burden of stunting throughout the country. The poorest sectors of Guatemala's population, who are largely rural indigenous Maya, have much higher stunting rates, making them the most stunted group in the world according to some estimates (Black et al. 2013). Such health indicators are deeply intertwined with the longstanding economic, social, and political marginalization of Maya communities in Guatemala, which includes state-sponsored genocide during a civil war from 1960 to 1996 (Oglesby and Nelson 2016).

We first briefly review the history of nutrition research in Guatemala before leading to a synthesis of the current state of the country's nutrition politics and policy. The historical overview showcases how Guatemala has served as a global nutrition research laboratory from the 1940s up to the present day. Among other significant work, we review how the Institute of Nutrition of Central America and Panama (INCAP) Cohort Study and its follow-up iterations, which are still ongoing, have had a remarkable influence on the scientific understanding of child malnutrition and on global nutrition policy. We then describe how findings from the INCAP study and related research have been put into practice within the contemporary Guatemalan health system under the "First Thousand Days" framework. Underlying this analysis is the uncomfortable reality that although Guatemala has served as an extremely productive nutrition research setting, stunting rates in the country persist at extraordinarily high levels.

After our discussion of nutrition research and policy in Guatemala, we provide a practical overview of a model of nutrition programming for highly stunted Maya communities developed by our nongovernmental organization, Wuqu' Kawoq | Maya Health Alliance (MHA). We then turn to a single-community case study of the implementation of this model to demonstrate its impact on child health. We conclude by reflecting on our experiences and discussing future research and programmatic priorities with regards to nutrition in Guatemala.

Stunting in Guatemala

Guatemala has an estimated population of 16.5 million people. The country has one of the largest indigenous populations in Latin America, with nearly 50% of the population self-identifying as indigenous Maya (Chary and Rohloff 2015; MSPAS 2017). Around the world, there are profound inequalities in health indicators and access to healthcare services for indigenous populations (Anderson et al. 2016; Gracey and King 2009). In Guatemala, stunting is a significant example of these

disparities, as 58% of indigenous Guatemalan children are stunted as opposed to 34% of nonindigenous children (MSPAS 2017). As mentioned above, according to some analyses, the poorest quintile of Guatemalans (mostly rural and indigenous) are the most stunted population in the world (Black et al. 2013).

Stunting is a proxy for many significant short-term and long-term health risks. In the short term, stunted children are more likely to face illness, die in childhood, and have early cognitive and neurodevelopmental delays (Black 2017). In the long term, these children tend to not reach their full academic, economic, and health potential. They have decreased school performance, worse economic prospects, and face increased reproductive risks as adults (Adair et al. 2013; Dewey and Begum 2011; Hoddinott et al. 2008). Additionally, an emerging literature suggests that children who are chronically malnourished have higher risks of chronic noncommunicable diseases as adults, such as obesity, cardiovascular disease, and diabetes (DeBoer et al. 2012).

Guatemala's Historical Nutrition Research Overview

Since the late 1940s, Guatemala has made important contributions to the global study of childhood malnutrition. At that time, research conducted by INCAP in Maya communities demonstrated how the provision of malnutrition preventative services and improvements in basic community living conditions could have greater impacts on children's nutritional status than curative services alone (Mata 1978; Scrimshaw et al. 1969). Findings from these earlier studies formed the basis for the conceptualization of the INCAP Oriente Study, a nutrition trial that began as a supplementary feeding program in eastern Guatemala villages from 1969 to 1977 (Martorell et al. 1995; Stein et al. 2008). The Oriente Study is one of the most famous and oft-cited longitudinal nutrition studies in the world. Longitudinal follow-up from the original cohort and subsequent generations have generated strong evidence on the longer-term positive effects of early nutrition supplementation (Martorell 2010). In addition, the study clearly documented for the first time that child malnutrition in Guatemala is primarily a problem of endemic stunting (low height-for-age) rather than acute malnutrition (wasting, low weight-for-height) or underweight (low weight-for-age) (Ruel et al. 1995) and that exposure to chronic infectious disease and low-quality diets were the principal causes of children's impaired growth (Martorell 2010). The latest wave of data collection in the Oriente Study is currently being carried out, and using detailed biologic samples, researchers hypothesize that better child nutrition will be protective against adult obesity and related noncommunicable chronic diseases (Stein 2014). An important final note is that although prior INCAP research had included the study of child nutrition in indigenous Maya communities, the Oriente Study included only Spanish-speaking (i.e., nonindigenous) communities due to logistical barriers and the unavailability of unbiased cognitive tools for this population (Flood 2015).

Guatemala's Historical Nutrition Policy Overview

The INCAP Oriente Study demonstrated that growth faltering of stunted children in Guatemala occurs early, usually in the first year of life (Ruel et al. 1995). Nevertheless, historically much of Guatemala's official nutrition policy remained focused on school feeding programs (Nutrinet 2009). However, since 2006, nutrition policy in Guatemala has finally seen important policy shifts toward more preventive and comprehensive interventions targeting the early childhood period. These national changes derive from advocacy by major international donors and policy makers, including the United States Agency for International Development (USAID) and the World Food Program, in favor of early childhood programs in "the first 1,000 days of life" window (FANTA 2010). In 2012, the government of President Otto Pérez Molina made the prevention of early childhood malnutrition a major priority, disseminating a new multilevel strategic plan called "Plan Hambre Cero" (Zero Hunger Plan, ZHP), derived from the global "Thousand Days Initiative" framework (Thousand Days 2014). ZHP was launched with the goal to reduce stunting rates by 10% by the end of 2015 from a baseline rate of nearly 50% (PPHO 2012). The ZHP strategy emphasized global evidence-based interventions such as the distribution of micronutrient powders, deworming, provision of supplementary fortified flour blends, growth monitoring, and maternal education.

The ZHP was designed to function within the government's existing rural health system known as the "Programa de Extension de Cobertura" (Expansion of Coverage Program, PEC). PEC was established in the late 1990s, after the conclusion of the Guatemalan civil war, as a system to provide basic preventative health services for rural underserved indigenous populations. However, after allegations of institutional corruption within PEC, the government dismantled the program in early 2015 (Avila et al. 2015; Espina 2015). Uncertainty and political instability followed, and basic healthcare services in rural areas were suspended for months. A government corruption scandal led to the impeachment and resignation of the Guatemalan president, vice president, and several other major government officials; among the allegations were that public health funds had been diverted to private coffers (Galicia 2016). The rural system has subsequently been reconstituted, but this back and forth political drama simply underscores the fact that rural health programs remain incredibly underfunded and extremely limited in the provision of quality services.

An important, probably unintended side effect of implementing the Thousand Days framework in Guatemala has been an inflexible prioritization by nutrition and government stakeholders on the prevention of stunting in children under 2, limiting consideration of other pediatric health issues including strategies to improve outcomes in the very large number of Guatemalan children who are already stunted. While prevention of stunting is highly cost-effective, this does not indicate that there is no social or economic benefit to policies that also include catch-up growth in already stunted children, or in children older than 2 years. Indeed, historical data

from the INCAP Oriente Study in Guatemala, as well as high-quality evidence from other countries, show that catch-up growth is possible and significant (Prentice et al. 2013; Roberts and Stein 2017; Stein et al. 2010).

Finally, the emphasis within Guatemala's rural health system of utilizing front-line health workers to deliver narrow, technical nutrition interventions to Guatemalan infants and children reflects a final point of departure from more holistic community health models pioneered in Guatemala many years ago. For example, in 1962, Dr. Carroll Behrhorst founded the Behrhorst Development Foundation, which attempted to address the underlying factors causing poverty and poor health among the rural Guatemalan population through community participation, empowerment, and integrated development programs. Central to the Behrhorst model were rural Maya community health workers trained to deliver curative and preventative medicine in their communities (Horton 1987). A case study of the Foundation was included in Kenneth Newell's 1975 book *Health by the People* (Newell and WHO 1975), which became highly influential during the primary health care movement in the lead-up to the Declaration of Alma Ata in 1978. In 1980s, the Foundation was severely impacted by the Guatemalan civil war, and after Behrhorst's death in 1990, decreases in international funding lead the Foundation to shift away from its original mission of community-based development (Maupin 2015).

Community-Based Nutrition Programming

Based on the foregoing analysis, we have been working for the last decade with rural Maya communities to reformulate community-based nutrition programming in a way that reclaims a focus on primary, holistic care; includes both preventative strategies and catch-up growth interventions for stunted children; and has a strong focus on caregiver education and empowerment. In this section, we describe the formative nutrition research and nutrition delivery model that we have developed, finally, moving to a detailed case study of its implementation in one rural community. The goal is to provide practical insights into comprehensive nutrition program design, as well as the potential impact of the approach, which will be of use to other practitioners around the world.

All of this work has been conducted within the institutional umbrella of Wuqu' Kawoq | Maya Health Alliance (MHA). MHA is a primary care organization, founded by ourselves and others in 2007, to provide culturally and linguistically nuanced services to rural Mayan-speaking populations. Over the years, MHA has grown into a full-service organization in central Guatemala delivering services in 20 rural highland communities to more than 20,000 patients per year. MHA also performs ethnographic and health services research relevant to Maya populations. With regards to child nutrition, MHA operates a large nutrition delivery program and has conducted numerous research studies, including clinical trials, on nutrition in this setting.

Formative Nutrition Research

Formative nutrition research in the years leading up to our nutrition program design has focused on ground-level factors that we have observed in our programmatic work to contribute to improved nutrition outcomes. Themes have included gender roles, food insecurity, breastfeeding, feeding practices, and community perceptions of stunting.

Importantly, a better understanding of the timing and onset of growth faltering has been a major concern. As also previously demonstrated in the INCAP Oriente Study (Ruel et al. 1995), we have noted that growth faltering in Maya communities starts usually at 6 months of age, corresponding to the time of transition to complementary foods, and negatively correlates with the household financial stability and availability of high-quality infant foods (Chary et al. 2011). For many indigenous families with young infants who are experiencing growth faltering, meeting food-based dietary recommendations is difficult due to the lack of economic resources for purchasing nutritious foods and the wide availability of alternative low-cost processed foods (Brown et al. 2014; Chary et al. 2013).

We have also investigated how poor child feeding indicators exist even in rural communities devoted to agricultural production, largely due to the pressures to enter the export agricultural market. For example, a recent study we conducted in a rural Maya community where most families dedicated themselves to agricultural production revealed that less than 3% of the children under the age of five met World Health Organization (WHO) standards for dietary diversity and meal frequency. In this community, most harvested produce was directed to exportation with minimal local consumption available for children (Webb et al. 2016). This is not really a matter of negligence so much as the fact that when the prevalence of child stunting is extremely high, its deleterious impacts on child health become normalized and are not easily perceived by caregivers (Brown et al. 2014; Chary et al. 2013). Finally, discrimination against Maya mothers by the formal health system exacerbates the impact of stunting by discouraging Maya caregivers from seeking out primary healthcare services (Chary et al. 2011).

Finally, we have explored strategies to overcome barriers to suboptimal breastfeeding and complementary feeding practices among Maya caregivers. For example, we have shown how mothers' relationships with their male partners and mothers-in-law contribute to feeding practices. Male partners often control all household funds, and mothers-in-law often make most food purchasing and preparation decisions. These family-level factors have a significant impact on child health and must be taken into consideration when designing programs (Brown et al. 2014; Chary et al. 2011).

Nutrition Program Model

Based on the results of this formative research, MHA has worked to design and adapt nutrition programs to meet the needs and sensibilities of clients and families in rural Maya communities. This work began in 2009 at a very small scale, serving

2 communities and approximately 70 children and their families. The program has continued to grow steadily; in 2016, it covered 20 rural communities and 1500 children under 2 years in three provinces (Chimaltenango, Sololá, Suchitepéquez).

The program model is designed to decrease the community prevalence of stunting through both universal preventative and targeted recuperative (catch-up growth) services. A basic package of preventative services is offered to all children under 5 years of age. This package is evidence-based (Bhutta et al. 2008) and in line with the Guatemalan government's own recommendations under the ZHP initiative (PPHO 2012), including growth monitoring, basic nutrition education for caregivers, micronutrient supplementation, and deworming. Notably, the provision of services for children older than 2 years of age is a departure from the thousand days framework (which recommends services up to 2 years as a policy priority) and is based on our experiences over the last 10 years that communities and families strongly prefer this programatic decision and that the more inclusive approach improves community buy-in. It is also in part a response to the evidence that catch-up growth is possible in stunted children older than 2 years (Prentice et al. 2013; Roberts and Stein 2017; Stein et al. 2010). In addition to this preventative community-based package, a more intensive 6-month catch-up growth intervention is targeted to already-stunted children younger than 2 years of age; this package is described in more detail below. All services are free-of-charge.

The program operates with indigenous auxiliary nurses and community health workers (CHW) as front-line workers, to whom we further henceforth as "nutrition technicians." Nutrition technicians are bilingual in Mayan and Spanish languages and use standardized clinical algorithms for the screening, management, and treatment of stunting, as well as for delivering nutrition education to the children's caregivers. In Fig. 1, nutrition technicians from MHA perform children's growth monitoring activities in rural Maya communities.

Nutrition technicians are supervised and supported by physicians and nutritionists, who perform monthly evaluation meetings. The nutritionists and physicians are on call for emergencies, and they evaluate children not responding as expected to the nutrition interventions. Staff physicians perform further medical evaluations for complex consultations or for primary care issues beyond the nutrition technicians' scope of practice. Integrating nutrition programming into this more comprehensive primary care safety net is, we feel, critical. Despite the ubiquitous nature of stunting in Guatemala, other treatable pediatric diseases such as inborn errors of metabolism or endocrine disorders can go undiagnosed without the input of expert practitioners (King et al. 2016). Care by nutrition technicians is primarily delivered by home visits, an approach which enables health care provision to patients who live far away from health care facilities.

The program's clinical protocols were derived from national, regional, and international recommendations for the prevention and treatment of childhood malnutrition (Bhutta et al. 2008; Dewey 2003; MSPAS 2010). In addition to preventative services mentioned above, which are provided to all children, stunted children under 2 years receive additional services. These include monthly home visits for more intensive, individualized nutrition assessment and counselling and

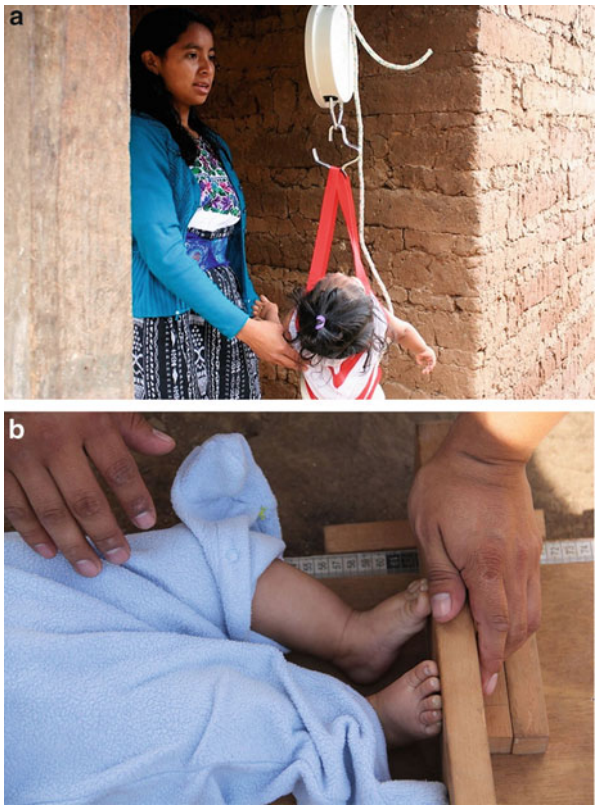

Fig. 1 Growth monitoring. Nutrition technicians perform children's growth monitoring activities of weight (**a**) and length (**b**) in rural Maya communities during home visits

food supplementation with a family food ration to offset food insecurity and to supplement the child's diet with specific quality calories and nutrients (particularly, protein) often lacking in the diet (FANTA 2010). Children who are wasted in addition to stunted also receive therapeutic milk formula (F-100) (Ashworth et al. 2003) or ready-to-use therapeutic foods (RUTF) (Ciliberto et al. 2005) as indicated by a staff nutritionist. As shown in Fig. 2, these services all together form a comprehensive primary care approach to child malnutrition, with key interventions designed to address four key drivers of malnutrition: food security, environmental health, health services, and caregiver's empowerment and education. To promote interinstitutional collaboration, individual nutrition technicians establish community-level partnerships with community leadership councils and local government health-care staff.

During home visits with stunted children, nutrition technicians perform individualized dietary counseling focused on two primary indicators – dietary diversity (number of food groups per day) and meal frequency (number of meals per day). To guide this interaction, they conduct a 24 hour dietary recall at each visit, based on the WHO's published template (WHO 2008). Through systematic collection of dietary recall data, nutrition technicians can identify deficiencies in each child's diet and

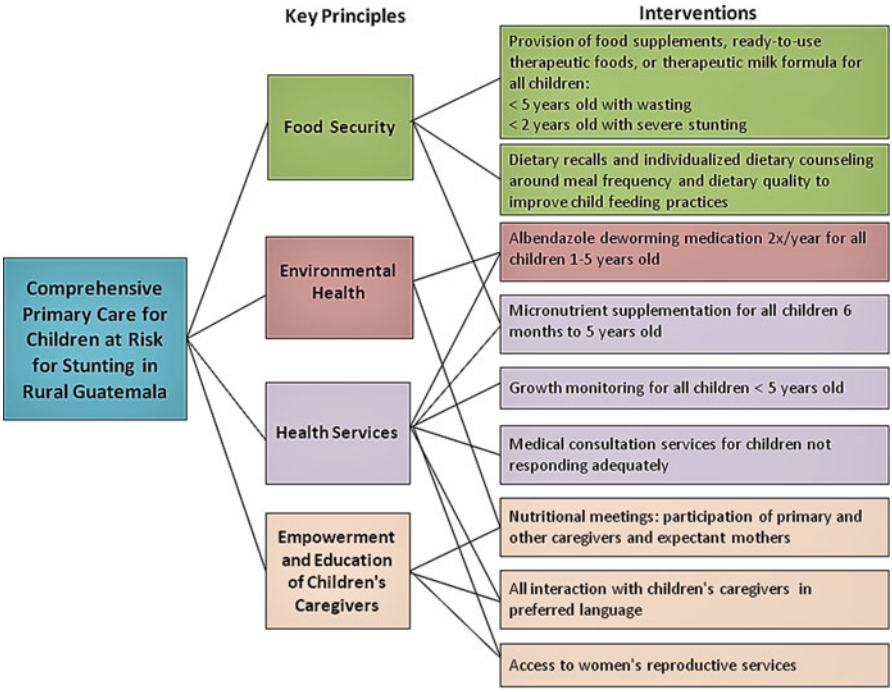

Fig. 2 Key drivers of child nutrition. Theoretical overview of a comprehensive primary care-focused model for treating child malnutrition in rural Guatemala developed and implemented in several rural-Maya communities by Maya Health Alliance

Fig. 3 Nutrition counseling Nutrition technician guides children's caregivers through child nutrition improvement strategies during a home visit

guide the primary caregiver through improvement strategies. Conducting this work in the home facilitates confidentiality. Over time, caregivers gradually feel more comfortable asking questions and sharing their experiences, concerns, and expectations. Finally, the home setting allows nutrition technicians to learn about each child's living situation, food accessibility, economic resources and family dynamics, and tailor interventions accordingly (Fig. 3).

Table 1 Themes covered during group educational meetings. Themes covered in the nutrition curriculum used for group meetings are shown. Caregivers and other participants attend five weekly sessions. Each session last 2–3 hours and ends with a food preparation activity

Session Theme	Description
1. The importance of good nutrition	Nutrition during pregnancy. Food classification in terms of micro- and macronutrients (vitamin A and C, iron, folic acid, protein, carbohydrates, fats). Hygiene and water purification
2. Breastfeeding and its values	Frequency and duration of breastfeeding episodes. Helpful posture and problem-solving techniques for quality breastfeeding. Common breastfeeding myths
3. Complementary feeding	Adequate frequency, quantity, quality, and consistency of complementary feeding. Strategies for improving diet diversity with inexpensive locally available fresh foods
4. Childhood malnutrition	Acute and chronic malnutrition, anemia. Causes, consequences, and solutions. Review of the value of micro and macronutrients for an adequate growth
5. Complete review	General review of each previous class. Time for additional questions and sharing of feedback. Closing ceremony

In addition to preventative and recuperative child-focused activities, the model concentrates heavy investments in caregiver education; all primary caregivers in the community with children younger than 5 years, as well as expectant mothers and other important family caregivers (such as grandmothers), are invited to participate in a weekly nutritional education program facilitated by the nutrition technician for five consecutive weeks. These sessions aim to empower the caregivers by increasing their ability to select a variety of high-quality foods for home consumption and diversifying their food preparation methods. Nutrition education meetings are conducted in a highly participatory manner, with usually 8–10 participants. As outlined in Table 1, we use our understanding of the local context of poverty and food insecurity to provide relevant and practical tips for improving child diets, placing emphasis on utilizing potential "hidden family resources" such as shifting household expenses away from junk food purchases (Brown et al. 2014). These meetings also always include meal preparation activities (Fig. 4), using only locally available food and resources.

Finally, because the nutrition model exists within a larger institutional primary care framework, nutrition technicians can connect other members of the family with other health care needs to potential medical resources. This is most important for female caregivers, who can access a full range of reproductive health services – including comprehensive reproductive education, cancer and sexual transmitted diseases' screening and treatment, and family planning – which are important elements for caregiver empowerment (Fig. 2).

Case Study

To provide additional programmatic details on the implementation of comprehensive, community-based nutrition programming, we present here a brief case study of the implementation of a nutrition program in one rural Maya community,

Fig. 4 Meal preparation activities. Nutrition technician performs a food preparation demonstration for children's caregivers, during these activities special focus is placed on the use of locally available foods and the use of possible hidden-resources

Table 2 Characteristics of Xik'injuyu' case study community prior to beginning nutrition programming. Basic demographic and nutrition-related characteristics are shown for the case study community. These characteristics are typical of the region and help to illustrate the stressors and risk factors of populations at high risk of stunting

Characteristics (n = 167)	Value
Household size (mean ± SD)	3.99 ± 1.93
Maternal illiteracy (%)	28
Adequate child diet (%)	49
Child nutrition status (%)	
Stunted	52
Severely stunted	22

Key: *n* sample size, *SD* standard deviation

Xik'injuyu', located in the western Guatemala piedmont (Table 2). MHA began building a primary care program – primarily focused on child nutrition and reproductive health services – in collaboration with the community in 2014. The community consists of approximately 360 families, most of K'iche' Maya descent. Potable water services are scarce. Most male heads-of-households work as seasonal agricultural day laborers on rubber, banana, or coffee plantations, while most female

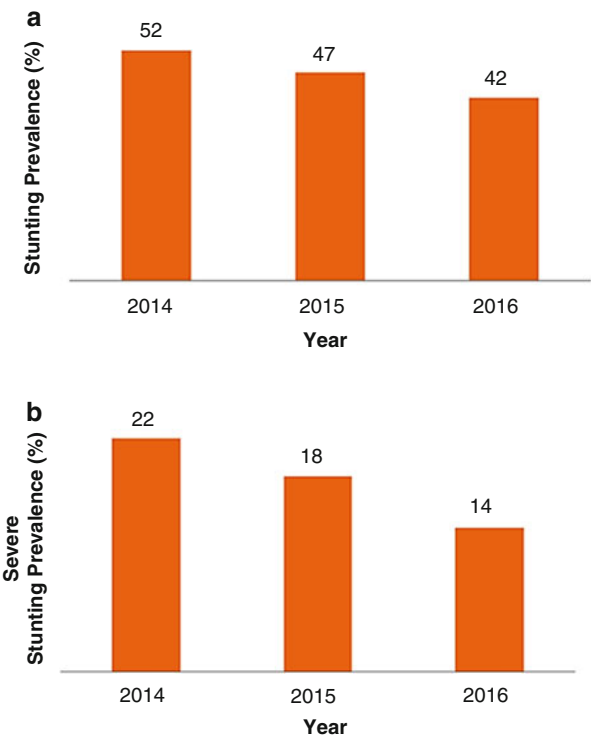

Fig. 5 (a) Change in stunting prevalence and (b) severe stunting prevalence over 2 years in Xik'injuyu'. Longitudinal change in the prevalence of stunting (**a**) and severe stunting (**b**) for children younger than 5 years in the community of Xik'injuyu' are shown. Note the decrease of both since the implementation of the Wuqu' Kawoq | Maya Health Alliance nutrition program in 2014

residents are homemakers. Underemployment is common and around 70% of families live in poverty (less than $2 USD/day).

When beginning our collaboration with the community, families reported to us how they struggled with access to nutritious food, especially due to droughts, increases in food prices, and periods of unemployment, and more than 60% reported family-level food insecurity. Very few families (less than one-third) own land, and so producing their own food is an unavailable strategy. Many families told us that they resorted to purchasing low cost processed foods at local stores, as these were less costly and more readily available than high-quality fresh foods. Because of these stressors, prior to initiating joint efforts in the community, the overall prevalence of stunting (height-for-age Z score [HAZ] < -2) based on WHO Child Growth Standards (De Onis et al. 2006) was 52%, and a full 22% of children were severely stunted (HAZ < -3).

Over the last 2 years implementing the primary care approach described in this chapter, we have seen important improvements in rates of malnutrition. As shown in Fig. 5a, the rate of overall stunting in children under 5 has declined from 52% to 42%, nearly a 20% improvement. The rate of severe stunting has declined even more rapidly, from 22% to 14%, a roughly 35% improvement (Fig. 5b).

Final Reflexions

In this chapter, we contextualize the global problem of child stunting with a close look at its history and dynamics in rural Guatemala, which suffers from some of the highest rates of stunting in the world. In the first section, we offer a review of nutrition research in Guatemala and a synthesis of the government's nutrition policy, which only recently has officially recognized the country's staggering stunting problem. However, national nutrition programs and policies have suffered from intermittent and ineffective deployment, a narrow focus on stunting prevention to the exclusion of treatment, and failure to address the root causes of stunting in a holistic fashion.

In the second part of this chapter, we offer a detailed, practical description of work in rural Guatemala with Wuqu' Kawoq | Maya Health Alliance, a nonprofit healthcare organization, to deploy evidence-based interventions for stunting within a comprehensive primary care model. Various premises of the model will be generalizable and useful to practitioners in other settings. First, well-supported nutrition technicians, who speak indigenous Maya languages, can provide high value nutritional care and are highly motivated to carry out time-consuming, high-contact activities such as home visits and education sessions. This is in line with the overall consensus in the literature that community-based interventions led by nurses and CHWs are critical for improving health outcomes (Lassi et al. 2016). Second, nutrition technicians can adopt and successfully utilize advanced interview techniques, such as 24-h dietary recalls, to better customize and individualize the interventions they provide to children and caregivers. Finally, by emphasizing home visits and respectful caregiver education, nutrition programming can promote an inclusive, collaborative environment, where caregivers feel comfortable sharing their experiences without fear of punishment or stigma, thereby learning about nutrition and building a network of trust and support.

In the final part of the chapter, we share additional details from a single rural community where we recently initiated a primary care nutrition program. In this program, over a space of 2 years, the overall prevalence of stunting declined 20% and the prevalence of severe stunting 35%. These findings are typical of our experiences in multiple Maya communities over the last 10 years. First, they reinforce that holistic, primary care approaches to malnutrition can have a significant impact on child health in these settings. At the same time, they also underscore that no existing stunting intervention is able to completely eradicate the problem. This fact is ultimately motivating, as it serves as a call for ongoing research, increased advocacy, and sustained commitments from healthcare organizations, civil society, governments, and policymakers together until every child's and every family's nutritional future is made secure.

Policies and Protocols

In this chapter, we have described practical details of how to implement culturally and linguistically sensitive, comprehensive nutrition programs for rural areas of Guatemala. Many of these details are also readily applicable to other settings and contexts. Here we highlight three of these:

1. Frontline nutrition workers should be cognizant of the culture and language of their clients. Administrators from both government and civil society groups should prioritize hiring practices that ensure these linguistic and cultural competencies. Monitoring for program quality should include provision of services in the client's preferred language.
2. Individualized education can improve caregiver engagement and child feeding practices. Implementers should consider focusing effort on training frontline workers to provide personalized interventions. A key area is dietary recalls to better focus assessments of dietary quality. Existing materials developed by the World Health Organization (WHO 2008) can easily be adapted.
3. In areas of high stunting prevalence, programming should include both preventative and (if resources allow) recuperative interventions. Home-based visits by nutrition technicians are an excellent strategy for implementing recuperative interventions, which can include more intensive feeding or education strategies.

Dictionary of Terms

- **Dietary diversity** – A term for dietary quality from the perspective of the regular consumption of a diversity of food items. Can be easily assessed on a dietary recall by counting the number of distinct food groups consumed in a given time period. The World Health Organization has published useful guidelines detailing methods for assessing food group consumption in young children (WHO 2008).
- **Meal frequency** – An important indicator of overall caloric adequacy in a child's diet, which can be assessed on a 24-h dietary recall. Each meal should consist of solid food items, not liquids. The World Health Organization has published detailed guidelines for the required number of meals based on the child's age (WHO 2008).
- **Stunting** – Also known as chronic malnutrition. Defined as a height-for-age Z-score of less than −2, compared to World Health Organization Child Growth Standards (De Onis et al. 2006). Severe stunting is defined as a Z-score of less than −3.
- **Underweight** – Defined as a weight-for-age Z-score of less than −2, compared to World Health Organization Child Growth Standards (De Onis et al. 2006). Severe underweight defined as a Z-score of less than −3.
- **Wasting** – Also known as acute malnutrition. Defined as a weight-for-length or weight-for-height Z-score of less than −2, compared to World Health Organization Child Growth Standards (De Onis et al. 2006). Severe acute malnutrition is defined as a Z-score of less than −3

Summary Points

- This chapter focuses on stunting, one of most important pediatric growth disorders in the world.

- Stunting causes early morbidity and mortality in childhood, as well as developmental delay, reduced school achievement, and loss of adult economic potential.
- The indigenous Maya population in Guatemala has one of the highest rates of stunting in the world.
- Although Guatemala has been an important source of child nutrition research, this has not translated into improved stunting outcomes for rural indigenous communities.
- Interventions to target stunting should take a comprehensive approach, targeting food security, environmental factors, access to health services, and caregiver education and empowerment.
- Frontline workers, such as nurses and community health workers, can effectively deliver nutrition interventions, especially if they have cultural and linguistic competency.
- Individualized education and nutrition assessments are an important part of nutrition programming, because they improve caregiver empowerment and the effectiveness of interventions.
- In high stunting prevalence communities, programs should ideally have both preventative and curative interventions.

Abstract

There is no greater major threat to public health worldwide than nutrient deprivation. Presently nutrient deficiency affects around 800 million people worldwide. Since time immemorial nutrient deprivation or overt starvation has caused organ dysfunction or death. Nutrient deficiency is not only the consequence of drought, famines, or civil upheaval. Malnutrition may arise for a number of

reasons. For example, some studies have reported that in hospitals as many as half of patients may be malnourished or at risk of malnutrition. The term malnutrition however is very broad and covers undernutrition, imbalance, and overnutrition. This book focuses on the former two umbrellas and coverage ranges from cellular events to public health policies. The detailed molecular events arising from nutrient deprivation are relatively recent discoveries in the overall time scale of research into malnutrition. At the other end of the spectrum, public health policies are constantly being updated to take into account prevailing social, geographical, political, and economic profiles of communities and countries. Within this are policies which encompass future trajectories which aim to prevent famines or undernutrition. Thus there is a complex continuum of knowledge that stretches from our understanding of how molecules in cells behave to the imposition of policies. To further aid colleagues in the acquisition of this knowledge, this chapter lists the resources on the regulatory and professional bodies, journals, books, and websites that are relevant to an evidence-based approach to famine, starvation, and nutrient deficiency, from cells to policy.

Introduction

Nutrient deprivation is a major threat to global public health. Starvation is the most extreme nutrient deprivation. It results from severe restriction of dietary energy and macro- and micronutrient intake below that needed to sustain life. Accurate data on the extent of starvation is relatively difficult to obtain. However, less severe nutrient deficiency affects around 815 million people on a global basis (Food and Agriculture Organization of the United Nations et al. 2017).

Famine has caused starvation and nutrient deprivation in humans since time immemorial. However, the understanding of the molecular changes relevant to the effects of worsening nutrient deprivation is relatively recent discoveries in the overall time scale of research in this field. It is important to remember that nutrient deprivation arises in a number of scenarios other than due to famine per se. These include undernutrition due to illness, poverty, societal imbalance, conflict, self-starvation, and so on. Nutrient deprivation is under-recognized in modern medicine and to some extent does not receive the attention it deserves. For example, over 20 years ago, Powell Tuck (1997) highlighted that the prevalence of malnutrition in hospital patients is between 19 and 55% using various criteria. Despite this,

undernutrition in the hospital setting still remains problematic (Kruizenga et al. 2016; Morris et al. 2018).

The treatment of starvation and nutrient deprivation may seem obvious and straightforward. However, the relatively recent discovery of the phenomenon known as the refeeding syndrome underlines the importance of gradual replacement of the calorie deficit (Friedli et al. 2017). Yet although refeeding syndrome was described more than 70 years ago, there is still no standard definition or recommendations for its prevention or treatment (Friedli et al. 2017).

Regardless there has recently been an explosion in the knowledge and understanding of nutrient deprivation and starvation. It is now difficult even for experienced scientists to remain up-to-date. To assist colleagues who are interested in understanding more about this field, we have therefore produced tables containing up-to-date resources in this chapter. The expert who assisted with the compilation of these tables of resources is acknowledged below.

Table 2 Journals publishing original research and review articles related to nutrient deprivation, famine, or starvation. We list the top 20 journals which have published the most number of articles over the past 5 years. Although we used Scopus to generate this list, other databases or the use of refined search terms will produce different results

Journals relevant to nutrient deprivation, famine, or starvation
Plos one
Nutricion Hospitalaria
Clinical nutrition
Scientific reports
The lancet
Nutrition
Autophagy
Journal of nutrition health and aging
Journal of parenteral and enteral nutrition
Nutrition in clinical practice

Food and nutrition bulletin
European journal of clinical nutrition
Journal of biological chemistry
Maternal and child nutrition
Bioresource technology
Public health nutrition
American journal of clinical nutrition
BMC public health

Resources

Tables 1, 2, 3, and 4 list the most up-to-date information on the regulatory bodies and professional societies (Table 1), journals on nutrient deprivation (Table 2), books (Table 3), and online resources (Table 4) that are relevant to an evidence-based approach to nutrient deprivation.

Summary Points

- Nutrient deprivation is a major threat to global public health.
- Starvation is the most extreme nutrient deprivation.
- Nutrient deprivation is under-recognized in modern medicine.
