Preface

There are numerous definitions of the terms malnutrition, undernutrition, and starvation, many of which are used interchangeably. Strictly speaking, malnutrition also refers to an "imbalance" and includes an excess of nutrients. However, within the context of this handbook we are primarily concerned with a lack or deficiency of one or more dietary components rather than an excess. Embedded within the deficiency states is "acute restriction" whereby food is withdrawn or deliberately not consumed at all. For example, individuals may refrain from eating to provide blood samples for subsequent analysis or food may be withdrawn from patients before surgery. Further downstream is the consumption of a fraction of the diet, or none at all. This may arise when there are restrictions in the amount of food available to an individual or population. The causes of such restrictions in dietary intake are varied and include poverty, conflict, and regional famine. In the sociogeographical context, refugees and displaced persons may also be vulnerable to undernutrition.

Some diseases will impact on the total food consumed, for example, when there are physical impediments (intestinal obstruction or dysphagia) or anorexia. There may also be restrictions in the availability of single micro- or macronutrients such as vitamins, minerals, proteins, lipids, or dietary energy. There may be increased bodily demands for certain nutrients in some diseases, but these may not be met by the existing diet, thus resulting in deficiency states.

The impact of such dietary restrictions is variable. Deficiencies in micro- or macronutrients will impact on cells, organs, individuals, and even populations. Quality of life measures, for example, are impaired in anorexia and in famine. Some communities are blighted by the absence of specific micronutrients which impact on physical and mental health: endemic iodine deficiency is a good example of this.

It is important to understand the causes of nutrient deficiencies and also to be aware of the impact on the cell-to-community continuum. The knowledge gained from understanding how cells and organs respond to nutrient deficiencies may be transferable to understanding and treating deficiency diseases. At the population level, it is important to know how to diagnose and treat nutritional deficiencies. In the wider context, food waste and food insecurity are at opposite ends of the spectrum but have in common the disparities between provision and need. Policies

and procedures to address the aforementioned are required to reduce food waste and food insecurity.

There is a wide range of information that interlinks the complexities of undernutrition, disease, famine, sociology, food waste, food insecurity, poverty, provision, need, policies, and procedures. Hitherto, this has been sporadically distributed across different publications. This is resolved in the *Handbook of Famine, Starvation, and Nutrient Deprivation: From Biology to Policy.* It has wide coverage and also includes social aspects, refugees, conflict, hunger, anorexia, screening tools, medical causes of malnutrition, endocrinology, metabolism, tissue systems, life stages, micronutrients, modeling, cellular and molecular biology, international aspects, and management.

There are 12 parts as follows:

1. General Aspects of Famine and Undernutrition: Setting the Scene
2. Effects of Famine
3. Food Insecurity, Security, and Waste
4. Biosocial and Social Aspects, Inequalities, Low Income, Refugees, and Conflict
5. Hunger and Anorexia
6. Screening Tools, Classifications, and Applications
7. Medical Causes of Malnutrition, Prevalence, and Impact
8. Effects of Undernutrition, Endocrinology, Metabolism, and Tissue Systems
9. Life Stages, Pregnancy, the Young and Elderly
10. Micronutrients
11. Modeling Systems, Cellular and Molecular Effects
12. International Aspects, Policy, Management, Case Study, and Resources

The editors recognize the fact that it has been difficult to allocate specific chapters to the different parts. Some chapters may be suitably placed in different parts of the book. Nevertheless, the information in the *Handbook of Famine, Starvation, and Nutrient Deprivation: From Biology to Policy* is wide ranging. To bridge the intellectual divide and to provide guidance, each chapter has three sections as follows:

Policies and Protocols
Dictionary of Terms
Summary Points

Contributors are authors of international and national standing, leaders in the field, and trendsetters. Emerging fields of nutritional science and important discoveries are also incorporated in this book.

This book is designed for nutritionists and dietitians, public health scientists, doctors, epidemiologists, biologists, health-care professionals of various disciplines, policy makers, governmental bodies, and strategists. The *Handbook of Famine,*

Starvation, and Nutrient Deprivation: From Biology to Policy is designed for teachers and lecturers, undergraduates and graduates, researchers, and professors and as a library resource.

About the Editors

Victor R. Preedy (**B.Sc., Ph.D., D.Sc., FRSB, FRSPH, FRCPath, FRSC**), is a staff member of the Faculty of Life Sciences and Medicine at King's College London. He is also a member of the Division of Diabetes and Nutritional Sciences (research) and the Department of Nutrition and Dietetics (teaching). Professor Preedy is also Director of the Genomics Centre of King's College London.

Professor Preedy graduated in 1974 with an honors degree in biology and physiology with pharmacology. He gained his University of London Ph.D. in 1981. In 1992, he received his membership of the Royal College of Pathologists, and in 1993, he gained his second doctorate (D.Sc.) for his outstanding contribution to protein metabolism in health and disease. Professor Preedy was elected as Fellow to the Institute of Biology in 1995 and to the Royal College of Pathologists in 2000. In 2004, he was elected as Fellow to the Royal Society for the Promotion of Health and to the Royal Institute of Public Health. In 2009, he became Fellow of the Royal Society for Public Health and, in 2012, Fellow of the Royal Society of Chemistry. Professor Preedy has carried out research at the National Heart Hospital (part of Imperial College London), the School of Pharmacy (now part of University College London), and the MRC Centre at Northwick Park Hospital. He has collaborated with research groups in Finland, Japan, Australia, the USA, and Germany. He is a leading expert in the science of health and has a long-standing interest in nutrition and disease. He has lectured nationally and internationally. To his credit, Professor Preedy has published over 600 articles, which include peer-reviewed manuscripts based on original research, abstracts and symposium presentations, reviews, and numerous books and volumes.

Vinood B. Patel School of Life Sciences, University of Westminster, London, UK

Dr. Vinood B. Patel (**B.Sc., Ph.D., FRSC**) is a Reader in Clinical Biochemistry at the University of Westminster and Honorary Fellow at King's College London. Dr. Patel graduated from the University of Portsmouth with a degree in pharmacology and completed his Ph.D. in protein metabolism from King's College London in 1997. His postdoctoral work was carried out at Wake Forest University Baptist Medical School studying structural-functional alterations to mitochondrial ribosomes, where he developed novel techniques to characterize their biophysical

properties. Dr. Patel is a nationally and internationally recognized scientist, and in 2014 he was elected as Fellow to the Royal Society of Chemistry. He presently directs studies on metabolic pathways involved in diabetes and liver disease, particularly related to mitochondrial energy regulation and cell death. He is currently conducting research to study the role of nutrients, antioxidants, phytochemicals, iron, alcohol, and fatty acids. His other areas of interest include identifying new biomarkers that can be used for the diagnosis and prognosis of liver disease and understanding mitochondrial oxidative stress in Alzheimer's disease and gastrointestinal dysfunction in autism. Dr. Patel has edited biomedical books in the areas of health preventive nutrition and biomarkers and has published over 150 articles.

General Aspects of Famine and Undernutrition: Setting the Scene

Biafran Famine

1

Mikael Norman and Peter Ueda

Contents

Abstract

Following ethnic, economic, and religious tensions, the republic of Biafra unilaterally declared independence from the rest of Nigeria in 1967. This action triggered the Nigerian civil war in which the inflow of food and supplies to Biafra was blocked.

V. R. Preedy, V. B. Patel (eds.), *Handbook of Famine, Starvation, and Nutrient Deprivation*, https://doi.org/10.1007/978-3-319-55387-0_8

The result was extensive famine, regarded as one of the great nutritional disasters of modern times. During the two-and-a-half years of armed conflict, an estimated one to three million people died, most of them from starvation.

Forty years later, adults in Enugu (the former capital of Biafra) who had been conceived or born during the famine and who survived the famine show health problems with two-to-three times higher prevalence of hypertension, glucose intolerance, and overweight than those born before or after the war. These findings support that undernutrition early in life have significant and adverse impact on human development and physiological design, eventually contributing to an increased risk for noncommunicable diseases in adulthood such as ischemic heart disease, stroke, and diabetes. The long-term effects of undernutrition during pregnancy and in infancy should be considered and receive high priority when setting goals for global health, education, and economic agendas.

SBP	Systolic blood pressure

Introduction

Epidemiological evidence supported by experimental data suggests that public health problems emerging in adult life are not only determined by genes and adult life-style, but also by perinatal factors acting before and shortly after birth (Barker 1998; Gluckman and Hanson 2004; Armitage et al. 2004; Gluckman et al. 2009). According to this concept, early living conditions – of which fetal nutrition is a key component – shape not only our ability to survive birth and infancy, but also our physiological capacity to respond to health challenges occurring later in life. In this way, developmental plasticity in response to early under- or malnutrition can be considered an important, underlying mechanism explaining why adults born small – a proxy for fetal starvation – are at increased risks for cardiovascular disease and diabetes.

In the twenty-first century, the prevalence of obesity, hypertension, and insulin resistance, i.e., the metabolic syndrome (sometimes also including a proinflammatory and prothrombotic state) has increased (Manson et al. 2004; Franks et al. 2010). The metabolic syndrome is the most important predictor of cardiovascular disease and type 2 diabetes (Rapsomaniki et al. 2014; Ekblom-Bak et al. 2009). In developed countries

around 15% of the adult population is affected and in the developing world, rates of metabolic syndrome are rapidly becoming even higher. As a result, 80% of all new cases of diabetes and 85% of all deaths in cardiovascular disease are estimated to occur in low-middle income countries by 2025–2030 (Joshi et al. 2008).

Although infections still plague many Sub-Saharan African countries, non-communicable diseases are emerging as leading causes of morbidity and death (Unwin 2001). Besides better economy and successful vaccination and educational programs, this change in epidemiology is commonly attributed to rural-to-urban shifts in adult lifestyle, typically involving obesity-promoting diet, lack of exercise, and cigarette smoking (Yach et al. 2004). However, there may also be a significant perinatal contribution to this development. In particular, people who suffered from undernutrition in utero and who later in life become exposed to nutritional affluence are thought to run the greatest risks of cardiovascular disease and diabetes (Barker et al. 1993; Barker 1998; Gluckman and Hanson 2004).

The role of undernutrition during pregnancy for future childhood and adult health has been evaluated in different settings exposed to famine, most of them outside Sub-Saharan Africa (1991; Ravelli et al. 1998, 1999; Roseboom et al. 1999, 2001; Victora et al. 2003, 2008; Bhargava et al. 2004; Richter et al. 2004; Sachdev et al. 2005; Grajeda et al. 2005). Given limited resources, previous and ongoing maternal – infant undernutrition (Black et al. 2008) and growing numbers affected by cardiovascular disease, obesity, diabetes, and hypertension (Ike 2009; Unwin 2001), the significance of poor fetal-maternal health for adult disease risk, would be of great importance to clarify in Sub-Saharan Africa as well. To do so, researchers from Sweden and Nigeria focused on long-term health among adult survivors of the Biafran famine occurring almost 50 years ago in Nigeria (Hult et al. 2010).

The Biafran Famine

In 1960, Nigeria became independent from United Kingdom. As with other new African states, the borders of the country did not reflect earlier ethnic boundaries, resulting in social unrest. As a culmination of ethnic and religious tensions, civil war broke out in Nigeria on 6 July 1967, after the Igbo people in the south-eastern part had declared independence as the Republic of Biafra. The struggle for control over the large amount of oil in the southeastern Nigeria is also likely to have contributed to armed conflict.

Disapproving of the secession, federal Nigerian forces rapidly encircled Biafran territory and inflow of food to this densely populated enclave was stopped. The resulting famine was extensive and has been regarded as one of the greatest nutritional disasters of modern time (Miller 1970). Of the estimated one to three million Biafrans that lost their lives, only a small fraction (10%) died in military actions and the rest from starvation. International relief actions were launched but they were insufficient and the majority of Igbos did not get access to food from these aid programs (Aall 1970). The war ended in January 1970, Fig. 1.

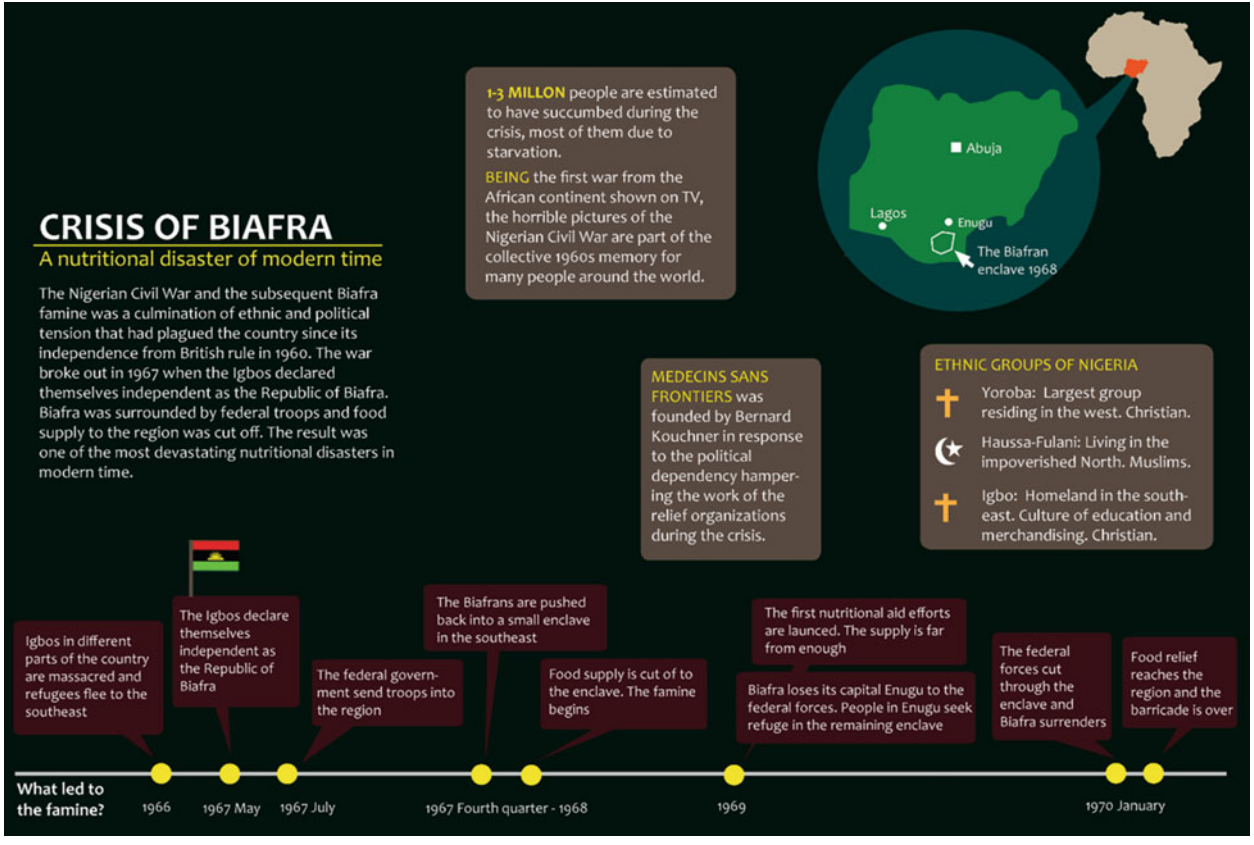

Fig. 1 Crisis of Biafra

Adult Health Forty Years Later

To examine the association between early life exposure to malnutrition and adult life health indicators, a cohort study was performed in 2009 in Enugu (the former capital of Biafra). In total, 1,339 adults aged 36–44 years and thus born before (1965–1967), during (1968–January 1970), or after (1971–1973) the years of famine were recruited at market places of the city, i.e., people representative for today's urbanization in sub-Saharan Africa and thought to be at the highest risk for noncommunicable diseases. Cardiovascular risk factors including blood pressure, plasma glucose, and body mass index were measured (Hult et al. 2010) and adjusted for sex and BMI.

The results showed that people born during the famine had higher systolic blood pressure (mean difference + 7 mmHg; p < 0.001), increased plasma glucose (+0.3 mmol/L; p < 0.05), and waist circumference (+3 cm, $p < 0.001$) than those born before or after the famine. As shown in Fig. 2, those born during the years of famine also had a higher risk of hypertension. Similarly, in this group the risks of impaired glucose tolerance and overweight were elevated. The highest risk for elevated systolic blood pressure was seen in those exposed to fetal-infant famine and ending up with overweight in adult life, Fig. 3.

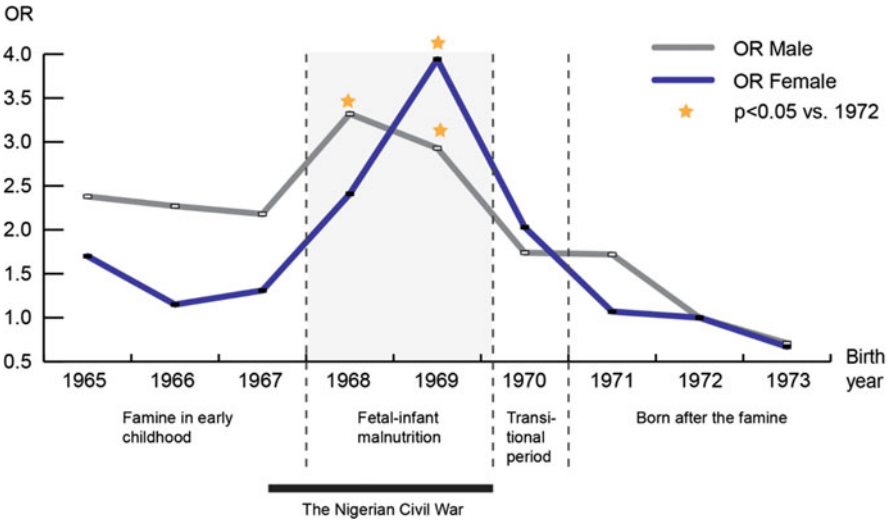

Fig. 2 Risk of hypertension in 2009 by year of birth before, during, and after the Biafran famine. Odds ratios (*OR*) for high systolic (≥140 mmHg) blood pressure in men and women in Enugu, the former capital of Biafra, at follow-up in 2009 according to year of birth (1972 reference) (With permission (this figure has a creative commons license); from Hult M, Tornhammar P, Ueda P, et al. (2010) Hypertension, Diabetes and Overweight: Looming Legacies of the Biafran Famine. PLOS ONE 5(10): e13582. ▶ https://doi.org/10.1371/journal.pone.0013582, http://journals.plos.org/plosone/article?id=10.1371/journal.pone.0013582)

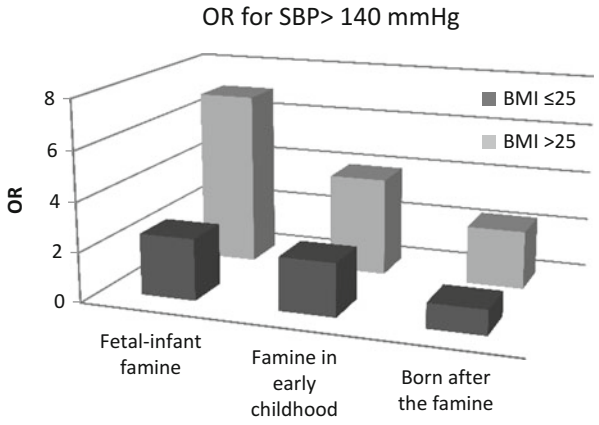

Fig. 3 Joint effects of exposure to famine in early life and adult overweight in survivors of the Biafran famine, as risk factors for a systolic blood pressure (SBP) ≥140 mmHg at 40-years-of-age. *OR* crude odds ratio, *BMI* body mass index. The *bars* represent the risk of high blood pressure for people born during the Biafra famine compared with those born after the famine, among individuals who are normal weight and overweight, respectively

What Could Be the Mechanisms?

During the Biafran famine, the fetal supply line was likely to be seriously compromised in most pregnant women. Although no birth records exist from that time, signs of almost universal fetal and infant undernutrition are obvious on photographs taken during the famine. Some misclassification may have occurred in the above mentioned study, but if anything, this could only have introduced a conservative bias, underestimating the true long-term effects of undernutrition in fetal life and in infancy.

Fetal starvation – as reflected by intrauterine growth retardation and low birth weight at term birth – can cause lasting endothelial dysfunction in small and large arteries, predisposing the affected individuals to atheroma formation and cardiovascular disease (Leeson et al. 1997; Martin et al. 2000a, b; Singhal and Lucas 2004). In addition, the vascular phenotype characterizing people born thin include smaller and stiffer arteries, premature intima-media thickening and capillary rarefaction, all of which are risk factors for later cardiovascular disease (Martyn and Greenwald 1997; Martin et al. 2000b; Singhal and Lucas 2004; Brodszki et al. 2005; Gale et al. 2006; Mitchell et al. 2008; Clough and Norman 2011). Poor fetal kidney development resulting in fewer nephrons may have contributed to the increased risk for hypertension seen in adult survivors of the Biafran famine (Brenner and Mackenzie 1997) and thinness at birth has previously been associated with lower glucose tolerance in childhood (Law et al. 1995) and adult life (Phillips et al. 1994a, b), especially after reduced protein intake during pregnancy and lactation (Smith 2006). Interestingly, maternal undernutrition may also result in behavioral changes in the offspring, such as sedentariness and increased appetite (Vickers et al. 2000, 2003) which could be in the casual pathway for development of overweight and obesity after famine in early

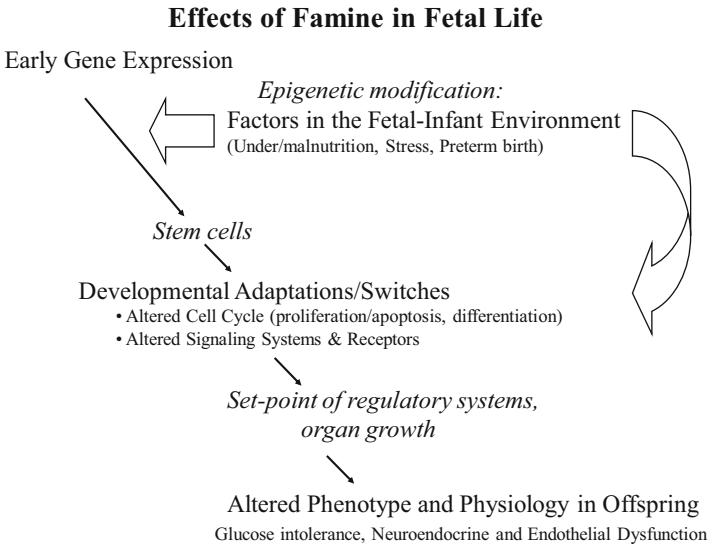

Fig. 4 Early life mechanisms shaping the phenotype

life. Accordingly, different adaptive responses to pre- and perinatal undernutrition can alter the phenotype in terms of physiology, neuroendocrine, and behavioral responses, processes sometimes referred to as "developmental programming," Fig. 4.

Protein Undernutrition in Fetal Life and Later Health

The Biafran famine was characterized by a particularly severe scarcity of proteins, manifested in a large number of infants and children suffering from kwashiorkor (Miller 1970). In experimental models, protein deficit in fetal life results in abnormal glucose homeostasis and vascular endothelial dysfunction in the adult offspring (Armitage et al. 2004).

The role of fetal protein restriction with regard to programming of high blood pressure is less clear. Besides the nutritional insult, pregnant women in former Biafra were living under conditions of war. Such stress for mothers and infants could also have contributed to higher blood pressure in later life, possibly mediated via sympathoadrenal overactivity (Johansson et al. 2007) or exaggerated responses to stress in the hypothalamic-pituitary-adrenal system (Welberg and Seckl 2001; Fish et al. 2004).

Role of Epigenetics

Besides direct effects of fetal-infant undernutrition on cell division, signaling systems, and organ size, early fetal gene expression may also be epigenetically modified in response to environmental exposures (Murphy and Jirtle 2003). One of the best studied epigenetic control mechanisms – in which gene expression is changed

without altering the genome – is DNA methylation (Jirtle and Skinner 2007). DNA-methylation status at birth has been related to both maternal pregnancy diet and to degree of adiposity in her child at age 9 years (Godfrey et al. 2011), and to aortic stiffness – a risk factor for cardiovascular disease – at school-age (Murray et al. 2016). Experimental data also suggest that diet restriction during pregnancy may increase the risk for type 2 diabetes in later life through epigenetic mechanisms (Sandovici et al. 2011).

The Importance of Timing

The importance of timing for later effects of early life famine has been demonstrated in follow-up studies of the Dutch famine, occurring in the end of the Second World War. These studies indicate that undernutrition during different parts of pregnancy may result in different adult risk profiles and outcome, with the highest adult disease risk seen in those exposed to undernutrition early in pregnancy (Painter et al. 2005; Roseboom et al. 2011; van Abeelen et al. 2012b, d). Although available information on the Biafran famine does not allow for a detailed analysis of the timing of the insult, the striking dose-response effect found between birth during years of famine and over-risk for hypertension in adult life (Fig. 2) supports the idea of a causal relationship.

Starvation and Growth in Childhood

As illustrated by the Biafran and Dutch famine follow-up studies (van Abeelen et al. 2012a, b, c), exposure to starvation not only in fetal-infant life but also in childhood is associated with increased risks (but not as pronounced as exposure in fetal-infant life) for hypertension and diabetes in adult life. Children and young adults with accelerated or exaggerated growth following famine in early life seem to be at highest risks (Eriksson et al. 2000; Adair and Cole 2003).

Implications

The famine triggered by the Nigerian civil war represents double misfortune with obvious immediate suffering and health problems for those people exposed to famine, followed in the next generation by increased risks for noncommunicable diseases for those who were conceived and born during famine and survived. Such health problems – originating from reproduction during famine and emerging later in adult life – are not restricted to those investigated herein, but also include increased prevalence of musculoskeletal problems, immune disorders, cognitive disabilities, and psychiatric diseases (Gluckman and Hanson 2006), Fig. 5. Therefore, the Biafran famine has and will have significant impact on health of the affected families, on the health care system, society, and economy.

The implications are important. On a population level, a 2–3 mmHg increase in mean blood pressure has been translated into an estimated increase in cardiovascular

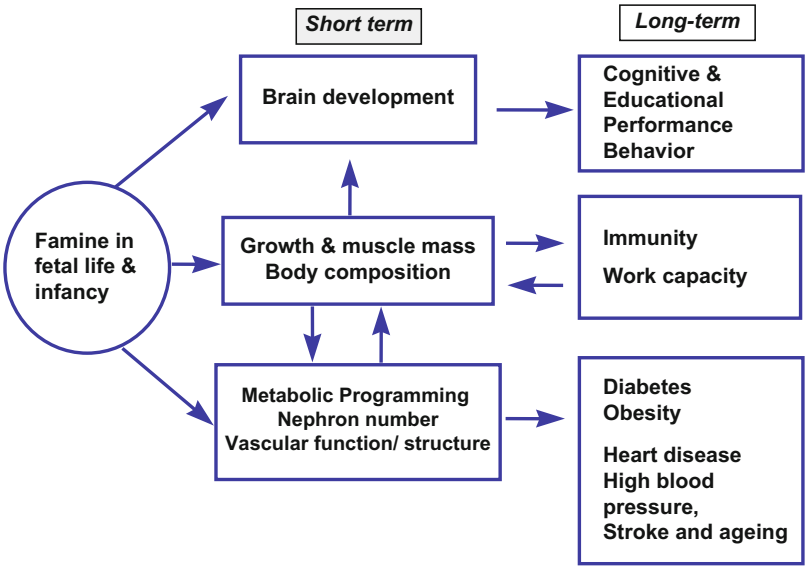

Fig. 5 Conceptual framework of mechanism behind the association between early exposure to the Biafra famine and health outcomes later in life

deaths by 25% and stroke by 32% (Yusuf et al. 2000). Given the combination of elevated blood pressure and glucose intolerance resting on a basis of prevalent obesity before middle age – characteristic for today's urban Nigeria – it is not surprising that morbidity and deaths from stroke and coronary heart disease are increasing. The increasing burden of noncommunicable diseases therefore poses a massive challenge to build-up sufficient health care systems infrastructure in sub-Saharan Africa. Although nutritional disasters with the same severity as the Biafra famine are perhaps not seen in sub-Saharan Africa today, maternal starvation, fetal growth restriction, and infant malnutrition are common and ongoing public health problems on the African continent. Prevention of fetal and infant undernutrition should be given high priority in national health, education, and economic agendas on how to limit the increase of noncommunicable diseases in many African countries.

Policies and Protocols

Measuring and Interpreting Blood Pressure, Blood Glucose, and Body Mass Index

In this chapter we have described health in 40-year-old survivors conceived and born during the Biafran famine. The health outcome variables of these people included determination of three common predictors of cardiovascular disease and diabetes: blood pressure, glucose levels in blood, and body mass index. When

measuring such outcomes, it is important to consider predefined standard operating procedures and to use validated devices (Topouchian et al. 2006). When interpreting data and results, it is also important that common and generally accepted criteria for hypertension, glucose intolerance/diabetes, and overweight/obesity (Alberti et al. 2006) are used.

Global and Local Governance over Health Care, Education, and Nutrition

In this chapter we have described that famine among pregnant women and their infants represents double misfortune: besides the immediate suffering and risk of death for both the woman and her fetus or newborn infant, famine in fetal-infant life will – even after the situation has resolved – results in a weaker construction and design of human physiology which cannot be fully repaired or compensated for later in childhood and adult life. This will result in increased risk for noncommunicable diseases in later life. Given that severe undernutrition and famine still is ongoing, in several cases in the same settings that now are facing an increasing burden of noncommunicable disease, nutrition, and health of pregnant women and their infants is the best investment for the future and should receive highest priority in global and national health, education, and economic agendas.

Dictionary of Terms

- **Endothelium** – The endothelium is the inner cell-lining of all blood vessels. The endothelium has many important function related to how the blood vessels function. The endothelium can actively open or close blood vessels, activate clotting, and open the vascular wall for white blood cells fighting infections in the tissue. Endothelium dysfunction is one of the earliest signals of increased risk for cardiovascular disease.
- **Capillary rarefaction** – The capillaries are the smallest blood vessels through which oxygen and nutrients can be released to the tissues and surrounding cells. The total surface area of the capillaries is comparable to that of a normal football court. Capillary rarefaction means loss of capillaries and surface area for exchange of oxygen and nutrients to tissues. Fewer capillaries will also contribute to build up pressure in the vascular system.
- **Intima-media thickness** – The intima-media is a part of the vascular wall. Thickening of the intima-media in arteries – for example to the brain – signals early atherosclerosis and increased risk for stroke in the future.
- **Atheroma** – An atheroma constitutes a local thickening in an artery caused by fatty accumulation and inflammation of the vessel wall. Atheroma precedes the formation of arterial plaques which means that the thickening of the blood vessel inner wall has been calcified. Once plaques are present, the vessel lumen is narrowed and eventually occluded by a clot. Depending on where the occluded

artery is located, it will result in myocardial infarction (heart attack), stroke, or peripheral ischemia, usually in a foot or leg.
- **Cardiovascular disease** – means ischemic heart disease (myocardial infarction or heart attack), stroke or more rare complications to atherosclerosis.
- **Glucose intolerance** – means elevated levels in blood or plasma of glucose but still not fulfilling criteria for diabetes. The limits are different for random blood glucose, blood glucose after an overnight fast or after ingestion of a standard amount of glucose. Glucose intolerance is associated with overweight and obesity and can precede gestational or type 2 diabetes. In turn, diabetes is closely related to accelerated vascular aging and atherosclerosis.

Summary Points

- Middle-aged survivors of the Biafran famine – regarded as one of the great human disasters of modern times – suffer today from hypertension, glucose intolerance, and overweight, predicting increased prevalence of cardiovascular disease and diabetes.
- These findings support that undernutrition early in life irreversibly affect human physiology so that noncommunicable diseases in adulthood – such as heart attacks, stroke, and diabetes – will increase.
- Perinatal contributions to adult disease are most pronounced in countries undergoing a rapid rural-to-urban transition in life-style and diet.
- Prevention of undernutrition during pregnancy and in infancy should therefore receive high priority in global health, education, and economic agendas.

The Great Irish Famine 1845–1850: Social and Spatial Famine Vulnerabilities

2

Declan Curran

"Several persons, residents of Castlebar, have informed us that while digging potatoes in their fields they encountered an intolerable stench, which, after examination, they found to proceed from the putrid state of the esculents they were in the act of unearthing [. . .] Should this fearful malady spread among the crops of the rural population, dreadful indeed must be the consequences to the poor, whose sole dependence in this country is the potato crop."
[Excerpt from Mayo Telegraph, reprinted in Freeman's Journal, Friday 19 September 1845, p. 4]

Contents

Abstract

This review chapter of the Great Irish Famine (1845–1850) discusses the famine onslaught in terms of uneven "famine vulnerabilities": pre-existing social and spatial disparities that characterized pre-famine Ireland and exacerbated the

famine hardship experienced by poorer classes in rural areas. More generally, this chapter advocates that episodes of famine be understood in terms of a complex interaction between the immediate catalyst of famine and the pre-existing social and spatial variations that define the local context in which the dire consequences of famine unfold.

Introduction

Early reports of the potato blight's arrival on Irish shores in September 1845 provide visceral accounts of a harvest rotting where it had been planted and warn of imminent, inevitable suffering on a national scale. However, as alluded to in the Mayo Telegraph excerpt above, the famine maelstrom into which Ireland was about to be thrust would not afflict all localities to the same extent. Rather it would reveal entrenched famine vulnerabilities which had crystalized in the prevailing socioeconomic and political landscape of the pre-famine decades (Curran 2015). These pre-existing famine vulnerabilities reflected national fissures that were both social – an estimated three million landless laborers and smallholders dependent on the potato as a subsistence foodstuff – and spatial – an established regional geography of deprivation and poverty. This chapter provides an overview of these pre-existing social and spatial famine vulnerabilities and traces their influence on subsequent famine mortality and famine relief efforts.

The immediate devastation wrought by the Great Irish Famine (*An Gorta Mór*) of 1845–1850 has been well documented: with an estimated 1 million famine-related deaths from a population of 8.5 million in 1845 and an emigration outflow in excess of 1 million Irish inhabitants, the Famine onslaught culminated in a 20% population decline over the period 1845–1851 (Boyle and Ó Gráda 1986; Mokyr 1983; Ó Gráda 2012). The longer term imprint of the famine on Irish development has also been well established, characterized as it was by continued population decline and emigration into the early decades of the twentieth century (Vaughan and Fitzpatrick 1978). These demographic trends were accompanied by a transformation of Irish social and economic structures, as landless laborers and smallholders – those who had borne the brunt of famine-era hardship – faced further difficulties in a post-famine agricultural landscape that was shifting from tillage to pasture, undergoing a consolidation of landholdings, and becoming increasingly mechanized (Guinnane 1997; Ó Gráda 2007).

This chapter begins by situating the famine onslaught and aftermath in the context of Ireland in the first half of the nineteenth century. While the famine left

an indelible mark on subsequent Irish socioeconomic development, the famine unfolded in a particular Irish socioeconomic setting that had established itself over the preceding decades.

Pre-Famine Ireland

The late 1700s and early 1800s represent a period of rapid Irish social and economic change, which can be seen as the product of intertwined domestic and international factors. In an international context, a series of technological improvements in textiles and a major geopolitical event, the Napoleonic Wars of 1793–1815, provided a great stimulus to Irish economic development and, through their interaction with existing social and economic structures within Ireland, these developments had far reaching consequences for Irish living standards. The Napoleonic Wars, in particular, brought great benefit to Irish agricultural interests, conferring on Ireland a near monopoly status in British wartime food importation due to blockade of continental trade (Daly 1981). These economic developments were accompanied by an unprecedented population explosion, particularly in Connaught and Munster whose greater proportion of small farmers reaped the benefits of the wartime boom (Donnelly 2002). This period also saw the emergence of textiles as an important cottage industry, supplementing rural farm incomes (Daly 1986). Linen was the most successful of the Irish textile industries and by 1800 linen had developed into a major rural cottage industry, emerging in north east Ulster and spreading across the northern half of the country and into isolated parts of the west. Many landless laborers and smaller tenant farmers earned additional income, either by spinning yarn or weaving coarser fabrics, while many weavers rented a plot of land where they grew potatoes but paid the rent from weaving earnings.

The end of the war in 1815, however, along with the collapse of the domestic textile industry, ushered in an era of economic instability between 1815 and the eve of the famine. The reopening of the British market to grain imports from continental Europe and the demobilization of the British army and navy created a more challenging environment for Irish agriculture. Economic difficulties intensified in 1820, as falling agricultural prices eroded public confidence in the abilities of small private Irish banks to meet their obligations and triggered a wave of bank closures (Cullen 1972; Ó Gráda 1994). Within a two-week period in May–June 1820, seven of the fourteen banks servicing the southern counties of Ireland had folded (Barrow 1975; Collins 1988). Further economic difficulties ensued in 1825–1826, in part as a spillover from financial crisis within the British financial system but also due to deflationary pressures arising from the implementation of the currency union between Ireland and Britain envisaged by the 1800 Act of Union. The economic consequences of the 1800 Act of Union, which abolished the Irish parliament and established a new political unit known as the United Kingdom of Great Britain and Ireland, involved the following steps: abolition of intra-Union trade barriers,

establishment of a common external tariff, consolidation of the exchequers, and the merger of the two currencies. The first two steps were implemented in 1801, the exchequers were consolidated in 1817, and the currencies merged in 1826 (Cullen 1972; Geary and Stark 2002).

Irish agriculture did overcome its post-war slump, as prices of grain, livestock, and dairy began to recover in the 1830s, and export volumes expanded once again (Ó Gráda 1994). However, the domestic textiles industry, which had been the second major area of economic expansion in eighteenth-century Ireland and had been an important source of supplementary income for the rural poor, entered into a terminal decline in the decades prior to the famine. While Belfast's large population of skilled weavers and existing mills enabled the region to establish the region as an early center of mechanized fine linen spinning, the rural cottage textile industry could not compete in the face of large-scale mechanized production (O'Malley 1981).

This decline of Irish industry and fluctuations in Irish agriculture led to a deterioration of the position of the landless poor and small tenant farmers, who accounted for at least half of the population prior to the famine, and left them particularly vulnerable to the famine onslaught when it struck. Landless laborers and smaller tenant farmers were now almost exclusively dependent on farming, and in particular the potato crop, for subsistence.

Pre-Existing Famine Vulnerabilities

The socioeconomic transformations experienced in the pre-famine decades created uneven famine vulnerabilities across the country, along both social and spatial lines, which exacerbated Ireland's susceptibility to famine. These distinct famine vulnerabilities are exemplified by the disparities evident in pre-famine living standards across social groups and regions and, related to this, the uneven economic geography which prevailed in Ireland at this time.

The 1841 census provides an invaluable insight into the socioeconomic variation prevailing within pre-famine Irish society. The 1841 census categorizes respondents as: (i) property owners, and farmers of more than 50 acres; (ii) artisans, and farmers of 5–50 acres; (iii) laborers and smallholders up to 5 acres; and (iv) "means unspecified." For rural districts of the country as a whole, the first two categories accounted for 30% of families. A further 68% of rural families consisted of laborers, small holders with less than five acres, and less prosperous artisans, while 2% of families were unspecified. However, these first two categories of larger landholding combined ranged from 40% to 42% in some eastern counties to below 23% in the western counties of Donegal, Sligo, Leitrim, Roscommon, Mayo, Galway, and Clare. Regional disparities in living standards are also evident from the illiteracy data reported in the 1841 census, which put illiteracy in the 16–25-year age cohort at 27.6% and 29.5% for Ulster and Leinster, respectively, compared to 48.5% and 62.5% for Munster and Connaught, respectively. The proportion of illiteracy for older age cohorts in Munster and Connaught resided within a range of 60–80%

(Mokyr and Ó Gráda 1988). The divergence in living standards between Irish social groups in the half century prior to the famine has also been documented in Mokyr and Ó Gráda's research, which finds that while the urban and middle classes may have experienced some moderate increase in their incomes, the landless poor experienced increasing impoverishment. Though the nutritional content of the potato and widespread access to heating fuel in the form of turf may have ameliorated conditions somewhat for landless laborers and cottiers, the collapse of the cottage textile industry had a devastating impact in many rural areas and led to an increased dependence on the potato crop as a means of subsistence. The analysis of Mokyr and Ó Gráda draws on a number of sources: responses to the Poor Inquiry Commissioners, a body appointed by the British parliament in 1835 which collected responses from 1,590 Catholic and Protestant clergymen on the conditions facing the Irish poor; consumption data of sugar, tea, and tobacco; as well as indicators of human capital formation such as illiteracy and school attendance.

A unique economic geography had established itself in Ireland prior the famine. The regional dispersion of agriculture across the country reflected the fact that commercial farming was prominent on the better and drier land of east and south east, which was also nearer to the British market, while the transport of grain from the midlands was facilitated by a network of canals. The more remote areas of the west, north-west, and south-west suffered from poorer soil quality, a wetter climate, and from greater difficulties in gaining access to export markets due to high transport costs (Cullen 1972; Daly 1986; Mokyr 1983). Concurrent regional and social obstacles to pre-famine agricultural commercialization are also identified by Ó Gráda (1988): the west of the country engaged in less commercial farming due to farm sizes being smallest and dependence on the potato as a subsistence crop being greatest, while smallholders and laborers nationwide engaged in less commercial farming as they consumed the subsistence potato crop produced on their plot of land and paid their rent mostly in labor.

As noted above, the retrenchment of the textile industry from a cottage-based rural dispersion to an industrialized core of north east Ulster increased the dependence of rural areas on agriculture. Underpinning the structure of Irish pre-famine agriculture was the contentious issue of land ownership: agricultural land in pre-famine Ireland largely resided in the hands of several thousand landlords, most of whom were descendants of families granted land either by Cromwell or the British Crown in the seventeenth century. Landlords were typically of Anglo-Irish stock and Protestant religion, though some traditional Irish landlords had survived. Few landlords were actively involved in managing their estates (Daly 1981). Landlords invested little in the maintenance or improvement of their estates, leaving the introduction of more efficient equipment or methods to the stronger tenants (Ó Gráda 1994). Instead, landlords rented their land on long-term leases in order to receive a secure fixed income. These leases were often granted to large tenants, known as middlemen, who then sublet portions of land to numerous smaller tenants (Daly 1981). This role of middlemen as intermediate landlords was all but eradicated during the famine years as their small tenants fell into insurmountable rent arrears (Donnelly 2002).

The labor requirements of tillage farming contributed to the division of landholdings into smaller plots. Commercial famers made agreements with permanent laborers known as *cottiers*, whereby the cottier provided his labor to the farmer for a fixed daily rate. The cottier would also rent a portion of land (*conacre*) from the farmer on a short-term lease for a fixed annual sum payable as days worked for the farmer. On this parcel of land, the cottier could build a cabin and grow the subsistence potato crop. Casual laborers (*spalpeen*) also rented conacre plots, but their employment was less secure than that of cottiers. These casual laborers often received monetary payment, although potatoes, turf, and other provisions were also used as a means of payment (Crotty 1966; Daly 1986). Subdivision of land also took place on smaller noncommercial farms. In some cases, small- and medium-sized farmers supplemented their income by subletting small plots of land to laborers. Subdivision was also undertaken within families in order to provide for a son or act as a dowry for a daughter's marriage. This process of subdivision led to the formation of ever smaller landholdings as families were pushed on to marginal land suitable only for potato cultivation. As Daly notes, by the eve of the Famine, the potato crop sustained an entire socioeconomic system (Daly 1997, p. 39).

The role of the potato in the average Irish diet was far greater than in the rest of Western Europe, with Irish daily potato consumption per capita more than double the Prussian or Netherlands equivalent (Vanhaute et al. 2007). Despite being unsuited to storage or transportation, the potato's high nutritional content, relatively dependable yield even in poor soil during the pre-famine years, and its suitability as a foodstuff for both man and livestock led to an over-dependence on the crop, particularly among the poorer layers of Irish society. It has been estimated that, in the pre-famine years, potato consumption of the average adult male among the laborer, cottier, and smallholder classes was 12–14 lb per day (Bourke 1993). Ó Gráda estimates that on the eve of the famine, Irish laborers, 40% of the Irish population, accounted for over 60% of human annual potato consumption. Cottiers (17% of the population) and small farmers (6% of the population) accounted for 13% and 5% of annual potato consumption, respectively (Ó Gráda 2012, p. 46). By 1845, the potato's share in tilled acreage was little short of one-third and about three million people were largely dependent on it for food (Ó Gráda 1988).

The Famine Onslaught

The immediate cause of the Great Irish famine was the fungus *Phytophthora infestans*, which decimated the Irish potato crop in the harvesting seasons of 1845, 1846, and 1848 (Bourke 1993). The presence of the fungus was detected in Belgium in late June 1845, possibly introduced via potato imports from South America (Neiderhauser 1993). By mid-July, the fungus had spread from Belgium to the Netherlands, and by mid-August it had been detected in France, Germany, and Southern England. By late August, *Phytophthora infestans* had arrived in Ireland, where it was first observed in the Dublin area (Dowley 1997). When the potato blight struck Ireland in Autumn of 1845, it destroyed about one-third of that year's potato

crop and nearly the entire potato crop of 1846. While 1847 marked a respite from potato blight, the 1846 crop failure led to a severe shortage of seed which resulted in the area planted in 1847 being only about 25% of that of the previous year. The potato blight returned with a vengeance in 1848, destroying most of that year's harvest (Dowley 1997).

Notwithstanding difficulties in reconstructing famine-era excess mortality statistics, estimates place the level of excess mortality due to the Irish Famine at one million deaths, nearly one-eighth of the entire population (Mokyr 1983). Indeed, this estimate would be greater were it to include births which did not take place due to the famine, estimated be the region of 300,000, or famine-related deaths abroad (Boyle and Ó Gráda 1986). Outright starvation was not a major cause of death during the famine years (Geary 1997). The vast majority of those who perished as a result of the famine succumbed to dysentery, typhus, typhoid fever, and other hunger-induced infectious diseases. Contagious fevers, such as typhus, were particularly virulent due to a famine-induced breakdown in personal hygiene, overcrowded workhouses, and famine-era migration and vagrancy (Daly 2007).

As the famine's grip tightened on the poorer classes of Irish society, famine-related mortality was distributed very unevenly across the country. The distribution of famine-induced excess mortality across Irish province has been estimated as: Connacht, 40.4%; Munster, 30.3%; Ulster, 20.7%; and Leinster, 8.6% (Donnelly 2002, pp. 176–178). Regional mortality rates also reflect the protracted nature of the famine. The south and west of the country bore the brunt of the Poor Law Amendment in 1847 (discussed below), which placed the full burden of financing poor relief on the Irish rate payer and thereby prompted large-scale evictions by landlords as they sought to lessen their poor rate obligations (Ó Gráda 1994; Donnelly 2002).

Famine conditions also triggered a mass exodus from Irish shores, with over one million people emigrating from Ireland between 1846 and 1851 (Cousens 1960; Boyle and Ó Gráda 1986). Irish emigration was not immediately impacted by the failure of the potato crop in Autumn 1845. It was the second, more widespread, season of blight in 1846 that triggered an immediate large-scale emigration flow in which migrants undertook risky winter transatlantic crossings with little or no food provisions (MacDonagh 1966). The first wave of emigrants were mainly poor cottiers, but were soon followed by smallholders of all types. It is the 1847 transatlantic crossings in particular that have come to be associated with appalling levels of suffering and mortality, the infamous "coffin ships" on which Irish emigrants made their way to ports in America and Canada, and outbreaks of disease at the landing posts (MacDonagh 1966; Daly 1986). While the relatively less severe potato deficiency in Autumn 1847 led to a brief respite in emigration flows, the total failure of the potato crop in 1848 lead to a resumption of emigration at levels previously experienced in 1846 and early 1847. Mortality rates were particularly high on crossings to Canada in 1847. Miller (1985, p. 292; 2008, p. 67) estimates that at least 30,000 emigrants may have died on the Canadian route or in fever hospitals on their arrival. This third season of blight appears to have broken the morale of those cottiers and small farmers who had up to that point held on to their landholdings.

Famine conditions also triggered internal migration within Ireland, though the extent and consequences of this remain under-researched aspects of the famine (Ó Gráda 2007). Cousens characterizes internal migration during the famine as a short-lived influx in to larger urban centers, which was curtailed as relief efforts at a local level were restricted to local residents (Cousens 1960). Donnelly also depicts a rural to urban migration pattern, with large crowds from the countryside congregating in urban areas and at workhouses, food depots, and soup kitchens (Donnelly 2002, pp. 172–173).

Policy Measures Aimed at Famine Relief

Initial publicly funded famine relief initiatives were implemented as temporary measures, funded in part by the British exchequer, with the aim of addressing an exceptional situation. In November 1845, the Tory government of Sir Robert Peel undertook the covert purchase of £100,000 worth of Indian Corn and meal in the United States, with the supplies arriving in Ireland from February to June 1846 (Donnelly 2002). Local relief committees and a network of food depots were set up to distribute the food, though with some delay. As Gray notes, Peel's commitment to free trade and the abolition of the Corn Laws limited the extent to which he was prepared to engage in such pragmatic interventions and by April 1846 Peel had eschewed anything other than marginal interventions in the food market (Gray 2007).

In early 1846, a scheme of public works, mostly involving road improvements, was established in order to provide employment so that the destitute could purchase food. The public works schemes were overseen by either county grand juries, in which case the entire cost of the works was borne by the county, or a local Board of Works, whereby half the funds advanced were to be repaid to the British treasury and half treated as a grant chargeable to the British consolidated fund. The public works schemes quickly came to be regarded by government officials as an unproductive use of public expenditure, a system open to widespread abuse, and a diversion of productive labor away from agriculture (Gray 2007). By March 1847, the public works employed seven hundred thousand people (one-twelfth of the Irish population). However, the public works schemes did not succeed in containing the famine, as they did not target the neediest, paid too low a wage, and exposed the malnourished and poorly clothed to harsh weather conditions (Ó Gráda 2007). Under the Whig government of Sir John Russell, which came to power in July 1846, the public works scheme was replaced in Spring 1847 with a system of soup kitchens. This measure was intended to be temporary, lasting until a revised Poor Law system had been put in place (Donnelly 2002). The soup kitchens were financed by local ratepayers and private subscriptions from local landowners, and at their peak in early 1847 provided meal-based gruel for three million people daily (Ó Gráda 1988). The soup kitchen scheme was brought to an end in September 1847, at a time when mortality rates appeared to wane, food prices had fallen, and demand for seasonal

work was anticipated. However, a further season of complete potato crop failure was to follow in 1848.

The British government's relief policy after September 1847 sought to bring famine relief measures under the auspices of the existing Poor Law system. The rationale here was to shift the burden of financing relief from the British treasury to Irish rate-paying landlords and tenants, with the workhouse system becoming the main thrust of subsequent relief efforts (Daly 1986). The Poor Law Amendment of 1847 allowed for the provision of outdoor relief to anyone unable to work due to age, disability, or ill-health, together with orphans and widows with two or more children (Crossman 2006). However, the able bodied poor could only avail of relief within the workhouse, unless circumstances such as the workhouse being full or infected rendered outdoor relief necessary. One particular provision within the 1847 Poor Law Amendment, the infamous Gregory Clause, prohibited tenants with landholdings of more than one-quarter of an acre from accessing relief. The Gregory Clause triggered a wave of land clearances and evictions, as landlords sought to remove impoverished cottiers from their property (Donnelly 2002). Estimates of the number of evictions over the course of the Famine vary greatly: Vaughan (1984) estimates that over 70,000 families were evicted over the period 1846 and 1853, while analysis undertaken by O'Neill (2000) puts the number of evicted families at 144,759 for the period 1846–1854.

The geography of land clearances yet again illustrates where heaviest burden the famine-era suffering was borne, with the heaviest toll recorded in Connaught and Munster. Indeed, one county in Connaught (Mayo) was the scene of 10.5% (26,000 tenants) of all evictions in Ireland during the years 1849–1854 (Donnelly 2002, pp. 156–157). As a result of the Gregory Clause, many smallholders were forced to give up their land in order to qualify for relief, losing their homes in the process and swelling the numbers dependent on the workhouse system. The numbers seeking relief within the workhouses rose to 932,284 in 1849, with a further 1,210,482 seeking outdoor relief (Daly 1986). The overcrowded workhouse system, with its regime of hard labor and conditions that spread contagious diseases, led to very high mortality rate within workhouses. Ó Gráda (2007, pp. 47–49) estimates that about one-quarter of all famine-induced excess mortality occurred within the workhouse system.

Conclusion

Irrespective of country or time period, all famine episodes are characterized by appalling levels of death and suffering. The Great Irish Famine (1845–1850) inflicted an estimated 1 million famine-related deaths on a pre-famine population of 8.5 million, not to mention the attendant wave of averted births believed to be in the region of 300,000, and triggered an emigration exodus in excess of 1 million Irish inhabitants. Irish population decline and emigration continued into the early decades of the twentieth century. Irish social structures were dramatically altered

by the famine, as landless laborers and smallholders – who had been the major casualties of the famine – struggled to adapt as post-famine agriculture switched from labor-intensive tillage to land-intensive pasture. As outlined in this chapter, episodes of famine should be understood in terms of a complex interaction between the immediate catalyst of famine and the pre-existing social and spatial variations that define the local context in which the dire consequences of famine unfold.

While the catalyst for subsistence, as opposed to man-made, famines may often be unanticipated climatic or environmental events, the human face of famine-era suffering ensures that famines are always inherently political. As such, issues such as inadequacy of government policy initiatives to alleviate famine-era distress have raised the contentious issue of culpability in interpretations of the Great Irish famine. In documenting the historiography of the Irish Famine, Lee (1997) and Donnelly (2002) note that academic scholarship had long been dismissive of the genocidal interpretation embodied by John Mitchell's *The Last Conquest of Ireland (perhaps)*, published in 1861. This divergence in famine narratives is clearly illustrated by the contrast between the two most prominent book length studies of famine to emerge prior to the 1990s: The Great Hunger: Ireland, 1845–1849 Woodham-Smith (1962), which shared many of Mitchell's sentiments, and The Great Famine: Studies in Irish History, 1845–1852 by Edwards and Williams' (1957), a revisionist work which eschewed the traditional nationalist view of the famine.

Since the 1980s, a more nuanced characterization of the Irish famine has emerged which challenges both nationalist and revisionist narratives (Curran et al. 2015). These "post-revisionist" studies have been influenced conceptually by contemporary studies of hunger and poverty and methodologically by the emergence of new statistical and econometric techniques (see for example, the quantitative work of Mokyr (1983) as well as the Ó Gráda (1998) discussion of Amyrta Sen's food entitlement view in the Irish context). One notable contribution to the discussion of famine culpability is that of Peter Gray, who analyses the response of British government and public opinion to the famine, in the context of famine-era debates about the nature and future of Irish society (Gray 1999). Gray, drawing on archival material and the personal correspondence of contemporaries, examines the prevailing ideologies among elite British politicians and civil servants during the famine years. What emerges is a dogmatic distain among British policymakers for publicly funded relief efforts, predicated on ideas of moralism, a providentialist view of the famine, and lassaiz faire economics, which had deadly consequences for those enduring the deteriorating famine conditions. However, even the very concept of *famine culpability* is one that warrants further interrogation. As Noack et al. (2012, p. 12) contend, a distinction should be made between culpability which centers on adequacy of government relief efforts and humaneness of intentions in the face of the crisis, and culpability in which the government is the instigator of the crisis.

Dictionary of Terms

- **An Gorta Mór** – Irish language term for the Great Irish Famine, 1845–1850.
- **Act of Union** – The Act of Union (1800) abolished the Irish parliament and established a new political unit known as the United Kingdom of Great Britain and Ireland.
- **Phytophthora Infestans** – A destructive plant pathogen which caused the potato blight that decimated the Irish potato crop in 1845, 1846, and 1848.
- **Cottier** – A peasant farming a smallholding of not more than half an acre.
- **Conacre** – A system of letting land in small patches or strips, usually for tillage.
- **Spalpeen** – A poor migratory farm worker in Ireland.
- **Gregory clause** – A provision of Poor Law Amendment Act introduced by the British government in 1847 which prohibited anyone holding one-quarter of an acre or more of land from receiving any assistance under the Irish Poor Law; also known as the *Quarter Acre Clause*.

Summary Points

- Great Irish Famine (1845–1850) unfolded in the context of pre-existing social and spatial disparities.
- The end of the Napoleonic Wars (1815) ushered in a period of economic instability that particularly affected those dependent on agriculture for employment and subsistence.
- The decline of the rural cottage linen industry, in the face of increased mechanization, removed a further source of additional income from small tenant farmers.
- Subdivision of landholdings among families into ever smaller portions was common practice, with the high yield of the potato as a subsistence crop partly sustaining this practice.
- As documented in the 1841 census, on the eve of the famine, localities in west and southwest of the country exhibited markedly lower living standards than the rest of the country.
- By 1845 the potato's share in tilled acreage was little short of one-third and about three million people were largely dependent on it for food.
- The famine resulted in an estimated 1 million famine-related deaths from a population of 8.5 million in 1845 and an emigration outflow in excess of 1 million Irish inhabitants over the period 1845–1851. Irish population decline and emigration continued well into the early decades of the twentieth century.
- Post-famine Ireland underwent a transformation of social and economic structures, as landless laborers and smallholders – those who had borne the brunt of famine-era hardship – faced further difficulties in a post-famine agricultural landscape that was shifting from tillage to pasture, undergoing a consolidation of landholdings, and becoming increasingly mechanized.

- Early famine relief efforts included temporary interventions in the grain market and the provision of food via soup kitchens. However, from 1847 onward, Irish famine relief was incorporated into the existing Poor Laws, which meant that burden of financing Irish famine relief was transferred to Irish ratepayers. From 1847, able-bodied poor could only receive relief within the workhouse system.
- Within the 1847 Poor Law Amendment, the Gregory clause has gained particular notoriety: this clause prohibited tenants with landholdings of more than one-quarter of an acre from accessing relief. The Gregory Clause triggered a wave of land clearances and evictions as landlords sought to clear indebted smallholders form their estates.
- In the aftermath of the Irish famine, nationalist narratives emphasized British culpability in exacerbating famine mortality. Subsequent revisionist narratives in turn eschewed this culpability argument. Since the 1980s, a more nuanced characterization of the Irish famine has emerged which challenges both nationalist and revisionist narratives.

Famine in Ghana and Its Impact

Contents

Abstract

In many developing countries, especially in Sub-Saharan Africa, agriculture plays a central role in economic life. This was particularly true in Ghana during the early 1980s, as the sector employed a little over half of the total labor force and accounted for close to 60% of gross domestic product (GDP; World Development Indicators). In the absence of any irrigation, rainfall levels largely determined agricultural output and therefore the livelihoods of much of the population. While Ghana experienced droughts throughout its history, the 1981–1983 drought stands out for its severity. This chapter examines the origins of the drought and the resultant famine before tracing out its immediate and long-run consequences on a wide range of health outcomes.

Introduction

Ghana stretches across six acro-ecological zones ranging from the more arid sudan savannah in the north to wetter coastal and guinea savannahs in the south (Antwi-Agyei et al. 2012). Rainfall in Ghana is seasonal with both a major and minor rainy season in the coastal and southern areas but only one rainy season in the North (Ghana Meteorological Agency). Although the average variability in rainfall is relatively moderate (coefficient of variation between 10% and 22.5% Ofori-Sarpong), rainfall totals can shift dramatically across years. For instance, the annual rainfall totals in the capital, Accra, have historically varied between 1,197 mm and 275 mm (Ofori-Sarponh 1986).

Agriculture in Ghana is generally inhibited by the low quality of soil, particularly in the north where the soil quality generally limits crops to maize, sorghum, and millet (Antwi-Agyei et al. 2012; Stryker 1990). Importantly, these crops require relatively high levels of water, particularly during their growth periods. Due to the almost complete lack of irrigation (only 0.2% in the early 1990s FAO 1994), agricultural production in Ghana and, in particular, the dryer north is vulnerable to droughts (Antwi-Agyei et al. 2012; FAO 1994).

The most severe drought in the modern history of Ghana began in 1981. With the exception of Accra and other parts of the South, the total annual rainfall in the country was only 70–90% of the local averages (relative to the 1931–1960 average) depending on the specific area (Ofori-Sarpong 1986. The drought further extended itself geographically in 1982 before encompassing the entire country in 1983. The rainfall levels in 1983 were particularly poor with several areas having less

than half of the normal rainfall totals. The drought was particularly severe in coastal areas where Accra had its second lowest recorded rainfall total (58% of the normal amount) with several other areas receiving their lowest recorded totals (Ofori-Sarponh 1986).

The effects of the drought were compounded by both natural and man-made events. For instance, in 1983, the dry conditions from 3 years of drought along with an extended harmattan (season with dry winds) led to extensive bush fires in the North of the country. USAID reported that up to 35% of total food production was destroyed in certain regions (USAID 194). The domestic food shortage was further aggravated by the expulsion of a large number of Ghanaian workers in 1983. Estimates range from several hundred thousand to close to one million workers. Irrespective of the true total, it was a substantial inflow as compared to the population of 11.5 million (Stryker 1990; USAID 1984; World Bank 2016).

While the food shortage could have (partially) been addressed through food imports, this was not possible as the country was in the middle of severe political and economic turmoil. Following failed coups and violent strikes in the preceding years, a new government had come to power after a New Year's Eve coup d'Etat. At the same time, the macroeconomic context had deteriorated (e.g., deficit spending of 139% of the tax revenue and triple digit inflation) and a failed attempt to borrow from the IMF (Stryker 1990). The fiscal situation was further complicated by the strong decrease in cocoa production, the main export crop and a significant source of government revenue (typically 20–50% of revenue); years of mismanagement along with the drought substantially reduced the production in 1983–1984. This harvest was only 28% of the peak production in 1964–1965 and roughly 40% of the 1972 production (Stryker 1990; Brooks et al. 2007).

The three consecutive years of drought culminated in substantial food shortfalls and domestic price increases in 1983. The tables are based on Stryker's (1990) attempt to create production and prices indices. The shortfalls in 1983 were not only substantial relative to a decade earlier (Table 1: column 1) but also relative to 1982 (Table 1: column 2), the second year of the drought. The production of almost every major crop declined compared to 1972, a normal agricultural year. While the decline was generally less steep relative to 1982, the production of certain crops notably declined between the 2 years. In particular, two of the three main crops in the North (maize and millet but not sorghum) declined by 50% from the already low totals in 1982.

The limited price data which are available suggests that the repeated years of drought and low production substantially increased food prices in 1983 (Table 2). The data show that the inflation in prices for crops outstripped general inflation. Notably, this was even true for the crops whose production increased between 1982 and 1983, such as rice, sorghum and yam (Table 1).

The prolonged drought and unfortunate combination of events greatly affected the nutritional situation. Per capita caloric availability dropped from roughly 95% of the required national total between 1961 and 1975 to only 65% in 1983, the most severe year of the drought (World Bank 1989). Unsurprisingly, per capita caloric consumption decreased from 1,900 to 1,600 between 1982 and 1983 due to a

Table 1 Production of major crops, 1983

	1983 Production relative to	
	1972	1982
Agricultural food production, per capita	64%	94%
Maize	43%	50%
Rice	57%	112%
Sorghum	57%	102%
Millet	37%	48%
Cassava	41%	47%
Yam	128%	147%
Plantain	20%	23%
Groundnuts	78%	173%

Based on Tables 6 and 7 (Stryker 1990)

	1982–1983
Inflation (consumer prices)	123%
Maize	360%
Rice	171%
Sorghum	190%
Cassava	254%
Yam	160%

Based on Table 10 (Stryker 1990) and the World Development Indicators

substantial food deficit, estimated at 378,000 tons for just maize (Stryker 1990). In fact, the 1983 daily calorie supply per capita was the lowest reported total for 1983 (World Bank 1986). The food crisis peaked in 1983–1984 and only abated with the return of rains 1984 and the arrival of food aid (Ampaabeng and Tan 2013).

While the data are not available, the poor were likely disproportionately affected. Poverty is primarily rural in Ghana where poor households predominately farm land and/or work in agricultural labor. The decreased agricultural production lowered household food availability and income precisely at the time when food prices were increasing sharply. The effect would have been aggravated by the repeated nature of the shocks. Repeated poor harvests decrease the available buffer stocks of assets which allow households to smooth consumption (i.e., to self-insure) against income and production shocks (and other covariate shocks).

The droughts and the ensuing famine affected the entire country. As noted earlier, the north was particularly vulnerable to droughts and two of three major crops declined by more than 50%. In the south, both food and cocoa (the major cash crop) production were affected. Due to the absence of regional crop and price indices, it is not possible to examine the spatial effect on production or prices. However, it is possible to obtain a sense of the regional distribution by examining the regional variation in the under-five mortality rates from trends which they obtain from DHS data by comparing deaths in 1983 to the 1985–1987 averages by

administrative region. Ampaabeng and Tan (2013) find that the Western and Central regions were the most affected with a greater than 1 standard deviation increase in deaths. With the exception of the central regions of Brong and Eastern, the rest of the country experienced roughly 0.5 standard deviation or greater mortality.

Framework

Recent developments in the Economics literature provide useful frameworks for tracing out the structural effects of initial (e.g., in utero) shocks, such as famine, on subsequent (both short-run and long-run) outcomes. A particularly influential body of work by Nobel Laureate James Heckman and co-authors (Cunha and Heckman 2007; Cunha et al. 2010; Heckman and Mosso 2014) builds on the classic family investment models of Gary Becker and Nigel Tomes (1979). These models emphasize the importance of the role of the family in developing various characteristics of the child across her lifecycle.

Formally, these models focus on the evolution of a set of child's characteristics, $\theta_{i,\,t}$, where i indexes the child and t indicates some stage in her lifecycle (e.g., early childhood, adolescence, adulthood, etc.). These characteristics may include health status, cognitive skills (as measured by IQ), personality traits (as described by the "Big Five," Openness, Conscientiousness, Extraversion, Agreeableness, and Neuroticism, for example), and so forth. The evolution of this set of skills across the child's lifecycle is modeled by a system of difference equations;

$$\theta_{i,t} = f_t\left(\theta_{i,t-1}, I_{i,t}, h_i\right)$$

where h_i denotes a vector of initial conditions for individual i; e.g., genes, initial health status at birth, parental characteristics (e.g., parental IQ, parental education, etc.), etc.; and, $I_{i,t}$ is a vector that is thought of as "investments" in the child at stage t. But, the definition of "investments" can be broad and could include parental investments in schooling and time, the nature of the family environment, any health shocks, etc. In the context of the famine in Ghana, the model therefore allows us to conceptualize the effects on birth outcomes of health shocks to the child experienced in utero (h_i), or, perhaps, a nutritional shock experienced after birth at stage t in the child's lifecycle (one element of $I_{i,t}$). The model is flexible enough to also allow for remedial interventions, for example, by the parents, in response to an in utero shock (another element of $I_{i,t}$). Cunha and Heckman (2007) demonstrate that we can obtain the following via recursive substitution:

$$\theta_{i,t} = m_t\left(I_{i,t}, \ldots, I_{i,1}, h_i\right)$$

That is, the stock of individual characteristics at stage t is determined by initial conditions and the series of investments up to that point.

Cunha and Heckman also introduced a set of useful concepts related to their model into the Economics literature. For example, they define the notion of a *critical*

(or, sensitive) development period. In the context of their model, a critical development period for an investment type j is a time s such that

$$\frac{\partial m_t\left(I_{i,j,t}, \overline{I}_{i,-j,t}, \overline{I}_{i,t-1}, \ldots, \overline{I}_{i,1}, \overline{h}_i\right)}{\partial I_{i,j,t}} > 0, \text{if } t = s \text{ and } \frac{\partial m_t\left(I_{i,j,t}, \overline{I}_{i,-j,t}, \overline{I}_{i,t-1}, \ldots, \overline{I}_{i,1}, \overline{h}_i\right)}{\partial I_{i,j,t}} \approx 0, \text{if } t \neq s$$

The sensitive period idea captures the idea that there may be particular stages in the child's development; e.g., early childhood, where certain investments or shocks (e.g., exposure to famine) may have particularly large effects. A critical period occurs when there is only one such (sensitive) period (Knudsen et al. 2006).

They also introduce the important idea of *dynamic complementarity* in the production of characteristics,

$$\frac{\partial^2 f_t}{\partial \theta_{i,t-1} \partial I_{i,t-1}} > 0$$

That is, the level of characteristics at a particular stage (*t-1*, in this case) affects the marginal returns to investment at a subsequent period. The existence of dynamic complementarities has many important implications. Crucially, it affects the optimal investment decisions of parents when deciding the allocation of resources across their children. As Heckman and Mosso (2014) point out, parental decisions to compensate (or, to reinforce) disadvantages in initial endowments of a child (e.g., as a result of experiencing famine while in utero) depends crucially on the curvature of the production function for characteristics. The stronger the dynamic complementarity between initial characteristics and investments, the more strongly incentivized parents are to actually reinforce initial disadvantages and to focus resources on their more advantaged children instead.

These family investment models generally take family structure as given. These models also ignore another important channel through which family circumstances or initial disadvantages may affect future outcomes; i.e., neighborhood or peer group effects; see, e.g., Brock and Durlauf 2001. However, if we wish to trace out intergenerational effects, we will also need to take into account models of assortative mating, and more generally, models of the marriage market that famine affected individuals will face when they reach mating age; see, e.g., Becker 1973, Durlauf and Seshadri 2003.

Physical and Cognitive Effects

Famine studies are not new in the development economics/health literature. In fact, famine incidence has been thought of as a natural "experiment" in this literature and thereby utilized to identify treatment effects on various short- and long-run

outcomes. This research agenda is deeply related to the fetal origins hypothesis (Barker 1992) that posits that exposure to shocks during critical periods in early development (e.g., in utero) result in long-run negative outcomes to recipients of those shocks.

A seminal example is the work by Stein et al. (1972) on the effects of in utero exposure to the 1944–1945 Dutch famine. In that paper, Stein et al. found no significant impact on the cognitive abilities (IQ) of male survivors at age 19 from in utero or early childhood exposure to the Dutch famine. Subsequent work, however, have found evidence of longer-term effects on outcomes such as obesity (Ravelli et al. 1999), glucose intolerance (Ravelli et al. 1998), self-reported health, coronary heart disease morbidity (Roseboom et al. 2001; Bleker et al. 2005), and psychological disorders (Neugebauer et al. 1999; Brown et al. 2000; Hulshoff et al. 2000).

Another well-studied example is the Great Chinese Famine of 1959–1961. In (rural) areas most severely affected by the famine, survivors of the 1959–1961 birth cohorts experienced significant, negative, short- and long-run effects on a range of outcomes including height/stunting (Chen and Zhou 2007; Meng and Qian 2009), obesity (Luo et al. 2006), disability incidence (Mu and Zhang 2011), mental illness (Huang et al. 2012), cognitive abilities (Tan et al. 2014) educational attainment (Meng and Qian 2009), labor market outcomes (Almond et al. 2010; Meng and Qian 2009), wealth (Almond et al. 2010), and marriage market outcomes (Almond et al. 2010; Brandt et al. 2008).

Despite the importance of famine in Africa and the increasing concentration of famines in Sub-Saharan Africa (SSA) (Devereux 2009; Ó Gráda 2007), there is relatively little research on the physical or cognitive effects of early life exposure to famines on surviving children for Sub-Saharan Africa. The most widely studied famine in SSA is the 1983–1985 Ethiopian famine where an estimated 400,000 to 1 million people died (Devereux 2000; Kidane 1990; de Waal 1991). However, we are only aware of three papers studying the health effects for survivors (Asfaw 2016; Dercon and Porter 2014; Tafere 2016). More broadly, there are only three other papers on SSA, one each for Ghana (Ampaabeng and Tan 2013), Malawi (Hartwig and Grimm 2012), and Uganda (Umana-Aponte 2011). Interestingly, neither the research in Malawi nor in Uganda finds any adverse effects on height (although they do find adverse effects on other outcomes). It is, however, possible to draw on a more developed literature on food insecurity (see for instance, Alderman et al. 2006) or even on non-food shocks, such as income shocks (see for instance, Adhvaryu et al. 2017), to predict the effects of famine exposure on health outcomes. We will explore some of these effects below.

As noted above, the literature that directly studies the impact of early exposure to the famine in Ghana is surprisingly sparse. To date, there appears to be only one such work; i.e., Ampaabeng and Tan (2013). In that work, the authors focused on cognitive outcomes as measured by an IQ test (Raven's Progressive Matrices). Specifically, they were interested in whether children who experienced famine during early childhood (aged 0–2 years during the famine) as opposed to later childhood (aged 3–8 years during the famine) did worse on the IQ test administered in 2003. Hence, they were primarily interested in the longer-term impact of the

famine on cognitive development. The authors were also interested in how the effects of early famine exposure on IQ could be quantified in terms of performance on a set of Math and English comprehension tests, also administered in 2003.

The data employed came from the GEIES. Only two waves of that data were available at the time of writing – in 2003 and in 1988/1989. The authors used the 2003 wave for data on their outcome variables. Because GEIES had data on school quality – e.g., the state of classrooms and the availability of textbooks, and the IQ of teachers – they were able to control for the schooling experience of the individuals in their sample all of whom would have been in primary (elementary) school during the 1988/1989 wave. This was an important thing to do since school quality variations during the formative years of a child may potentially (partially) remediate any negative impacts on cognitive development from famine exposure and was therefore one of the distinguishing aspects of this paper. The authors were also able to control for individual, family, and community characteristics such as respondent's age, height-for-age, gender, household size, parental schooling, rural or urban status, etc. In terms of the treatment variable, the authors employed under-5 mortality deviation from trend during the famine years calculated using data from the 1988 DHS. They also used rainfall deviation from trend during the famine years obtained using data from the World Bank's Africa Rainfall and Temperature Evaluation System as an instrument for their treatment variable.

The main finding by Ampaabeng and Tan is that early childhood exposure to the famine in Ghana did result in substantial negative consequences in terms of cognitive development for survivors. According to their benchmark specification, exposure during early childhood to a 1 standard deviation increase in famine severity led to an expected loss of 1.29 IQ points. For perspective, in terms of achievement on the Math and English comprehension tests, "the effect of such a loss on cognitive achievement test scores translates on average to a corresponding loss of around one half of a year (two-fifths in many cases) of schooling with the larger effects applying to the Math tests (Ampaabeng and Tan 2013, 1025)." Following calculations analogous to those in Maccini and Yang (2009), the authors find that such a loss translated into a corresponding reduction of 0.4% in 1997 GDP (as measured in 2000 dollars).

We next examine the effects of the famine on anthropometric measures of child development. Consistent with theory and evidence from other settings, the anthropometric data show a sharp decrease in nutritional intake for infants before a nutritional recovery. For instance, data from Maternal and Child Health (MCH) Clinics collected by Catholic Relief Services (CRS) measures weight-for-age across time. These data likely suffer from some selection bias as not all children attend MCH clinics in general or those affiliated with CRS in particular. However, these data are still suggestive as to the magnitude of the shock and its temporal nature. For instance, in the last "normal" year of agricultural production, only 35% of children fell below the 80th percentile in the NCHS/WHO standards for weight-for-age. By 1983, it had surged to 80% before returning to pre-drought and pre-famine levels (35%) in 1986. In the space of only 3 years, the number of underweight children more than doubled before returning back to normal within 3 years.

Table 3 Short health outcomes for children

Panel A	**<80% of NCHS weight-for-age**	
1986		
Aged 0–5 months	15.3%	
Aged 6–11 months	32.2%	
Aged 12–23 months	69.9%	
Aged 24–35 months	71.8%	
Aged 36–47 months	62.4%	
Aged 48–60 months	64.8%	
Panel B		
1987–1988	***Stunted (%)***	***Wasted (%)***
Boys		
Aged 12–24 months	33.3	18.8
Aged 24–60 months	39.5	4.7
Girls		
Aged 12–24 months	31.7	14
Aged 24–60 months	39.1	5

Panel A is drawn from World Bank (1989): Appendix Table 9. Panel B is drawn from Alderman (1990): Table 2

The initial effects are visible in a pair of surveys immediately following the drought (Table 3). First, a national nutritional survey in 1986 reported the proportion of children in Ghana under the 80th percentile in the NCHS/WHO reference (Table 3: Panel A). The World Bank report (1989) divides the children into six groups: the oldest three groups were affected by the drought (24–35, 36–47,48–60 months), the youngest two were not affected at all (0–5 and 6–11 months), and the last group (12–23 months) was not directly affected by the drought but potentially experienced some of its effects via food or consumption shortfalls in families affected by 3 years of droughts. The data show a clear pattern: children in the cohorts affected by the drought or immediately following it were substantially more likely to be below the 80th percentile for weight-for-age. However, children who were conceived and born after the drought were substantially healthier.

While weight-for-age provides an indication of child health, it reflects both short-run and long-run malnutrition. Short-run nutrition is typically measured by data on weight-for-height while long-run nutrition is indicated by height-for-age. These indicators are available in the 1987–1988 Ghana Living Standard Survey (GLSS 1) (Table 3: Panel B). The first column in Panel B measure the percent of children under the age of 5 who were stunted (i.e., who have abnormally low height-for-age). The older age group contains a combination of children exposed and not exposed to the drought while the younger age group was exposed (in utero or after birth) to the drought. In both boys and girls, the exposed cohort has a more than 6% point higher rate of stunting, roughly an 18–20% higher rate. Interestingly, the rate of wasting, a measure of low weight-for-height, shows the opposite effect: younger children suffer from worse short-run nutrition. The

Table 4 Height of women by age group in 2003 (Aged 19–49)

	Height (cm)	< 2 Std Dev %
1. Affected by famine (born 1979–1984)	158.4	13.1
In utero during famine (1981–1983)	157.8	16.7
Born during famine (1982–1984)	158.0	14.1
Aged 1–2 during famine (1979–1980)	158.8	10.3
2. Affected in peak year of famine (1983) (born 1981–1984)	158.2	25.4
In utero peak famine (1983)	158.9	16.2
Born peak famine (1984)	157.3	18.2
1–2 peak famine (1981–1982)	158.6	36.0
3. Women not born between 1979 and 1984 (born after 1984)	159.2	9.8

Authors' calculations based on the 2003 Demographic and Health Survey

difference between the stunting and wasting rates suggests that the higher stunting in the older age group is due to nutritional deficiencies during the drought as opposed to in later years.

Although the deterioration of nutrition was limited to several years, the effects were permanent as exposed cohorts display important physical and cognitive (as discussed earlier) deficiencies even years later. The physical consequences, already apparent as children, are clearly visible in the sample of adult women in the 2003 DHS. Table 4 presents information on adult height for a nationally representative sample of woman aged 19–49. The women are divided into three broad categories: (1) women who were conceived, born, or aged 2 or younger during the drought (1991–1983); (2) women who were conceived, born, or aged 2 or younger in the peak year of the famine, 1983; (3) all women who were not conceived, born, or aged 2 or younger during the drought. Note that the second group is a subset of the first group. Within the first two groups, the women are further divided into whether they were conceived, born, or born prior to the (peak year of) famine.

The first column reflects the average height (in cm) for each age group. The average height of women who were not affected by the drought is always higher with height "deficits" ranging from 0.3 to 1.9 cm. To put these numbers in perspective, the estimated deficits of adults who were exposed to the 1983–1985 Ethiopian Famine, which is widely recognized as one of the worst in Africa, range from roughly 0.43–5 cm (Dercon and Porter 2014; Tafere 2016). Beyond their intrinsic importance, these deficits are linked via lower earnings to lower adult economic outcomes (Case and Paxon 2008; Currie 2009). The second column reflects the percent of women who are 2 standard deviations below the median of the reference group, a similar measure to stunting. While there are important differences between groups 1 and 3, the outcomes from group 2 are particularly notable. Overall, women in group 2 are more than twice as likely to be abnormally short with those aged between 1 and 2 in 1983 almost three times more likely.

Policies and Protocols

An extensive literature links early life nutrition to adult health outcomes, from adult stature to the incidence of diseases to longevity (see Ó Gráda 2007 for a recent review). In this view, famines represent the extreme tail of a continuum of deprivation. Consequently, as with other less severe forms of undernutrition, early nutritional interventions may be particularly important. The importance of such investments is magnified by the existence of sensitive or, especially, critical periods in child development. This suggests the importance of food transfers targeted towards pregnant and nursing women as well as infants.

More broadly, two factors generally distinguish famines from less severe forms of food insecurity. First, since countries are typically able to withstand exposure to individual adverse events, such as extreme weather and associated crop failure, the more severe impacts from famines are often associated with repeated shocks (de Waal 1997; Ó Gráda 2007). It is the repetition of such shortfalls that overwhelms countries. The emerging literature on the effects of climate change on temperature extremes and the increased frequency of adverse tail events (Dell et al. 2014) suggests that repeated weather shocks may be a "new normal" that the least prepared countries may nevertheless have to face.

This ability to withstand individual shocks provides a short window during which national and international resources can be mobilized before local conditions may become aggravated by a second year of shortfalls. The inability of state actors to properly address the effects of such shocks once they have occurred is often amplified by the existing deficiencies of markets, state institutions, and production technologies. Consequently, it is important to consider the broader development framework in addressing concerns over policy (both short-term and long-term). Are food markets segmented or well-connected so that food moves to areas in need? Are government and local institutions investing in irrigation so as to lessen the reliance of agriculture on rainfall?

Similarly, households are often able to cope with one-off shocks but are very vulnerable to repeated shocks within a short period. Since developing countries are typically characterized by incomplete (or missing) formal and informal insurance markets, households frequently rely on their own asset reserves to smooth out their consumption. That is, by consuming or selling their assets, they are able to replace some of the lost income. Repeated shocks reduce or exhaust the ability of households to deal with shocks and therefore lead to sharp swings in consumption with important consequences, including the health of children. These effects are magnified when income directly depends on asset stocks (Zimmerman and Carter 2003). This suggests that particularly attention should be paid to poorer households with low asset holdings and areas with limited access to formal or informal insurance.

Second, over time, the causes of famines have somewhat shifted away from weather-created food shortages and have increasingly involved conflicts (Ó Gráda 2007). Conflict can affect food availability through a variety of channels such as when food and its availability becomes a "weapon." More recently,

research suggests that household responses to the threat of violence can shift agricultural production practices and lower dietary diversity (Dabalen and Paul 2014; Rockmore 2012). In part, this may explain the observed sharp increases in stunting in cohorts exposed to conflict in early life (Akresh et al. 2011, 2012; Minoiu and Shemyakina 2014). This underlines the importance of providing food aid in areas afflicted with violence and the threat of violence (Rockmore 2016).

Dictionary of Terms

- **Covariate shocks** – Covariate shocks which affect a large proportion of households in geographical area (such as drought, floods, or price increases). This contrasts with idiosyncratic shocks, such as sickness of a household member, which affects only the household.
- **Standard deviation** – The standard deviation is measure of the distance of a data point from the mean of a set of data points. Formally, it is defined as $\sqrt{\frac{1}{N}\sum_{i=1}^{N}(x_i - \bar{x})^2}$ where $\bar{x}$ is the sample mean.
- **Stunting** – Stunting is defined as being 2 standard deviations below the median height-for-age for the reference child growth standard. This is typically viewed as a measure of long-run malnutrition.
- **Wasting** – Wasting is defined as being 2 standard deviations below the median weight-for-height for the reference child growth standard. This is typically viewed as a measure of short-run malnutrition.

Summary Points

- Ghana experienced its worst drought in modern history from 1981 to 1983.
- The drought peaked in 1983 and was compounded by substantial bush fires and the expulsion of large number of Ghanaians from Nigeria in the same year.
- Food production dropped dramatically in 1983 leading to widespread food shortages.
- Effects of famine in Ghana (and in Sub-Saharan Africa) are relatively unstudied.
- Early life exposure to the famine resulted in the loss of IQ and worse performance on Math and English comprehensive exams.
- The aggregate costs of these cognitive losses are 0.4% of the 1997 GDP.
- There are important physical consequences of early life exposure to the famine. In the short-run, it is associated with higher stunting rates. In the long-run, it is associated with 2–3 times higher probability of women being of short stature.

The Greek Famine of 1941–1942 and Its Impact

4

Sven Neelsen and Thomas Stratmann

Contents

Abstract

The Greek Famine of 1941–1942 provides a natural experiment to test the fetal origins hypothesis. This hypothesis states that exposure to detrimental conditions during the fetal stage leads to worse health and socioeconomic outcomes in adulthood. This chapter first describes the Greek famine's causes. It then reviews the impact of the Greek famine on the education and labor market outcomes of the individuals exposed to the famine in utero or in early childhood. Corroborating Barker's hypothesis, the evidence indicates that the Greek famine significantly reduced educational attainment for those who experienced it before their third year of life. The famine also reduced labor market success for those with famine

exposure in their early childhood. This finding is partly driven by a shift towards rural birthplaces in the famine years. The sum of the findings underscores the importance of averting early childhood malnourishment.

Introduction

According to *The State of Food Insecurity in the World 2015* (FAO 2015), there are approximately 795 million people around the world who suffer from hunger, most of whom come from rural areas of developing and middle-income nations. While hunger is a problem in and of itself, a growing body of evidence indicates it also has adverse long-term consequences for health, education, and labor-market outcomes, and that this may especially be the case for those who are deprived of adequate nutrition early in life.

In 1986 epidemiologist David Barker conducted a study that found a relationship between prenatal malnutrition and coronary heart disease later in life (Barker and Osmond 1986). This led to the fetal-origins hypothesis, which proposes a causal relationship between nutrition received in utero and later health outcomes. One mechanism posited to drive these long-term effects is the development of *thrifty phenotypes* (Hales and Barker 1992; Barker and Hanson 2004). Here, the fetus develops permanent adaptations to the low-nutrient environment experienced in utero and these adaptations produce long-term adverse health consequences for the individual.

Many of the early studies following Barker's findings suffered from methodological problems that made it difficult to ascertain a causal relationship between prenatal malnutrition and later-life health outcomes. For instance, due to a lack of data on prenatal nutrition, some of these early studies used birth weight as a proxy (e.g., Launer et al. 1993; McCance et al. 1994; Barker 1995). Body weight at birth may, however, vary for many reasons other than prenatal nutrition, including genetic endowment, gestational age, and maternal behavior (Rasmussen 2001; Paneth and Susser 1995). If these factors are unaccounted for, associations between birth weight and later-life health outcomes will yield limited information on the possible impact of prenatal malnutrition.

Even if accurate data on prenatal nutritional status are available, the problem that malnutrition is endogenous to other determinants of later-life socioeconomic status

and health remains. For instance, having better-off parents likely improves later-life outcomes not only by reducing prenatal exposure to malnutrition but also through other factors such as access to better education. Therefore, comparisons of individuals with different degrees of prenatal malnutrition that do not control for confounders such as parental education and wealth will yield only biased results.

A newer strand of the fetal-origins literature therefore moved away from individual-level comparisons. Instead, famines were used as natural experiments. This approach attempts to sidestep the biases of individual-level comparisons by comparing, on the one hand, the outcomes of entire cohorts that were in the fetal stage or infancy when a famine struck, and, on the other hand, the outcomes of the surrounding cohorts without famine exposure at crucial developmental stages. Assuming the exposed and unexposed cohorts would have had the same outcomes in the absence of the famine, the approach views famine as an exogenous shock that randomly assigns cohorts to a nutrient-deprived treatment group and a nondeprived control group.

One extensively studied event in this literature is the Chinese famine that occurred during the *Great Leap Forward* period of 1959–1961. Approximately 30 million people died in its course (Yao 1999). Studies have found, for example, that individuals who experienced the famine in utero were more likely to develop adult-onset schizophrenia (St. Clair et al. 2005) and had worse literacy, labor market status, wealth, and marriage market outcomes (Almond et al. 2007). Other famines studied include the German siege of Leningrad, which took place from 1941 to 1944 (Stanner et al. 1997; Stanner and Yudkin 2001), and the Finnish famine of 1866–1868 (Kannisto et al. 1997). According to the studies neither famine caused long-lasting negative health effects.

However, the extended length of these famines as well as their severity – the Finnish famine, for instance, killed around 8% of the Finnish population – complicates attempts to infer causality. For instance, with famines lasting multiple years, cohorts exposed in utero typically also experienced malnutrition as young children. This makes it difficult to disentangle at what stage of development undernourishment matters most. Furthermore, the length and severity of the famine likely gives rise to substantive selection in reproductive behavior and survival in the cohorts exposed at early age (Song 2009). In other words, if people experiencing unobserved factors conducive to good socioeconomic and later-life health outcomes reproduce more than others during a famine, and if the least healthy children in the early exposed cohorts die, the estimated impact of famine from cross-cohort comparisons will be biased downward.

Another famine that has received significant attention is the Dutch famine, occurring from 1944 to 1945 as the result of the Nazi blockade of the Western Netherlands. This famine is better suited to studying the effects of in utero and early childhood malnutrition because it was relatively short and mild. Studies analyzing this famine find that in utero exposure was associated with impaired nervous systems and coronary heart disease (Roseboom et al. 1999, 2000a, b, 2001), antisocial personality disorder (Neugebauer et al. 1999), and glucose resistance and obesity (Ravelli et al. 1998, 1999). Less is known about the effects of the Dutch famine on socioeconomic outcomes. However, a recent study finds not only increased

hospitalization rates in the years before retirement for people who suffered middle or late gestational exposure, but also that those exposed during the first trimester of gestation were less likely to be employed at age 53 (Scholte et al. 2015).

This chapter reviews the evidence on long-run effects of the Greek famine of 1941–1942. Like the Dutch famine, the Greek famine was relatively short and mild, reducing the likelihood that selective mortality and reproductive behavior during the famine biases impact estimates. Moreover, in Greece, educational and labor-market outcomes for individuals with early childhood exposure have been observed at various points in their adulthood, so that famine effects could be tested over almost the entire duration of working lives.

Causes and Course of the Greek Famine

In early 1941, Greece came under attack by Italian and Bulgarian troops allied with Nazi Germany, in a push of the Axis powers to assert authority over South-Eastern Europe. With support from the British Army, Greek forces were initially able to halt the invasion, but on April 30, just 24 days after German troops joined the Italian-Bulgarian invaders, Greece was forced to surrender (Hionidou 2006; Mazower 1993).

The British responded to the Axis powers' occupation of Greece with a full naval blockade, which shut down all external trade. This represented a massive shock to a country which traditionally relied on foods imports – for instance, during the late 1930s, Greece imported 45% of its wheat supply (Hionidou 2006).

Actions by the Axis powers contributed to a rapid deterioration of the nutritional situation as well. The occupying armies requisitioned large amounts of foods for their own consumption. By the end of 1941, official records showed that 4,000 tons of figs, 181,000 tons of raisins, and 10,000 tons of olive oil had been confiscated (Helger 1949; Hionidou 2006). Further, they imposed on farmers a 10% in-kind tax on all agricultural production. Restrictions on internal trade and mobility proved even more harmful than the food requisitioning. The occupiers divided Greece into 13 economic zones, between which the movement of goods and people was severely restricted. To enforce the restrictions, all fuels and transport vehicles including fishing boats, pack animals, and carts were confiscated.

In an attempt to control food prices in light of diminishing supply, the occupying forces mandated farmers to sell their products well below market rates and tightened existing rationing policies. This, however, discouraged the production and sale of foods. The shortages were amplified and prices on the emerging black markets soared. Soon, the nutritional situation of the poor population in particular deteriorated, and by fall of 1941, the shortages had turned into a full-blown famine in most of the country, affecting not only the destitute, but also large parts of the urban middle-class (Hionidou 2006). Mortality rose sharply (see Fig. 1), with disproportionate increases among the youngest and elderly, as well as for male adults who had limited access to food from charitable organizations and often forwent meals in favor of their children and wives (Helger 1949). By the end of the winter of 1941–1942, the famine had caused 100,000–200,000 deaths (Hionidou 2006).

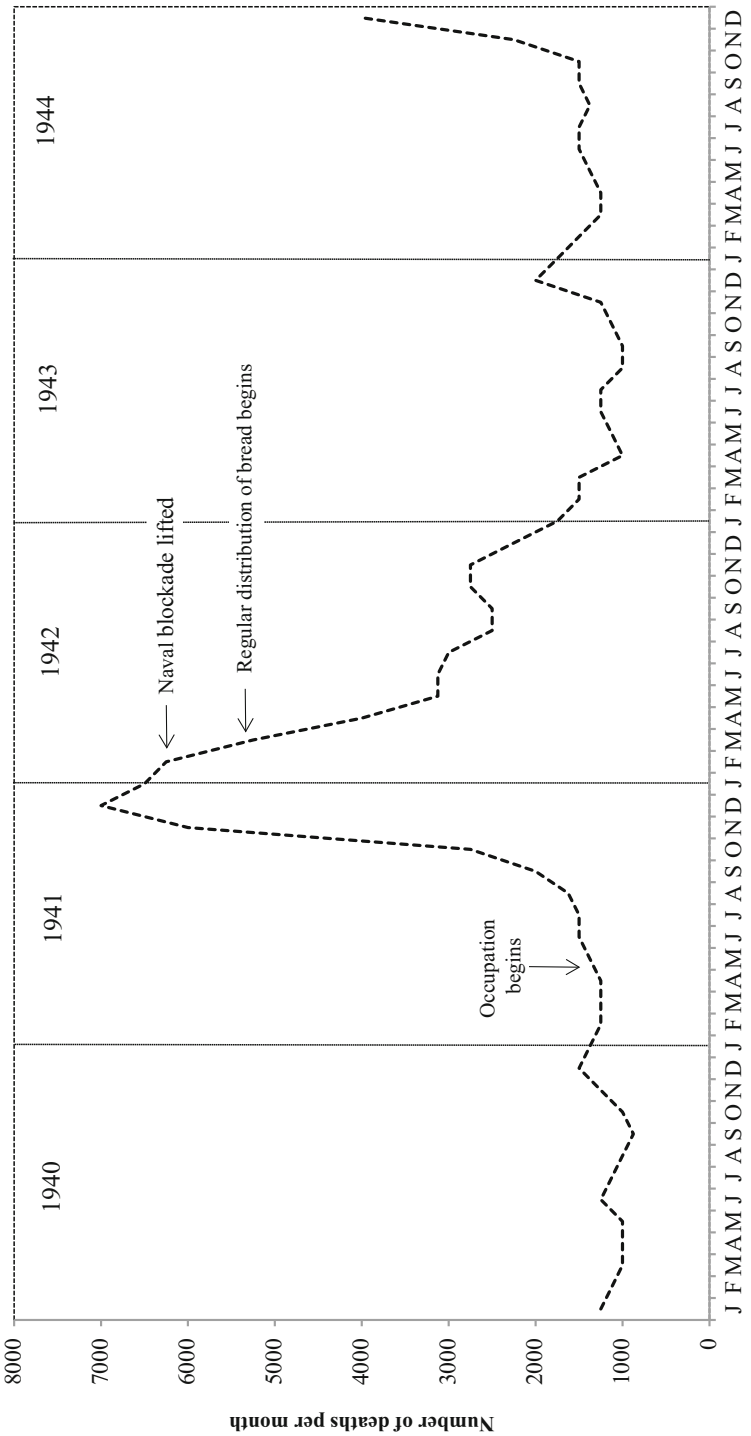

Fig. 1 **Numbers of deaths in Athens and Piraeus 1940–1944, by month**. Number of deaths in Athens and Piraeus from administrative records, showing sharp increase in mortality in the fall of 1941 shortly after the occupation began and subsequent sharp decline in the spring of 1942. Figure based on Valaoras (1946)

With large parts of the Greek population facing starvation, civil unrest increased and the occupiers grew increasingly concerned about widespread destabilization of their regime. Disagreement between Italy and Germany about who bore responsibility for food provisions for Greece, however, stalled relief efforts. The two countries eventually reached a compromise at the end of 1941, but Germany subsequently failed to meet its commitments, overstretched by attempts to control similar nutritional crises in occupied Belgium, Holland, and Norway. Ultimately, full responsibility for food provisions to Greece fell upon the Italians – a task far beyond their capacity at the time (Mazower 1993).

The Axis powers publically shifted the blame for the famine to the British naval blockade, demanding Britain to lift its blockade in order to end the suffering of the Greek population. The British initially refused. However, news of the famine leaked out of the country and media coverage received international attention. Public pressure in the Allied countries to allow international humanitarian aid to enter Greece rose. In early February 1942, the British eventually lifted the blockade and soon after, wheat shipments began. By March 1942, the Axis and Allied powers agreed to establish the Swedish-run Joint Relief Commission, which was put in charge of reorganizing food distribution in Greece. Furthermore, the Axis-power occupiers relaxed regulations on internal trade and prices, and committed to replacing agricultural products appropriated from Greek farmers with food of equal caloric value. The combined actions of the Axis and Allied powers along with the rising temperatures of spring 1942 rapidly improved food availability. By June 1942, the nutritional problems in most parts of the country had returned to acceptable levels, leading to sharp declines in mortality (Fig. 1) (Helger 1949; Hionidou 2006).

Long-Run Socioeconomic Impacts

The Greek famine's immediate effects on the health of the Greek population were devastating – beyond its estimated death toll of up to 200,000 victims, contemporary data indicate that the famine not only dramatically increased the rate of underweight children, but also led to severe, short-term growth retardation (Valaoras 1946).

Neelsen and Stratmann (2011, 2013) investigate the possibility of long-term adverse famine effects. Specifically, they examine whether exposure to the Greek famine during crucial, early life developmental periods had negative consequences on the individual's socioeconomic achievements during adulthood.

To study this question, they use data from the 1971, 1981, 1991, and 2001 decennial Greek National Population Housing Census. Their samples consist of individuals from these censuses born between 1936 and 1946 – during and shortly before and after the famine. Thus, the 1971 census sample consists of individuals aged between 25 and 36, and the 1981 census consists of individuals aged between 35 and 46, and so forth.

The medical literature suggests that the most severe long-term effects arise when malnutrition is experienced between conception and age two (Brenner and Chartow 1994; Hales 1997; Hoet and Hanson 1999; Walker et al. 2007; Victora et al. 2008).

Motivated by this literature, Neelsen and Stratmann define individuals exposed to the famine at these ages as the treatment group. The treatment group cohorts are therefore those born in 1940, 1941, and 1942, as they would have been in utero or younger than 3 years during the 1941–1942 famine. The sample cohorts without direct famine exposure – those born in 1943 or later – and those with famine exposure after the critical early life stages – individuals born in 1939 or earlier who in the majority were exposed after their second birthday – form the control group.

Neelsen and Stratmann study the effects of the Greek famine on educational attainment, and for the working subsample, job prestige. For education, impact estimates are shown for a dummy variable indicating whether an individual is literate; a dummy variable indicating whether the individual completed upper secondary school, which is the equivalent of obtaining a US high school diploma; and a variable reporting the number of years of schooling an individual has completed at the time of the census. The International Socio-Economic Index (ISEI) is used to measure job prestige (Ganzeboom and Treiman 1996; Ganzeboom et al. 1992). The ISEI ranks census occupational groups on a scale of 16–90 according to the level of education required to enter the occupation and the income associated with it. A higher rank indicates higher job prestige.

Figure 2 shows the percentage of individuals who completed upper secondary education among those born in each year from 1936 to 1946, as well as the linear trend in upper secondary school completion over this period. There is a clear upward trend in completion rates over time. However, for the 1940–1942 treatment group cohorts, completion rates are below the long-run trend, providing indication that early life exposure to the famine may indeed have harmed educational achievement.

To address potential confounders in bivariate associations of early life famine exposure and adulthood socioeconomic outcomes such as shown in Fig. 2, Neelsen and Stratmann estimate multivariate ordinary least squares regression models. Their basic specification regresses the outcome of interest on three dummy treatment variables indicating 1940, 1941, and 1942 birth cohort membership, as well as on controls for the year of birth and the year of birth squared to account for overall time-trends in outcomes, and a gender-dummy to account for outcome changes related to shifts in cohort gender composition.

The regression analysis reveals the causal effects of early life famine exposure under the assumption that the cohorts with early life famine exposure would have followed the same outcome trend as the surrounding cohorts in the absence of the famine. If the members of the famine-exposed cohort differed in unobserved physical or social endowments from other cohorts, then the estimates resulting from this regression would be biased and not capture the true causal effect of early life undernourishment. For instance, if the famine-exposed cohorts of 1940, 1941, and 1942 had better adulthood outcomes because of some form of positive selection into reproduction and survival during the famine, the estimated effects on educational attainment and job prestige would be biased downward. In this case, the impact estimates form lower bounds of any negative long-term effects of early life malnutrition.

Neelsen and Stratmann obtain the following pattern of results from their basic regression model. For the cohort born in 1940 that was in the majority exposed

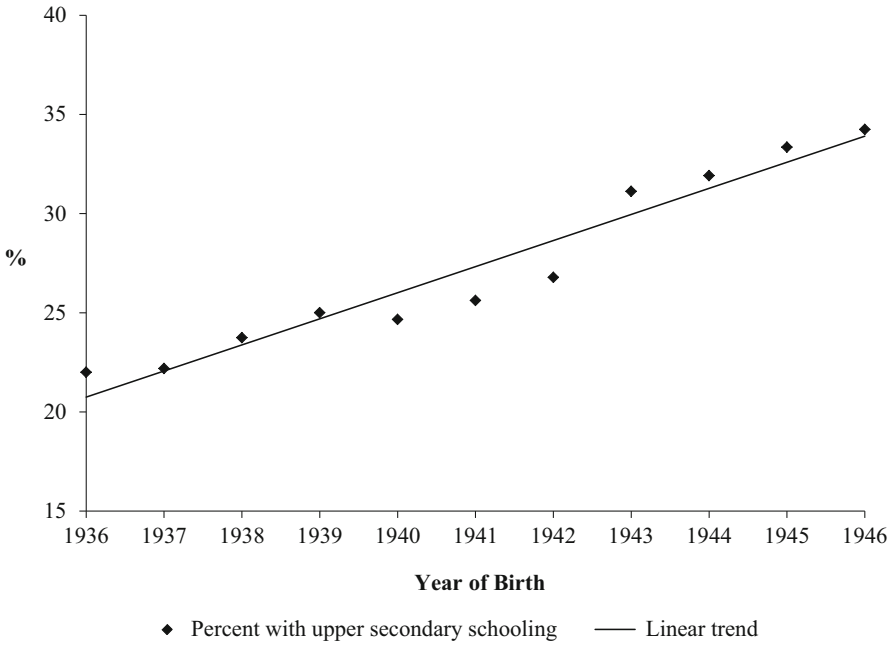

Fig. 2 Percentage of 1936–1946 Greece-born individuals in 2001 Greek census who have completed upper secondary schooling (with linear trend). Upper secondary schooling completion rates for the 1940–1942 cohorts who were exposed to the Greek famine during critical early life stages are below the overall trend

between their first and second birthday, the famine is estimated to have lowered literacy rates by about half a percentage point in the 1981 and 1991 censuses, though no reductions are found in the 1971 or 2001 census. The estimated reductions are small in relative magnitude, with mean sample literacy rates of over 95%.

Impacts are more meaningful and consistent across census waves for completion of upper secondary school and years of education. Famine effects on the 1940 cohort are negative and significant across all waves, and range between reductions of 1.3–1.8 percentage points in the probability to finish upper secondary education – large relative impacts given a sample mean completion rate of around 25% – and between 0.14–0.18 fewer years of education with a sample mean of about 7.5 years. In the 1971 and 1981 censuses, the 1940 cohort was also significantly more likely to rank lower on the ISEI job prestige score with estimated reductions of 0.5 and 0.7 points against a sample mean of about 36 points.

The group of people born in 1941, who experienced the famine during the first 12 months after birth – as infants – tend to have larger negative treatment effects than the 1940 cohort of people who were exposed at older age. With the exception of its ISEI score in the 2001 wave, the 1941 cohort experiences significant reductions across all socioeconomic outcomes. This cohort had a 0.5–1.0 percentage point reduction in literacy rates, had between a 1.8 and 2.4 percentage point less of a

chance to complete upper secondary education, had completed 0.17–0.29 fewer years of education, and had 0.5–0.8 points lower ISEI scores.

For the cohort born in 1942 that was in its majority exposed in utero, Neelsen and Stratmann do not find statistically significant reductions in literacy rates across any of the four censuses. The 1942 cohort is, however, from 2.1 to 2.6 percentage points less likely to finish upper secondary education, a similar point estimate as that for the 1941 cohort. Additionally, individuals in the 1942 cohort finished from 0.15 to 0.18 fewer years of education and scored from 0.47 to 1.1 points lower on the ISEI scale, indicating adverse effects similar in size to the effects for the 1941 cohort, which was exposed to the famine during infancy.

As discussed above, positively selective reproduction and survival among the cohorts with early life famine exposure would lead to downward bias in Neelsen and Stratmann's impact estimates. However, a factor that may cause upward bias – an overestimation of adverse effects – in their basic model estimates is that the famine was more severe in urban areas (Helger 1949; Hionidou 2006). Due to larger famine-related reductions in fertility and larger increases in early life mortality in urban areas, rural-born individuals take up a higher share of the 1940–1942 treatment group cohorts than in the surrounding control group cohorts. Thus, if rural-born individuals are less endowed with characteristics that improve their later-life socioeconomic outcomes – for instance, through having less access to higher-level education – the above results may reflect a famine-related increase in the share of those born in rural areas rather than the direct impact of early life nutrient deprivation.

Neelsen and Stratmann use birthplace information in the 2001 census to address this possible source of bias. When they add prefecture of birth dummy variables interacted with an urban birthplace indicator to their basic specification, the negative treatment effect estimates generally reduce in magnitude, and in some cases, statistical significance is lost. Among the 1940 cohort, the negative impact estimates on secondary school completion rates (see Fig. 3) and years of education diminish but remain statistically significant, and for the 1941 cohort with exposure as infants, statistical significance is maintained for all educational outcomes but not for job prestige. For the 1942 cohort the authors no longer find statistically significant famine impacts on any outcome after accounting for famine-related shifts in birthplaces. It should be noted, however, that the absence of significant negative long-term impact estimates in the in utero-exposed cohort does not amount to evidence against Barker's hypothesis. Instead, positively selective survival and, in particular, reproduction are likely greatest for this cohort that was conceived during the famine and experienced it during the earliest, most vulnerable life-stages (Hionidou 2006). With individuals with favorable socioeconomic backgrounds likely overrepresented in the in utero-exposed 1942 cohort, any downward bias in Neelsen and Stratmann's negative famine impact estimates would be larger than in the older cohorts that were exposed later in life.

To investigate if adverse long-run effects increase with the degree of early life famine exposure, Neelsen and Stratmann moreover separate the 2001 census data into subsamples of rural-born and urban-born Greeks. The split-sample analysis reveals that the significant reductions in educational attainment found for the full

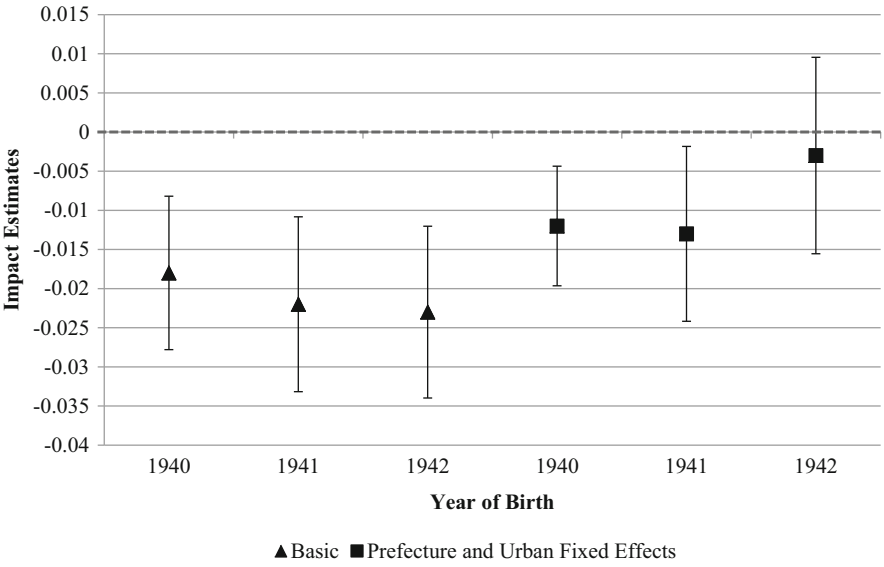

Fig. 3 Estimated impacts of early life famine exposure on upper secondary school completion and 95% confidence intervals – basic specification and specification with controls for prefecture and urban birthplace fixed effects. Graph shows famine exposure impact estimates on the probability of completing upper secondary school obtained from ordinary least squares regressions using data from Greece-born individuals in the 2001 census. The *Basic* specification includes indicators for whether an individual was born in 1940, 1941, or 1942, the year of birth and its square, and a sex indicator. The *Prefecture and Urban Fixed Effects* specification in addition includes 53 birth prefecture of birth dummies interacted with an urban birthplace indicator. Whiskers represent 95% confidence intervals based on Huber-White robust standard errors for the *Basic* specification and based on robust standard errors clustered at the prefecture of birth level for the *Prefecture and Urban Fixed Effects* specification

sample are indeed driven by those born in urban areas where the famine was most severe. For rural-born individuals, by comparison, famine impact estimates are small and largely insignificant across all three exposed cohorts.

Finally, the authors provide a falsification test by estimating famine "impacts" for the subsample of foreign-born individuals in the 2001 census who had no systematic early life famine exposure in the 1940–1942 cohorts. Reassuringly, none of the estimated coefficients significantly differs from zero.

Policies and Protocols

The Greek famine provides a good case to study the long-term effects of early life malnutrition due to its relatively short duration and relatively low mortality rate. These salient features minimize problems of endogeneity and selection bias that are more likely to be present in more severe famines, such as the Chinese famine of

1959–1961. Stratmann and Neelsen find that exposure to the Greek famine has a negative impact on educational attainment for individuals who experienced it as infants or one-year-olds. Furthermore, they find that famine exposure harms those born in urban areas more than those born in rural areas, which is consistent with the greater reported severity of the famine in the urban parts of the country. Promising policies to reduce the immediate suffering include two main aspects:

- Policies that ensure adequate nutrition for pregnant women and young children in areas affected by famine or malnutrition
- Policies that develop an institutional environment that allows for free trade and exchange

Stratmann and Neelsen's study demonstrates that the effects that famines have on young children can be severe, stretching out over a lifetime. Food aid for pregnant women and young children therefore not only has a humanitarian rationale – it is also an important means for economic development. In fact, recent papers have shown that investing in children during the earliest life stages yields the highest economic returns (Doyle et al. 2009; Currie and Rossin-Slater 2015).

Furthermore, as barriers to trade, war, and poor economic incentives were a main contributor to the Greek famine, policies that promote an institutional environment of open trade and exchange both locally and internationally can help reduce the chances of famine and famine-related problems. Economists from Adam Smith to Amartya Sen and beyond have discussed how the causes of famine are not limited to acts of god – such as weather conditions – but that famine often arises, and can be exacerbated, through trade restrictions and poor economic policy (Smith 1976; Sen 1981).

Dictionary of Terms

- **Fetal Origins Hypothesis** – A theory that proposes that events which occur during the gestational period of an individual may have lasting effects on their development and long-term wellbeing.
- **Gestational Age** – A measure of how far along a pregnancy is. Typically the end of a woman's last normal menstrual period is used to estimate the age.
- **Natural Experiment** – A natural experiment is an empirical method that claims that nature, or some other force external to the experimenter, has successfully randomly assigned individuals to different treatment groups. This allows for causal inference from observational data even though no controlled experiment has been conducted.
- **Pre-natal Nutrition** – The nutrition that a fetus receives from the mother while in utero. Insufficient nutrition during this period is hypothesized to have lasting consequences for the fetus.
- **Thrifty Phenotype** – The thrifty phenotype is a hypothesis that asserts that if a fetus' gestational stage is relatively nutrient deprived, then the fetus will develop adaptations that may result in chronic conditions later on in life. These include coronary heart disease, diabetes, and stroke.

Summary Points

- This chapter focuses on the Greek Famine of 1941–1942 and the long-term socioeconomic effects it had on individuals that were exposed to the famine during early life.
- The Greek Famine arose as a result of the combination of the occupation by the Axis powers and a naval blockade implemented by the Allied powers.
- The fetal-origins hypothesis proposes that adverse events that occur during gestation, such as significant malnutrition, may have lasting consequences for the affected individual.
- The Greek famine provides a natural experiment that allows us to study the consequences of early life exposure to undernourishment. The famine can be iewed as an exogenous shock that randomly assigns individuals into treatment groups.
- Individuals that were exposed to the Greek famine before the age of two were found to have lower levels of educational attainment and occupational status.

Aspects of Gender in Famine: Evidence from the Chinese Great Leap Forward Famine

5

Contents

Abstract

It is important to consider gender in famine studies. This chapter reviews two gender issues which affect how famine impacts women versus men. The issues discussed are female mortality advantage during famine, and son preference in intrahouse resource allocation under extreme economic constraints. Both female mortality advantage and son preference imply that female survivors would be more negatively affected by famine than male survivors. Analysis of the Chinese Great Leap Forward Famine shows a greater negative impact on disability and illiteracy for women than for men. Exploring heterogeneities in son preference

among different ethnic groups, further analysis shows the bigger negative impact on disability for women most plausibly reflects female morality advantage, whereas a decline in female education outcomes is probably better explained by the culture of son preference. The evidence that exposure to famine in utero increases the likelihood of disability and illiteracy later in life implies the importance of timely health and nutrition interventions for vulnerable pregnant women, infants, and small children. Moreover, policies aimed to help affected people during crisis shall be designed with gender in mind.

Chinese Great Leap Forward Famine · Gender · Female mortality advantage · Son preference

Introduction

Many rights advocates, governments, and international organizations aim to remove the gender-based disadvantages of girls and women. We have observed significant progress in narrowing gender gaps in some areas over the past three decades. For example, globally, more women attend university than men, and women's labor force participation has grown more rapidly than men's (World Bank 2012). Despite steady improvement in education and employment opportunities for girls and women, certain dimensions of gender inequality remain. One manifestation of persistent gender disparity is the higher mortality of girls and women – the underlying force driving the phenomenon of "missing women" (Sen 1990). Based on the assumption that females are born and die at the same rate relative to males, it is estimated that six million women are missing every year (World Bank 2011). Salient gender disparity in other dimensions, too, including earnings, asset ownership, and holding public office, illustrate the importance of considering gender in social and economic studies. Famine study is no exception.

One rather unanticipated and intriguing gender aspect of famine has drawn attention from demographers, epidemiologists, historians, sociologists, and anthropologists. The phenomenon dubbed "female mortality advantage" refers to the age-specific excess death rates for women that are lower than those for men during famines. As salient gender disparity in mortality unfavorable to women exists during normal times (World Bank 2012), one may expect that women would be *more* vulnerable during a famine, and more likely to suffer from the worst outcome of famine: death. Surprisingly, famine literature suggests the opposite is true: women seem to have a higher chance of surviving a famine. This female advantage in excess mortality has been identified in most historical and contemporary famines, including the Ukrainian Famine (Holodomor), the Great Irish Famine, Bangladeshi Famine, and the Darfur Famine (Table 1). Indeed, among the 15 historical famines examined by 22 studies published prior to 2000, Macintyre (2002) finds that women have a mortality advantage over men in nearly all cases. Researchers have proposed biological, behavioral, and social factors as the main drivers for the observed "female advantage" in famine survival. No single

Table 1 Sample of studies identifying female mortality advantage with mortality numbers

Famine	Year	Indicators	Indicator Value	References
Ukrainian Famine (Holodomor)	1932–1933	Male excess mortality (absolute number)	1,517,000	Mesle and Vallin (2012)
		Female excess mortality (absolute number)	1,065,000	
Great Irish Famine	1845–1852	Male excess mortality (absolute number)	511,000	Boyle and O Grada (1986)
		Female excess mortality (absolute number)	474,000	
Bangladeshi Famine	1974–1975	Neonatal odds ratio of infant mortality (boys/girls)	1.2	Razzaque et al. (1990)
Darfur Famine	1984–1986	Male excess mortality (mortality per 1000 people)	30.8	de Waal (1989)
		Female excess mortality (mortality per 1000 people)	26.2	
		Child excess mortality rate, aged 5–9 (mortality per 1000 people)	19.5	
Early English Famine	1622–1624	North region, male, number of burials	450	Healey (2015)
		North region, female, number of burials	416	

factor is believed to be the dominant cause for all observed female advantage, as each famine is likely to be context-specific.

Importantly, having a better chance of surviving famine does not mean that the famine consequences are less severe for women. Conditional on survival, the negative impacts of famine are often disproportionally borne by women. For example, adult women who were exposed to the Dutch famine during early gestation are more likely to be overweight, whereas the impact on men is relatively mild (Ravelli et al. 1999). Luo et al. (2006) and Yang et al. (2008) show that female survivors of the Chinese Great Leap Forward Famine (Chinese Great Famine) have a higher rate of overweight status. Mu and Zhang (2011) shows a higher incidence of disability and illiteracy among women born during the Chinese Great Famine. Some of the gender disparity in famine consequences is linked to the fact that households' coping strategies during and after famine are often unfavorable to women and girls, particularly in places where son preference is a social norm.

Therefore, to understand the gender aspects of famine, one has to consider these two somewhat opposite forces when appropriate: female advantage in excess mortality during famine and son preference in cultural norms. This chapter first presents a brief review of literature on gender difference in mortality in the context of famine and the consequences of son preference during crises. Then, it uses the Chinese Great Famine as a case study to highlight the role of son preference and female

mortality advantage in shaping the gender difference in the long-term impact of the famine. It also presents empirical strategies designed to separate out the two forces in estimations. The case study on the Chinese Great Famine is largely based on Mu and Zhang (2011).

Gender Specific Excess Mortality During Famine

Many famine studies conducted by historians and demographers have consistently identified female advantage in excess mortality in different famines, on nearly every continent, and across time. (For a comprehensive review of female mortality advantage during famine, please see Macintyre (2002).) Given that girls and women are, in general, disadvantaged economically and socially, their survival advantage during famines seems a rather surprising phenomenon. Various explanations have been proposed, but there is no consensus as to what causes male vulnerability during famines. The explanations largely fall into three categories, emphasizing respectively data issues, biological determinants, and gendered socioeconomic factors.

Data collection during famine can be challenging. There is a concern that women's deaths are often ignored and underreported (UN 1998), resulting in an inaccurately low female mortality rate. This explanation essentially dismisses the existence of female mortality advantage and regards it as an artifact of poor data quality. However, a growing body of literature focusing on physiological gender differences seems to support the biological underpinnings of female mortality advantage. For example, medical studies have shown that male fetuses are less physiologically robust than female fetuses and have more delayed lung development (Hassold et al. 1983; Jakobovits 1991). Consequently, male fetuses are at greater risk of death (Shettles 1961; Mizuno 2000). Boys are also subject to higher infant mortality (Wilson 1975; Waldron 1998). In addition, hormonal and chromosomal genetic differences may lead to females having a lower mortality risk for certain diseases. (For literature review on hormonal and chromosomal gender differences, see Zarulli et al. 2017.) Having smaller body sizes with a higher fat proportion may also improve women's survival chances. (For literature review on body fat hypothesis, see Macintyre (2002).) Another brand of literature focuses on gender differences in survival strategies and highlights the socioeconomic factors that give women an edge over men in famine survival. For example, as men are more likely to participate in famine-induced temporary migration or public works in return for aid, they are more exposed to infectious diseases and subjected to physical stress (Pitkänen 2002). When the survival of families depends mainly on women during a famine, a woman-mother has to resort to various coping strategies and life-saving practices (hiding food, etc.) to protect themselves and their families, which contributes to female mortality advantage (Kis 2013).

Gender difference in excess mortality during a famine has important implications for studying the impacts of famine. Excess mortality not only measures famine severity, it also captures famine selection effects. Given the same exposure to a famine, survivors are inherently stronger and healthier than those who died.

Compared to the general population in the absence of famine, survivors of a severe famine may or may not be less healthy moving forward. This is because through mortality selection they are inherently healthier on average than those not exposed to famine, but their average health outcomes are likely to be negatively affected by famine. If male excess mortality is higher relative to female excess mortality, then one would expect that the selection effect is stronger for males, hence the health advantage of male survivors over a nonfamine cohort is larger than the health advantage of female survivors. In other words, female advantage in excess mortality implies a health *dis*advantage of female survivors.

Gender Bias Under Severe Economic Constraints

In many outcomes, gender inequality is often driven by two forces working together: economic underdevelopment and the social norm of son preference. As argued in Jayachandran (2015), agriculture- and manufacturing-based economies reward physical strength, giving men a comparative advantage. Low levels of economic development are also associated with higher fertility and higher maternal mortality rates, which negatively affect women's welfare significantly (Jayachandran 2015; Duflo 2012). These features of underdevelopment exacerbate gender inequality and produce outcomes that are favorable for men. However, economic development itself does not guarantee more gender equality. This can be easily seen in India, China, and South Korea where sex ratio at birth remains male-skewed despite continued economic growth (Das Gupta et al. 2003). These countries hold deeply rooted cultural norms that perpetuate the view that girls and women are less desirable, which in turn reduces the incentive for parents to invest in their daughters. The key cultural element common to these countries is that their family structure is rigidly patrilineal and patrilocal (Das Gupta et al. 2003). Such a family system dictates that males are valued more than females, and that parents desire to have at least one son. Studies on immigrants from East and Southeast Asian countries in USA show that the sex ratio at higher birth orders is still skewed toward male (Almond and Edlund 2008; Abrevaya 2009). These results provide evidence that the culture-based son preference is persistent and does not disappear just because income is higher.

Son preference does not necessarily mean that daughters are discriminated against in everyday life. Actually, evidence on intrahousehold resource allocation often fails to show clear and strong gender discrimination under normal circumstances (Deaton 1997). But when household resources are severely limited by negative shocks (e.g., a sudden disaster or illness), gender bias is most salient and households tend toward unequal treatment of household members. As in a "lifeboat," tough decisions are made to guard certain members' welfare at the expense of other members. Family members who are perceived to be less productive or less worthy would receive less nourishment and medical care relative to others. These family members are typically female. Evidence of unfavorable treatment of girls and women during lean times has been found in many countries. For example, during

drought in India, mortality rate is much higher for girls than boys (Rose 1999). Indonesian families are more likely to reduce educational expenditures for girls than for boys when they experience crop loss (Cameron and Worswick 2001). The pollution caused by smoke from massive wildfires in Indonesia has a stronger effect on female mortality relative to male mortality (Jayachandran 2009). Baird et al. (2011) concludes that infant mortality in developing countries increases during recessions, and the increase is larger for female infants under 12 months. When investigating the effect of weather shocks around the time of birth on the adult outcomes of Indonesians, Maccini and Yang (2009) provides evidence that the impact of gender bias occurred during the negative shocks in early life continues to be felt decades later. This implies that the exposure to a negative shock early in life tends to entail more harmful long-term impacts on women.

Chinese Great Leap Forward Famine and the Gender Differences in Its Long-Term Effects

As the largest famine of the twentieth century, the Chinese Great Leap Forward Famine (1959–1961) caused 20–30 million excess deaths and was associated with elevated risks of miscarriage and stillbirths (Johnson 1998; Cai and Wang 2005). This section explores the long-term impacts of the Chinese Great Famine on the people born during the famine, with a focus on gender differences in the impacts.

Chinese Great Leap Forward Famine

A famine can be viewed as a tragic magnification of market and government failure (Ravallion 1997), and the Chinese Great Leap Forward Famine is no exception. Launched in 1958, the Great Leap Forward Movement aimed to catch up with or surpass Western countries in economic development. The initiative emphasized advancing heavy industries through mass mobilization. To facilitate mobilizing resources from rural areas to industrial production, farmers were organized into cooperatives. The shift to communes, implemented in 1958, eliminated household farming (Huang et al. 2008). In communes, material incentives and monetary rewards were rejected and an identical gender and age specific work-point standard was created for all members (Lin et al. 1996; Naughton 2007). The lack of incentivization resulted in low work effort and free riding across the agricultural sector (Lin 1990). Grain production in 1959 and 1960 dropped by 15% compared with the previous year and in 1961, it barely matched the 1960 level (Lin et al. 1996). While the organization of agricultural production can be blamed for lower production output, socialist-era pricing policy further discouraged efficient production – the price of staples was kept artificially low to allow the state to keep industrial wages low (Huang et al. 2008). At the same time, in the overheated ideological environment, local officials competed to inflate statistics and falsely reported higher levels of agricultural outputs. Driven by this same ideological fever and blinded by false

statistics, top leaders reduced resources available to agricultural production – particularly grain production – and increased the compulsory food delivery to the state. A severe famine broke out in 1959. In 1960, local food shortages escalated to regional shortages, creating a massive subsistence crisis nationwide (Naughton 2007). Through the end of 1961, this unprecedented famine resulted in 25–30 million excess deaths and an estimated 30 million delayed births (Peng 1987).

Researchers have traced the famine to policies adopted during the time. For example, excessive food consumption in collective dining halls (Chang and Wen 1998; Yang 1996; Yang and Su 1998), lower production incentives (Lin 1990), and preferential supplies of food to cities (Lin and Yang 2000) have been identified as contributing factors to the famine. Li and Yang (2005) concludes a possible mix of these factors, together with disastrous weather, led to the catastrophe.

With data on the cohorts affected by the Great Famine increasingly available, there has been an emerging body of studies on its long-term consequences. These studies commonly exploit the natural experiment aspect of the famine in their estimations to compare the outcomes between those who were exposed to the famine prenatally and those who were not exposed to the famine. Most of these studies are guided by the "Barker hypothesis" or "fetal origins hypothesis," which postulates that nutritional deprivations during the fetal period could lead to higher incidences of disease in adulthood (Barker 1992). It is expected that those who were exposed to the famine would have worse later-in-life outcomes than those who were not. These famine studies have identified significant negative impacts on outcomes across several domains: mental health, physical health, educational attainment, household wealth, and employment.

St. Clair et al. (2005) examines rates of adult schizophrenia among those prenatally exposed to the famine in Wuhu region of Anhui province. Their results indicate that the adjusted risk of developing schizophrenia in later life increased significantly among those born during the famine. Meng and Qian (2006) explores long-term impacts of the famine from an adult health and labor market perspective. Their empirical results show significant negative impacts on survivor height, weight, weight-for-height, educational attainment, and labor supply. The exposure to famine seems much worse for health outcomes than economic outcomes, consistent with the hypothesis that a reduced size for the famine cohort could benefit survivors and potentially offset the negative effects of famine through health channels. Similarly, Chen and Zhou (2007) indicates the prevalence of stunted growth among the cohort exposed to famine. There is also evidence showing negative impacts on agrarian per capita income. In a similar vein, Almond et al. (2007) finds higher famine intensity is associated with a greater risk of being illiterate, out of the labor force, marrying later (men), and marrying spouses with less education (women). An intriguing result in this study is that famine exposure lowered the sex ratio of both the famine cohort and their offspring, suggesting that prenatally exposed women are themselves more likely to bear daughters. The tendency toward female offspring found in Almond et al. (2007) is consistent with findings in Song (2012), a study exclusively focused on sex ratio at birth. Song (2012) identifies an abrupt decline in sex ratio at birth between April 1960 and October 1963. These findings provide evidence supporting

the Trivers–Willard hypothesis (1973), also known as the adaptive sex ratio adjustment hypothesis, which states that parents in poor conditions would skew the offspring sex ratio toward daughters, as daughters have higher reproductive success than sons under poor conditions. The Trivers–Willard hypothesis has been tested by examining the relationship between birth sex ratio and status, and the evidence is mixed; out of 54 analyses, 26 support the hypothesis (Lazarus 2002).

Recent studies also find the impact of famine on the offspring of the famine cohort. For example, Kim et al. (2014) finds a significant 5–7% reduction in second generation male and female entrance into junior secondary school. Li and An (2015) finds stunted growth occurs in children if both parents were exposed to the Great Famine. These findings uncover an extensive time horizon in famine impacts.

In terms of gender differences in famine impacts, Shi (2011) found that women exposed to the famine in the first year of life were, on average, less likely to complete high school, while their households had less housing areas and less number of rooms per capita. None of these effects were found among men. The following section, based on Mu and Zhang (2011), focuses on gender difference in famine impacts and introduces empirical strategies used to examine causes for the gender difference.

Gender Difference in the Long-Term Effect of the Chinese Great Leap Forward Famine

Decades after the famine experience, the gender composition of the cohort born during the famine still shows signs of the famine. Based on tabulations from the 2000 China Population Census, Fig. 1 plots the total living population in rural China and the male-to-female sex ratios by age. Due to excess mortality during the famine, the population size of the famine cohort (1959–1961) is significantly smaller than that of the neighboring cohorts. In addition, the sex ratio of the 1961 birth cohort is 100.3, signifying a substantial drop from 109.6 for the 1958 birth cohort and 103.9 for the 1962 cohort. Even though there is a considerable variation in sex ratios over birth cohorts, the drastic deviation of sex ratio in 1961 suggests that either male excess mortality exceeded female excess mortality in 1961 or the sex ratio at birth dropped dramatically that year, or both.

Like the above reviewed famine studies, Mu and Zhang (2011) is also guided by the "Barker hypothesis" hypothesizing that, compared to cohorts not born during the famine, the famine cohort exhibits worse health outcomes and consequently worse education outcomes. The famine cohort is defined as those born during the 1959–1961 period. The cohort born right after the famine (1963–1965) is chosen as the control group. The 1962 birth cohort is not included in the control group because some members were conceived during famine, and there is no way to correctly separate them into the treatment or control group.

The main dataset used in the analysis is the 1% sample of the 1990 China Population Census, which contains information about individual disability status, education, ethnicity, age, and rural or urban residential location. The urban

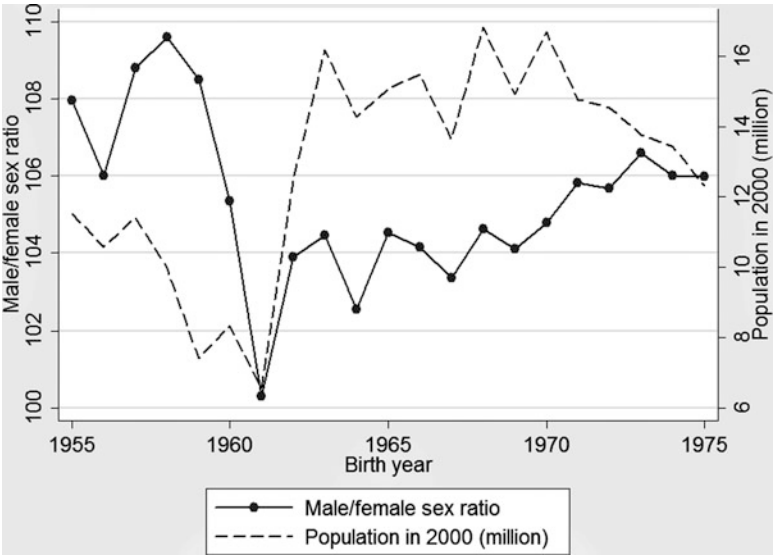

Fig. 1 Male-to-female sex ratio and population in rural China. (Data Source: 2000 China population census) (Note: The famine cohort was born between 1959 and 1961) (Source: Mu and Zhang 2011)

Table 2 Summary statistics of outcome variables

	Women		Men		Gender Difference	
	1959–1961	1963–1965	1959–1961	1963–1965	1959–1961	1963–1965
Disability rate (‰)	2.493	2.197	3.52	3.569	−1.027	−1.372
Illiteracy rate (%)	20.004	12.945	4.777	3.341	15.227	9.604
Observations	125,167	273,608	132,669	284,425		

Data Source: 2000 China population census
Source: Mu and Zhang (2011)

population is excluded from the analysis since the famine was much less severe in urban areas, and they did not suffer from as much excess mortality as the rural population (Lin and Yang 2000; Song 2009). Table 2 presents the gender-specific mean disability rate and illiteracy rate for the famine cohort and the control group. Women have a lower disability rate in both groups. The female disability rate relative to that of males is 0.10% points lower for the famine cohort, while this difference is 0.13 for the control group. Women in both groups also have a higher illiteracy rate. For the famine cohort, women are 15% more likely to be illiterate than men. The gender gap is 9.6% for the control group. These descriptive statistics suggest that, compared to the control group, women in the famine cohort may be worse off in both health and education outcomes.

Table 3 Gender difference in famine impact

	Disability Rate			Illiteracy Rate		
	Female (1)	Male (2)	(1)–(2)	Female (1)	Male (2)	(1)–(2)
Famine cohort	−0.092	−2.765[b]	2.673[a]	1.932[c]	0.345	1.587[b]
	(0.944)	(1.074)	(1.382)	(0.614)	(0.330)	(0.697)
Number of Obs	398,775	417,094	815,869	398,775	417,094	815,869

Note: The robust standard errors (corrected for serial correlation within county and arbitrary heteroskedasticity) are in parentheses. [a]Significant at 10%; [b]Significant at 5%; and [c]Significant at 1%. The famine cohort is a dummy variable coded as 1 for the age cohort of 1959–1961 and as 0 for cohorts born during 1963–1965. Other variables included in the regressions but not reported are age, polynomials of age, a dummy variable for gender-neutral ethnic groups, and county fixed effects
Source: Mu and Zhang (2011)

The regression analysis reported in Table 3, controlling for age, age polynomials, ethnicity, and county-fixed effects, further confirms that the gender difference reported in Table 2 is statistically significant. Regarding the disability rate, the impact of famine on women is not significant, whereas it is negative and significant for males. The insignificant coefficient for females implies that, conditional on survival, the female cohort is no worse than the cohort born right after the famine. The negative coefficient for males shows that the famine survivors are healthier than the control cohort. The estimated gender difference in the famine impact is 2.673. This means that, compared to the control group, women born during the famine are 2.673% more likely to be disabled than their male counterparts. Given that the gender difference in the disability rate for the nonfamine cohort is −1.372‰ (Table 2), a coefficient of 2.673 indicates that famine leads to a huge reversal of the gender gap in disability rate.

With respect to education, the coefficient for the famine cohort is 1.932 and statistically significant for the female survivors, while it is 0.345 and statistically insignificant for the males. These estimates show that the female famine survivors have higher illiteracy rates than the control group, and the male survivors also fare worse in education, although the effect is not significant. The gender difference is pronounced and statistically significant, and the exposure to famine increases the gender gap in illiteracy rate by 1.587%.

In summary, the impacts of the Chinese Great Famine on disability and illiteracy are bigger for women born during the famine than men of the same cohort.

Two Hypotheses Explaining the Gender Differences: Mortality Selection and Son Preference

The above analysis shows that the famine has impacted women more negatively. This gender difference in famine effects could be caused by two forces: mortality selection during the famine and son-preference culture. Due to mortality selection, the observed sample of survivors is likely to be the healthier portion of the total population exposed to the shock. In the case of the Great Famine, Song (2009) finds

Table 4 Heterogeneity of gender difference in famine impact

	Disability Rate			Illiteracy Rate		
	Female (1)	Male(2)	(1)–(2)	Female (1)	Male(2)	(1)–(2)
Famine cohort (α_1)	−0.139	−2.764[b]	2.625[a]	1.852[c]	0.189	1.662[b]
	(0.945)	(1.079)	(1.371)	(0.612)	(0.325)	(0.698)
Famine cohort × gender-neutral ethnic groups (α_2)	3.747[b]	0.267	3.480	0.212	2.916[b]	−2.704

Observations	396,768	414,973	811,741	396,768	414,973	811,741

Notes: The robust standard errors (corrected for serial correlation within county and arbitrary heteroskedasticity) are in parentheses. [a]Significant at 10%; [b]Significant at 5%; and [c]Significant at 1%. Gender neutral ethnicity is defined as the sex ratio at birth in 2000 for the second child, and is less than 107. Other variables included in the regressions but not reported are age, polynomials of age, a dummy variable for gender-neutral ethnic groups, and county fixed effects are included
Source: Mu and Zhang (2011)

that the postnatal mortality rate among the famine cohort was lower than that among the pre- and postfamine cohorts, suggesting a strong famine-induced mortality selection. With males having higher excess mortality, as documented by literature reviewed in section "Gender Specific Excess Mortality during Famine," the mortality selection hypothesis predicts that for the cohort exposed to famine early in life, adult men may have better health outcomes than women, when compared to the cohort not exposed to famine. At the same time, the culture of son preference that persisted in many parts of China may improve the average welfare of the surviving boys relative to that of the girls, likely resulting in better outcomes for men.

Consistent with the empirical results presented in section "Gender Difference in the Long-term Effect of the Chinese Great Leap Forward Famine," both the mortality selection effect and the son preference effect predict that women would be more negatively affected by famine. Further investigation is needed in order to understand how the two effects shape gender difference in famine impacts. For this purpose, Mu and Zhang (2011) explores heterogeneities in son-preference culture across different ethnic groups in China. Some ethnic groups do not exhibit the same degree of son preference as others (Chen and Chen 2004; Zhang 2006). If son preference causes gender difference in the famine impacts, one would expect little gender difference among the ethnic groups without son preference. However, if the mortality selection effect were the main force underlying the gender difference, we would expect female survivors to fare worse, regardless of their ethnic identities.

The level of son preference is measured using the sex ratio of second births (Zeng et al. 1993; Das Gupta 2005). Given the evidence that the culture of son preference is persistent over time (Almond and Edlund 2008), the sex ratio of second births calculated from the more recent census (2000) could reasonably measure the culture of son preference at the time of famine. To assure reliability in the

measurement of the sex ratio, the 19 ethnic groups (out of 56) whose population is larger than one million are included in the analysis. An ethnic group is defined as being "gender neutral" if the sex ratio of the second births is less than 106, and "gender biased" if it is over 106. By this definition, four ethnic minorities (Uygur, Tibetan, Dai, and Bai) are identified as being gender neutral.

Table 4 presents results on heterogeneity of the gender difference in the famine impacts by gender. In the regression framework, the summation of the coefficient on "famine cohort" and the interaction term between "gender neutral" and "famine cohort" gives the famine impact for the gender neutral group, and the coefficient on the famine cohort itself is the famine effect on the gender biased group. For disability rate, the results show that in both ethnic groups, men exposed to famine have lower disability rates. For the ethnic group with son preference, the estimated gender difference is statistically significant. For the gender neutral ethnic group, the F-statistics shows that the gender difference is significant as well. Given that son preference does not apply to the gender neutral group, these results imply that son-preference culture is not the driving force for the observed gender difference, and very likely mortality selection underlies the gender difference in the famine impact on disability (Table 3).

With respect to the education outcome, the results show that men in gender neutral ethnic groups are more negatively affected by famine than men in the ethnic group with son preference. The gender difference is only significant in the group with son-preference culture but not in the gender neutral group. The results imply that son preference is likely to be the major cause for the observed gender difference in the famine impact on education.

Overall, there is strong evidence that exposure to famine in utero increases the likelihood of disability and illiteracy for women born during the famine, relative to men of the same cohort. Both female mortality advantage and son-preference culture can explain this gender difference but for different outcomes. Female mortality advantage explains the gender difference in health outcome, suggesting that female survivors adapted to a hunger environment early in life would suffer from more adverse health later in life. Whereas son preference leads to gender difference in the impact of famine on education outcomes: females of the famine cohort have a higher illiteracy rate than their male counterparts.

Policies and Protocols

To identify the long-term impact of nutrition deprivation in early life, a shock – such as a famine, pandemic, or disastrous weather – that occurs during the early life of an individual can be used as a natural experiment. With this approach, this review on studies of famine, and the Chinese Great Famine in particular, confirms the existence of such long-term impact and provides evidence on the importance of early childhood nutrition. The policy implication of this finding is clear: timely health and nutrition interventions for pregnant women, infants, and small children vulnerable to nutrition deprivation are both important and smart.

During famine, boys are likely to be favored over girls in household resource allocation. This son-preference culture, prevalent in many countries, has led to more negative famine impact on the education outcomes for Chinese women born during famine. Hence, policies aimed to help affected people during crises should be designed with gender in mind. Programs, such as conditional cash transfer programs, that can potentially change household behavior should be considered.

Lastly, understanding famine requires a gender perspective and also requires contributions from different disciplines, including anthropology, epidemiology, demography, economics, history, medicine, and sociology. Together with other chapters in this book, this chapter shows that famine study must be interdisciplinary.

Dictionary of Terms

- **Great Leap Forward Famine** – The Great Leap Forward Campaign was an economic and social movement launched in 1958 by the Chinese Communist Party. The goal was to catch up with or even surpass the Western countries in economic development through rapid industrialization and collectivization. In 1959, a severe famine broke out and through the end of 1961, the unprecedented famine caused about 25–30 million excess deaths and another roughly 30 million delayed births. Researchers have traced the famine to various policies adopted during the Campaign and the famine is thus known as the Great Leap Forward Famine.
- **Sex ratios** – Conventionally reported as the number of males per 100 females, sex ratios summarizes the gender composition of a population. A higher sex ratio is more male biased and a lower sex ratio is more female biased. Sex ratios for human populations average 105–106.
- **Excess mortality** – It is a measure of the deaths, due to a negative circumstance, which occurs over and above what the regular death rate would predict.

Summery Points

- Many famine studies have consistently identified female advantage in excess mortality in different famines, on nearly every continent, and across time.
- Evidence of unfavorable treatment of girls and women during lean times has been found in many countries.
- To understand the gender aspects of famine, one has to consider these two somewhat opposite forces when appropriate: female advantage in excess mortality during famine and son preference in cultural norms.
- Researchers have traced the Chinese Great Famine to various factors related to policies adopted during the time.
- Studies on the Chinese Great Famine have identified significant negative impacts on outcomes across several domains, particularly in mental health, physical health, educational attainment, household wealth, and employment in adulthood.

- The impacts of the Chinese Great Famine on disability and illiteracy are higher for women born during the famine than for men of the same cohort.
- Female mortality advantage explains the gender difference in health outcome, whereas son preference leads to gender difference in the impact of famine on the education outcome.
- Timely health and nutrition interventions for pregnant women, infants, and small children vulnerable to nutrition deprivation are both important and smart.
- Policies aimed to help affected people during crises should be designed with gender in mind.
- Understanding famine requires a gender perspective and also requires contributions from studies from different disciplines.

Understanding Famine in Ethiopia: Bio-physical and Socio-economic Drivers

6

Fatemeh Taheri and Hossein Azadi

Contents

Abstract

The aim of this review study is to examine the persistence of famine in Ethiopia in the framework of sustainability which includes both bio-physical and socio-economic drivers. On one hand, the authors argue that famine occurrences are linked to drought, climatic change, and change in agricultural land use that have increased the vulnerability of Ethiopian households to hunger over time and reduced the inflexibility to environmental and economic shocks. On the other hand, the authors argue that the cause of Ethiopia's recurrent famine is not only

natural interference, but it is also the reaction of society and governments that create a famine. Food security for Ethiopia requires an integrated long-term response to household vulnerability on the part of Ethiopian governments, civil society, and international partners by incorporating new technologies, local expertise, and active involvement of Ethiopian communities living with the realities of recurrent famine. Accordingly, the paper outlines a conceptual framework and concludes that famine cannot be explained exclusively in terms of resource shortage and politics is no less important. The framework creates a useful tool for policy makers to analyze the famine prevention approaches.

Introduction

Ethiopia has a long history of recurring and devastating famine. On the surface, it appears that erratic weather conditions have repeatedly triggered large-scale hunger and starvation. In recent years, famine has unfortunately become Ethiopia's trademark and even now, despite changes in regimes, the threat of famine continues. In 1973, during the Imperial regime, almost three million Ethiopians were affected by food shortages and total excess mortality in the country hovered at around 250,000. A decade later, during the "Marxist-Leninist" Derg regime, approximately 7.8 million Ethiopians were caught struggling for survival, out of which excess mortality was conservatively estimated at 700,000 (Vadala 2009). And in the year 2000, amidst the "free-market" orientation of the EPRDF (Ethiopian People's Revolutionary Democratic Front) regime, 8 million people required food aid, out of which excess mortality was estimated to be over 6000 in one district alone (Howe and Devereux 2007). Three years later, the number of Ethiopians requiring food aid rose to 14 million. For Ethiopia, 2016 was a challenging year as it faced with the worst El Niño impact in the last 50 years. The beginning of El Niño combined with failed Belg (spring harvest) and Meher (main harvest) rainfall in 2015 and resulted in need of emergency food and nutrition assistance for 10.2 million people. At the same time, Ethiopia was dealing with both residual needs from the 2015/2016 El

Niño-induced drought and new drought in lowland pastoralist areas due to below average 2016 autumn rains in the southern and southeastern parts of the country, as well as in pocket areas across the country. As a result, 5.6 million people in Ethiopia require emergency food assistance in 2017. In addition, 2.7 million children and pregnant and lactating mothers require supplementary feeding, 9.2 million people need support to access safe drinking water, 1.9 million households need livestock support, and 300,000 children between 6 and 59 months old are targeted for the treatment of severe acute malnutrition in 2017. Nutrition reports by Emergency Nutrition Coordination Unit indicate worsening nutrition situation in Ethiopia in future (FSNWG 2017).

Webb and von Braun (1994), in their discussion of famine in Ethiopia, define famine as "a catastrophic disruption of society as manifested in a cumulative failure of production, distribution and consumption systems" (p. 35). The principal consequences of famine are a concentrated decline of food consumption resulting in chronic weight losses for individuals and sharp increases in excess mortality, massive social disruption, and long-term resource depletion. Although famine has long been considered a discrete event triggered by external causes and amenable to technical solutions, researchers, and scholars have recently challenged this view, arguing that famine must be understood as a long-term socioeconomic process that accelerates destitution of a society's most vulnerable groups to the point where their livelihood systems become untenable (Baro and Deubel 2006).

Many experts relate Ethiopia's cyclical famine with the country's dependence on rainfed smallholder agriculture, drought, rapid population growth, or agricultural market dysfunctions (Vadala 2009; FSNWG 2017). Although these factors do have significant role in the matter, they tend to hide the critical cause of hunger in the country – lack of rights and accountable government. To fully understand the vulnerability of the Ethiopia population to famine, we need to understand the concurrent impact of bio-physical and socio-economic drivers. Hence, there is a clear need for research considering both bio-physical and socio-economic drivers of famine in Ethiopia. Drawing on sustainability framework, this chapter reviews drivers of famine in Ethiopia which include both bio-physical and socio-economic drivers.

Drivers of Ethiopia's Famine

Bio-Physical Interference

Famine mainly resulted from natural disasters. Natural disasters lead to reduction in food production for a particular duration and with no doubt droughts have created severe food deficiencies in the case of Ethiopia, (Vadala 2009). According to the June Food Security and Nutrition Working Group (FSNWG), food security remains a concern in north-eastern parts of Ethiopia previously hit by drought (FSNWG 2017). According to the World Bank (2015), the whole Ethiopian economy is dependent on rainfall and data on rainfall variation and GDP growth from 1982 to

2000 illustrate that there is a positive correlation between the two. Thus, natural disasters have obvious negative impacts on food production and even on the economic performance of the country. The causes for the famine can be attributed to a variety of interrelated and complex factors. The main causes include climatic change and change in land use (Shegro 2016).

Climatic Change

Climate change is widely recognized as one of the prime challenges facing Africa, and the continent is often cited as the hardest hit by potential transformations (Boko et al. 2007). Sub-Saharan Africa has been identified as one of the main parts of the world most expected to suffer from climate change due to high reliance on its agricultural sector, the main sources of people's livelihoods (Niang et al. 2014) and accounting for approximately 96% of overall crop production (World Bank 2015; Serdeczny et al. 2016). The impact varies from country to country causing substantial welfare losses and countless suffering. In East Africa, for instance, changes in rainfall patterns are expected to reduce crop yield by at least 10–20% by 2050 (Kotir 2011; Thornton et al. 2011) and will drop by 20–50% in West Africa by 2050 (Sarr 2012). Climate models suggest that Ethiopia will see further warming in all seasons between 0.7 °C and 2.3 °C by the 2020s and of between 1.4 °C and 2.9 °C by the 2050s. As a result, under moderate global warming cereal production in Ethiopia expected to decline by 10–12% (MOA 2011).

IPCC reports that rising temperature and changing precipitation patterns will likely lead to an acute decline in rain fed crop production (IPCC 2007). Temperature and precipitation alterations will also affect hydrological cycle and water availability. The groundwater levels of aquifers have also been affected by climate change due to recharge variations. Whereas the exact effects are still unknown, it is quite clear that Ethiopia will need to make far-reaching adaptations in its farming systems to accommodate changed rainfall patterns and cropping seasons by planting new crops and crop varieties and adopting new farming practices. The narrow range of agricultural products determines Ethiopian's vulnerability and Ethiopia has major heavy dependency on agricultural products to support its economies, which often fail due to pest outbreaks, climate variation, and changes in prices. Further food insecurity for rural people has increased due to climate change, inappropriate land use, or land tenure policies (Harnevik et al. 2007).

Change in Agricultural Land Use

Ethiopia's principal natural resource is its rich endowment of agricultural land. Agriculture which constitutes 46 percent of GDP directly supports about 85% of the population in terms of employment and livelihood. It contributes about 50% of the country's gross domestic product (GDP), generates about 88% of the export earnings, and supplies around 73% of the raw material requirement of agro-based domestic industries. It can be considered as the main source of food for the population and then the leading contributing sector to food security. In addition, the country's overall socio-economic development is expected to speed up by agriculture sector which plays a key role in generating surplus capital (Finnish Foreign Ministry 2009).

In the contemporary era of ecological change and global land rush, the politically contested nature of land control and land access among rural dwellers has become even more difficult a challenge across many developing countries. In the context of Ethiopia, most livelihoods are fundamentally grounded in the agricultural sector (Shegro 2016). The growth of the agricultural sector greatly determines the economic growth of the country. However, the sector is dominated by subsistence rain-fed farming systems and trapped by numerous challenges. These challenges include shrinking farm sizes, high farmland fragmentation, high population pressure, land tenure insecurity, farmland scarcity, erratic rainfall, environmental degradation, low farm income, and productivity (Nega et al. 2003; Tolossa 2005). These issues have been assumed to constrain the process of agrarian change and differentiation in rural areas. Although land remains at the center of rural livelihoods, these problems have particularly resulted in declining levels of access to this key resource by the poor, thereby affecting food security and livelihoods of most households in many rural areas (Shegro 2016). It is also plausible to decline access to land resources among the rural poor while increase access to the same resource by other actors including the state, state-owned enterprises or private corporate actors. In a new era of global land rush and climate change, the challenges of poor rural people are likely to intensify further. Many studies in rural Ethiopia (e.g., Carswell 2002; Devereux 2009; Tolossa 2005) indicate important changes in the composition and sources of rural incomes propelled by these factors.

Socio-Economic Intervention

Famine affects only certain countries while nature's forces and climatic conditions can affect any country. Drought may result in famine in many sub-Saharan countries including Ethiopia while with the same intensity in Australia causes no famine at all. It has become clear in recent years that nature's forces and climatic conditions like drought cannot solely be responsible for famine causation as was the dominant mode of thinking five decades ago. There are more events which lead to famine than just drought or other adverse climatic events (Vadala 2009). As a result, theories of famine have shifted from an emphasis on environmental causes to economic and sociopolitical causes (Baro and Deubel 2006). This section addresses the major causes and explanations of famine in Ethiopia within such a framework.

Economic Development

Out of the top ten fastest growing economies in the world since 2011 seven are African. With an average annual real GDP growth rate of 8.1%, Ethiopia ranks seven (The Economist 2011). Ethiopia's development has been articulated with the ultimate goal to become a middle income country by 2025. In order to achieve this goal, strategic sectors such as agriculture and energy will require transformation, as both sectors will have to accommodate a great demographic intensification (see Table 1) (UNESCO 2017).

Table 1 Projecting Ethiopian Demographics from 2012 to 2050 (Adapted from UNESCO 2017)

	Year		
Demographic Indicators	2012	2032	2050
Population (millions)	83.7	133.5	171.8
Employed (percentage of population)	56	61	68
Dependent population (percentage of population)	44	39	32

An old-aged (i.e., a decade) base of strong agricultural growth conclude a Ethiopia's Growth and Transformation Plan (GTP) and the forthcoming Growth and Transformation Plan II (GTP II) in order to produce a wide range of inputs (including improved seeds, fertilizer, mechanization, land), energy use (hydropower), irrigation as well as maintenance and land repossessions goals. For example, Ethiopia intends to increase cultivable land by 13%; therefore, the conversion of grazing and/or forest lands into crop lands is required in this policy. Also, it has been planned to increase irrigated land by more than 400% over the same period. Finally, in order to achieve significant productivity increases in agricultural output (30% increase in crop productivity of various crops), fertilizer use is expected to increase by approximately 100% (Ministry of Finance and Economic Development (MoFED) 2010). In addition to these traditional economic objectives of growth, GTP also outlines a National Resource Conservation Plan that seeks, among other things, to rehabilitate land and increase forest cover. These conservation targets are further detailed in Ethiopia's Climate Resilient Green Economy Strategy (CRGE) which seeks to achieve economic development in a sustainable way (Federal Democratic Republic of Ethiopia 2012).

All these transformative changes, in combination with population growth and changing consumption patterns, create an increasing demand for natural resources and ecosystem services. Along with climate change, additional pressures manifested in resource degradation result in many millions of people continue to lack basic human (food, energy, and water) securities (Karlberg et al. 2015).

Land Tenure System

According to the Constitution of the Federal Democratic Republic of Ethiopia (GOE 1997), the right of land ownership and other natural resources of the country are exclusively granted to the State and the peoples of Ethiopia. This implies that all subsidiary laws and regulations of the country which could be issued either by the Federal or Regional State bodies recognize usufructuary rights to land which can be in the form of state, communal or group, and private holdings. Private ownership of land is prohibited although the right to use and inherit land is possible (Teklemariam et al. 2017). Insecure land tenure or the lack of land ownership also restricts the farmers' access to the credits that are required for improved land practices. This lack of access to credits forces them to go for traditional land-use practices, despite their willingness to change. Thus, national policies affect the land-use systems by influencing institutional arrangements such as credit and marketing facilities, and infrastructure development.

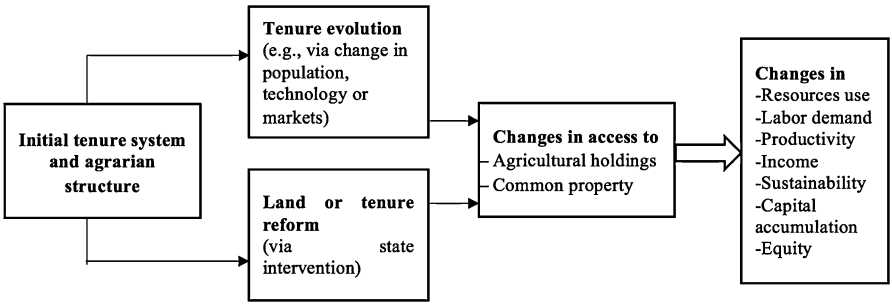

Fig. 1 Conventional characterizations of tenure's impact on agricultural production. (Adapted from Finnish Foreign Ministry 2009)

In brief, the land reforms are concentrated on food security, greater equity, productivity, better conservation practices from changes in tenure. Thiesenhusen et al. (2017) noted the following outcomes from land tenure reform: (i) food security, (ii) reduction in social polarity, (iii) increased investment, (iv) transparent production incentives, (v) poverty reduction, (vi) increased employment, and (vii) greater equity. The relationship between land tenure (either through legal changes or through institutional reforms) and agricultural productivity is depicted in Fig. 1 (Finnish Foreign Ministry 2009).

Food Availability Decline/Inappropriate Land Use

Early work on famine was heavily influenced by Malthus who proposed that famine followed excessive population growth and served to keep carrying capacity in check by reducing populations to a level consistent with food production (Baro and Deubel 2006). In his work, which dates back to 1798, Malthus entertained the notion that population growth has to be balanced with food production; failure to do so would force nature to take measures into its own hands by wiping off the "excess." There have been several critics on his work; the fact that nowadays the world is over-producing food at a time when there are almost seven times more people than the 1 billion Malthusian "limit" could be cited as an example. Malthus' analysis may have several inconsistencies, but the central theme is not so erroneous; there is indeed a limit as to the carrying capacity of the earth, though no one knows for sure how much is "full house." In the case of Ethiopia, the more relevant issue in this connection is the carrying capacity of land for agricultural purposes to a population that grows at a yearly rate of 2.3 per cent. It will be imprudent to ignore the problem of decreasing land-size holdings for agricultural purposes in the country, not least, because around 85 percent of the population is engaged in subsistence agriculture (Vadala 2009).

If people shift from agriculture to other sectors of the economy for their livelihood, then population pressure on agricultural land can be part of the explanation of famine in Ethiopia. Two thirds of households farm are on less than 0.5 hectare, a size which is known to be insufficient to support a family, at the same time high

population growth is increasingly putting a pressure on land (Ziegler 2005). Coupled with droughts and other unfavorable weather conditions, increasing population pressure on land is a challenge to famine prevention in Ethiopia.

Food Accessibility Decline

In the last two or three decades, there has been a revolution in thinking about the explanations of famines. The entitlement's approach by Amartya Sen brought the issue of food accessibility to the forefront of the academic debate on famine. Sen noted that there is often enough food available in the country during famines but all people do not have the means to access it. More specifically, famines are explained by entitlement failures, which in turn can be understood in terms of endowments, production possibilities, and exchange conditions among others (Sen 1981).

Ethiopia is a good case in point where, for instance, food was moving out of Wollo when the people in the region were affected by the 1972–1973 famine (Sen 1981), and even today some regions in Ethiopia produce surplus, while people in other regions face famine threats. There are of course infrastructural problems in the country to link the surplus producing regions to the food-deficit ones. However, the question goes beyond this simplistic level, as some people simply do not have enough entitlements to have a share of the food available in the country, a situation which can be described as a case of direct entitlement failures (Tully 2003). Or else, peasants do not find the right price for their surplus, as in the 2002 Bumper Harvest which ended up in an 80 per cent price drop, illustrated a failure in peasants' exchange entitlements. Alternatively, the most irrigated land of the country in the Awash River basin, for instance, is used primarily for cash crop production to be exported to the western world (even when there is drought) leading the vulnerability of various pastoralist groups to turn into famine or underpinned by what is known as a crisis in endowments and production possibilities.

In short, while drought and population pressure can partly explain famine threats in Ethiopia, the entitlements approach provides an explanation from an important but less visible angle. The approach points to the direction of policy failures by shifting the attention from the absence of food to lack of financial access to food. The point that only some classes in society are affected by famine clearly indicates that policy failures are central to the understanding of famine. In the next section, the success or failure of famine prevention policies and practices will be measured against internationally recognized standards, and one such standard is the right to food (Vadala 2009).

The Right to Food

The following agreements of many international accords concerning the right to food and the numerous countries who have agreed with this right have possibly created a worldwide right to food. The right to food has become internationally established due to the creation of international human rights treaties and international conventions worldwide. By agreeing to such covenants, signatories agree to live up to the covenants' purpose and procedures, which suggests that such states accept the proposition that a right to food is a basic human right that every person ought to have (Tenente 2007).

The UDHR (Universal Declaration of Human Rights) presents the right to food in article 25, which outlines the idea that everyone has the right to a standard of living adequate for the health and well-being of himself and of his family, including food. The UDHR later served as the foundation to the ICESCR (The International Covenant on Economic Social and Cultural Rights) to which Ethiopia became a state party in 1993. The covenant is legally binding on all state parties including Ethiopia. Article 11(2) of the ICESCR elaborated on the right to food. The States Parties to the present Covenant, recognizing the fundamental right of everyone to be free from hunger, including specific programs, are as follows (Vadala 2009):

(a) Improvements in methods of production, preservation, and distribution of food through full use of technical and scientific knowledge. It is achievable by spreading principles of nutrition knowledge and/or by promoting or reforming agrarian systems in such a way as to gain the most efficient development and utilization of natural resources;
(b) The problems of both food-importing and food-exporting countries must be considered to ensure an equitable distribution of world food supplies in relation to need.

This being said, the FDRE (Federal Democratic Republic of Ethiopia) Constitution is one of only 20 constitutions in the world which makes reference to food (FAO). Article 90 of the Constitution, under the banner of social objectives, states that "to the extent the country's resources permit, policies shall aim to provide all Ethiopians with access to public health education, and clean water, housing, food and social insurance." Constitutionally, food is regarded as a social objective rather than a human right; nevertheless, this is not to say that Ethiopia is not bound by the right to food. Ethiopia has been a party to the ICESCR since 1993 and has made no reservations to any articles when ratifying the covenant; hence, it is legally bound by it.

To date, there has been no court case where the right to food has been a subject of contention in Ethiopia; reference in courts to the international human rights conventions in general is "very minimal at best, nil at worst" (Rakeb 2002). To make matters more complicated, most rural citizens resort to religious, customary, or social courts at the Kebele level where the notion of human rights is unheard. There is thus a need to take all appropriate measures to make the right to food, and particularly the freedom from hunger, justiciable in the Ethiopian legal system starting from the local courts. Effective human rights in education should also be provided for beneficiaries to claim rights; unless people are aware that they have these human rights, it will be very difficult to raise the issue of freedom from hunger in Ethiopia. Defining food as a right is very important in order to prevent famine in Ethiopia, not least because the country has repeatedly been facing famines throughout the past four decades. Additionally, in order to be free from hunger ensuring direct food entitlements and legal guarantees is not enough, but agricultural development policies and land tenure systems must be ensured equally as well (Vadala 2009).

The Political Setting

In recent years, there have been attempts to determine if there is a link between the political system of a country and famine prevention, and if such a link exists, which political system can best protect the people from famine. Sen (1999: 178) asserts that "there has never been a famine in a functioning multiparty democracy," indeed, for him, it is not at all difficult to prevent famines; in addition to economic rights like the right to food, civil and political rights are of utmost importance. More and more scholars agree that recent famines, also known as new famines, are political because they are almost always preventable (Howe and Devereux 2007). In an attempt to further refine and complement Sen's theory, de Waal (2000) came up with the notion of an antifamine political contract with the objective of preventing famines. Antifamine political contracts are necessary as well as democracy, according to de Waal assumption. Such contracts aim to further politicize famine by presenting an incentive for governments to meet their responsibilities. Ineffective government action and even inaction can cause a heavy political cost through politicizing famine.

Such a political contract attempts to explain why some socio-economic rights are important enough to require a political guarantee. In fact "famine is so self-evident and so visible that it readily offers itself as a political cause" (Sen 1999). The antifamine political contract ensures a long-term solution to the problem by making the prevention of famine and starvation a priority in the governments' agenda. In the absence of civil and political rights, the government is not forced to put the fight against famine and starvation as a priority (Devereux 2000). We cannot make sure that liberal civil and political rights assist in freedom from famine unless famine is politicized (de Waal 2000). Furthermore, such political contracts could work only in democracies. Famine in this sense ceases to be the result of natural disaster or a challenge to charity and becomes a political issue. Such a political contract makes famine and starvation an electoral question (de Waal 2000). The free election of a government depends, among other things, on its agenda, and its re-election on the fulfillment of that agenda; famine therefore must appear as one government agenda in a political contract. This is instrumental in getting the attention of any government facing famine threats, and where there is free and fair election, the political contract is different from the notion of food as a right in the sense that it provides a clear incentive for a government.

Ethiopia has repeatedly been mentioned in the discussion on democracy and famine prevention. The previous regimes of Emperor Haile Selassie and the Derg serve as good examples where, respectively, the 1973–1974 and 1984 famines inter alia occurred in the absence of democracy. At present, not many people (not even the government itself) dare to assert that Ethiopia is a full-fledged democracy. In 1995 and 2000, elections were not very competitive; opposition parties that participated were weak, and election practices were not uniformly free and fair over the whole country (Pausewang et al. 2002). The last elections in 2005 were much more competitive but ended with controversial results and, among others, the main CUD opposition party leaders, most of whom were elected, found themselves behind bars. The European Union Election Observation Mission (2005) stated that overall "the elections fell short of international principles for genuine democratic elections."

Famine is still a threat in Ethiopia in part because of the lack of a functional multiparty democracy. Where opposition political parties, civil society organizations, and independent media cannot operate freely, there is no certainty that the government will put famine prevention as a priority. Democracy, according to Sen, is the one element that all famines lack; in other words, the presence of nondemocratic government is the common denominator in all famines. In Ethiopia, the issue of famine has already been politicized to some extent. The 1974 famine, for example, came at a heavy political cost for the Imperial government. However, where a full-fledged democracy is lacking, the effective politicization of famine and starvation is by no means evident (Vadala 2009).

Conclusion

Indicating the main reason or identifying one single factor which can explain the occurrence of famine in Ethiopia is very difficult. In conclusion, an important paradigm shift is underway in the field of famine and food security studies. Famine is now explained less in terms of an anomalous disaster event and more commonly as a process rooted in long term social, economic, and political inequalities. The conceptual framework (Fig. 2) emphasizes interlink ages among and between bio-physical and socio-economic intervention and famine and the need for coordination and integrated management and governance across sectors. Based on the figure, it can be argued that famine has its roots in the notion of access to resources

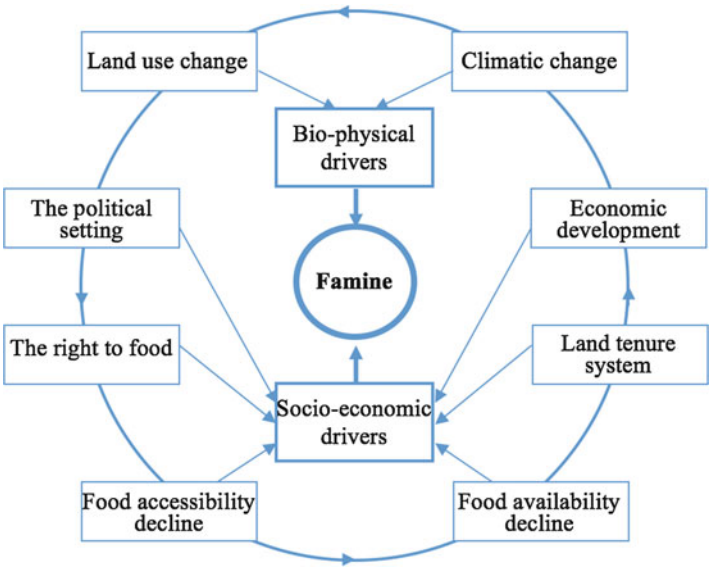

Fig. 2 Bio-physical and socio-economic drivers of famine in Ethiopia

(especially the distribution and productivity of land) and vulnerability of livelihoods to shocks (especially climate change). Therefore, the production and reproduction of rural poverty in the country cannot be de-linked from land. Climate change has also an impact on Ethiopian agriculture and especially increasing temperature is damaging. Many regions have been severely affected by climate changes in Ethiopia. Therefore, it is essential to have a policy implication worth thinking about and planning before damage occurs. Ethiopian government must design and employ adaptation policies that counteract the harmful impacts of climate change. There are numerous adaptation options such as investment in technologies, irrigation, drought tolerant, and early maturing crop varieties, promoting institutional set-ups working in research, and educating farmers and supporting ownership of livestock, as owning livestock may secure them against the effects of crop failure or low yields during harsh climatic conditions (Hassan and Nhemachena 2008).

According to the figure, nature's forces like climatic conditions and change in agricultural land use cannot solely be responsible for famine causation, but the figure also considers socio-economic drivers including economic development, land tenure system, food availability decline, food accessibility decline, the right to food, and the political setting. Economic development creates an increasing demand for natural resources and ecosystem services. The application of technologies for agricultural and natural resource management is affected by land tenure and property rights. Sufficient incentives to the farmers are provided by secured property rights which increase their efficiencies in terms of productivity and ensure environmental sustainability. The decline of food availability and accessibility caused by population pressure is the major determinant of famine in Ethiopia. There may be enough food at the national level, but still entitlement failures in some regions can cause famine. It is natural that without secured property rights farmers do not feel emotional attachment to the land they cultivate, do not invest in land development, and will not use inputs efficiently. Defining food as a right is very important in order to prevent famine in Ethiopia, not least because the country has repeatedly been facing famines throughout the past four decades. Finally, the fulfillment of the right to food also requires the respect of civil and political rights.

In developing countries where famine is a threat, a functional multiparty democracy tends to ensure that famines do not occur. Here again, democracy by itself is not sufficient; but it will render governments accountable by imposing a heavy political cost to failed famine prevention policies. Politics is therefore one major determinant in the famine equation. This approach can better provide a famine prevention strategy, and it can also shape our understanding of famine – that famine is not only the result of natural or economic problems, but that it is the result of political problems as well. In view of the fact that Ethiopia is presently not a full-fledged democracy, addressing famine requires more than just applying technical or economic fixes to a partly political problem. The protection of human rights could be considered as an antifamine political contract as well as helping in the fight against famine. In order to have a permanent solution, it is important to address the problem is an antifamine political contract, the outcome of which would inevitably depend on the strength and commitment of all contracting parties.

Policies and Protocols

- Development seems to be achievable only through damaging the environment. It is essentially required to have a new approach to resolve improvements in human securities and aspirations for better lives, with sustainable management of natural resources and ecosystems.
- The land belongs to the government is recognized as the general problem related to land policy in Ethiopia. The farmer can work on a land as long as he/she stays on the farm and neither can sell nor lease land legally. Thus, exiting tenure security is vital to have a successful agricultural development in Ethiopia, where about 85% of the population lives in rural areas.
- Future food security for Ethiopia depends on good governance, sound economic growth policies, and active preparedness. If the underlying issues of political accountability and economic disparity are adequately addressed in the context of Ethiopian governance and civil society by international humanitarian interventions and local development planning, the persistence of hunger will continue to plague most Ethiopian nations well into the twenty-first century.
- More research on the household-level impacts of famine and contextual knowledge in crisis situations is necessary to understand better the nature, scale, and history of crises and the evolution of different aspects of food security as conditions change during crises.

Dictionary of Terms

- **Bio-physical drivers** – Bio-physical drivers of famine comprise a wide range of natural disasters including climatic change and change in agricultural land use.
- **Socio-economic drivers** – Socio-economic drivers of famine comprise a wide range of economic and sociopolitical causes including economic development, land tenure system, food availability, and food accessibility decline.
- **Marxist-Leninist** – The Ethiopian Marxist–Leninist Revolutionary Organization, commonly known by its Amharic acronyms Malered or Emelared, was a communist organization in Ethiopia active from 1974 to the late 1970s.
- **El Niño** – is an irregularly occurring and complex series of climatic changes affecting the equatorial Pacific region and beyond every few years, characterized by the appearance of unusually warm, nutrient-poor water off northern Peru and Ecuador, typically in late December.
- **Kebele** – Local administrative unit, comprising about 100,000 people, was introduced during the military ("derg") regime.

Summary Points

- Famine occurrences are linked to drought, climatic change, and change in agricultural land use that have increased the vulnerability of Ethiopian households to hunger over time and reduced the inflexibility to environmental and economic shocks.

- The cause of Ethiopia's recurrent famine is not only natural interference, but it is also the reaction of society and governments that create a famine.
- Famines and food shortages in Ethiopia are linked to persistent vulnerabilities, which are often the result of bio-physical and socio-economic processes that limit the options and opportunities of households.
- Famine has its roots in the notion of having access to resources especially the distribution and productivity of land and vulnerability of livelihoods to shocks especially climate change.
- Economic development, land tenure system, food availability decline, food accessibility decline, the right to food, and the political setting are the major socio-economic determinants of famine in Ethiopia.

Abstract

This chapter discusses the role of malnutrition in children under the age of 5 growing up in India. Malnutrition is an ongoing public health challenge in children around the world and specifically within this subcontinent. Malnutrition includes both undernutrition and obesity. Some common forms of undernutrition include stunting, wasting, and micronutrient deficiencies. In an effort to help address undernutrition, several studies have examined various contributing factors. Some of the challenges in addressing undernutrition have been: regional differences in the burden and determinants, rapid urbanization, and the social and economic status of families/individuals. In addition, the consequences of ongoing undernutrition in Indian children are severe. Some of the risks associated with undernutrition include: mortality, morbidity, impaired growth and development, and reduced economic productivity. Thus, addressing the biological and social risk factors contributing to poor nutrition in children under age 5 in India is a critical imperative for achieving optimal health and development of its growing population.

Keywords

Nutrition · Malnutrition · Child nutrition · India · Stunting · Wasting · Micronutrients · Mortality · Morbidity · Risk · Growth · Development · Economic · Inequality

List of Abbreviations

AHS	Annual health survey
LBW	Low birth weight
MDG	Millennium Development Goals
NCD	Noncommunicable disease
NFHS	National Family Health Survey
WHO	World Health Organization

Definitions of Words and Terms

1. Stunting: Being at a length/height below that of one's age group (minus two standard deviations from the median length for age of reference based on the WHO Child Growth Standards median).
2. Wasting: Not meeting weight expectations based on height (minus two standard deviations from the median height of reference population based on the WHO Child Growth Standards median).
3. Underweight: Not meeting weight expectations based on age. Moderate and severe underweight is being below minus two standard deviations from the median weight for age of reference population. Severe underweight is being below minus three standard deviations from median weight for age of reference population.
4. Micronutrient: A substance or chemical needed in small amounts to meet the growth and development needs of an individual.
5. Low birth weight: Being at a weight below 2,500 g or 5.5 pounds at birth.

Global Overview of Malnutrition Epidemiology, Determinants, and Consequences

Epidemiology and the Burden of Malnutrition

Malnutrition, which includes undernutrition and obesity, is one of the most widespread challenges experienced by children and adolescents worldwide (Black et al. 2013). Almost half of the deaths occurring among children under 5 years of age can be attributed to undernutrition (Ahmed et al. 2012; Black et al. 2013; UNICEF 2015). Two of the most commonly recognized forms of undernutrition are stunting (chronic, intergenerational undernutrition) and wasting (acute undernutrition). Micronutrient deficiencies are the third major form of undernutrition and are themselves a major contributor to malnutrition and possibly stunting among children. Inadequate vitamin and mineral intake can lead to deficiencies and increased susceptibility to disease. In effect, micronutrient deficiencies may also be associated with impaired fetal development, subsequent stunting, and other forms of undernutrition. Not meeting the nutrient needs of children is an indicator of the health of the population and future populations (Black et al. 2008, 2013; Ahmed et al. 2012). Unlike the prevalence of undernutrition, which has steadily decreased over the past two decades, albeit at an exceedingly slow rate, overnutrition is a rapidly growing epidemic that affects high-, middle-, and low-income countries. Therefore, many low-and-middle income countries are beginning to experience a double burden of malnutrition (Black et al. 2008, 2013; Ahmed et al. 2012; UNICEF 2015).

Stunting and other forms of undernutrition can reduce a child's chance of survival, increase the risk of infection, and hinder optimal health and growth. Stunting is also associated with suboptimal brain development, which can have long-lasting harmful consequences on a child's cognitive ability, school performance, future earning potential, and, consequently, the economic productivity of a nation (Black and Dewey 2014; IIPS 2017; John et al. 2017). Stunting in children under the age of 5 is estimated to affect as many as 178 million children worldwide. A group of 36 countries account for 90% of these cases, which is approximately 160 million children (Black et al. 2008). As of 2011, India alone accounts for 38% of stunted children under the age of 5 worldwide (UNICEF 2015).

Acute forms of undernutrition, such as moderate or severe wasting, afflict over 52 million children under-5 globally (Black et al. 2013). The prevalence of wasting in South Asia is also among the highest and is estimated to be 16%, which is one in six children. In fact, India also has the highest burden of wasting globally with approximately 25 million children wasted (UNICEF 2015).

Undernutrition and micronutrient deficiencies potentially account for 3.1 million deaths per year (Black et al. 2013). Some common micronutrient deficiencies present in low- and middle-income countries include: vitamin A, iron, iodine, zinc, and folic acid. Vitamin A deficiency in preschool-aged children is as high as 1 in 3 globally (UNICEF 2015). Subclinical vitamin A deficiency affects 90 million children under-5 worldwide, and 5–17 million children have night blindness due to this deficiency (WHO estimates (1995–2005)) (Black et al. 2013). The prevalence was found to be highest within Africa and Southeast Asia (Black et al. 2013;

IIPS 2017). Anemia due to inadequate oral intake of iron can also impede growth and development in children. Global estimates from 2011 for iron deficiency anemia due to inadequate iron consumption were as high as 18.1% for children under 5 years (Black et al. 2013). In India, The National Family Health Survey 2005–2006 indicated that 69.4% of Indian children 6–59 months were anemic and the most recent NFHS-4 data shows that 58.4% of children are currently anemic (IIPS 2017). However, the prevalence of iodine deficiency has decreased widely through the implementation of fortified salt in diets from 2003 to 2011. Although zinc deficiency is estimated to affect 17% of the population worldwide, only limited data is available for children in many regions. The prevalence of zinc deficiency is believed to be highest among children in Asia and Africa (Black et al. 2013).

Fetal growth and nutritional status at birth is an important contributor to childhood malnutrition. Globally, the incidence of low birth weight (LBW) in infants was estimated to be 15%, which means approximately 20 million children are born small (UNICEF 2015). Currently, the World Health Assembly has set out to decrease the frequency of LBW to below 30% between 2010 and 2025. India alone makes up a third of the global burden with recent estimates indicating 28% of children are born small (UNICEF 2015, 2016). Alongside suboptimal weight at birth, inadequate weight gain in children can increase the risk of infection and mortality. Worldwide estimates from 2011 indicate that as many as 101 million children were underweight. The highest prevalence of underweight children was in South-Central Asia (30%) (Black et al. 2013). Data collected in the NFHS-4 indicates that 35.7% of children in India were underweight between 2015 and 2016 (IIPS 2017). Decreasing the prevalence of underweight children was a part of Millennium Development Goal (MDG) 1 on reducing poverty. Worldwide, only 30 countries met this indicator. However, progress could be blurred by the higher prevalence of overweight children and sustained presence of stunting in children growing up in these regions within the past two decades (UNICEF 2015). The burden of overweight children under the age of 5 has grown from 28 to 42 million between 1990 and 2011. This proportion in 2011 was estimated to be 69% in low- and middle-income countries alone. Of these children, seven million are believed to be from East Asia (UNICEF 2015).

India, the Epicenter of Child Malnutrition

Historical Trends and Present Scenario

Efforts to track maternal and child health in India have focused on gathering data on the following: fertility, mortality, family planning, maternal and child health, as well as policy instruments to address countrywide nutrition and health care. Subnational data on these public health concerns have been collected using the following surveys: National Family Health Survey (NFHS), the District Level Household Survey (DLHS), and the Annual Health Survey (AHS). Specifically, NFHS provides data on national and subnational trends in child malnutrition within India in addition to a range of additional information. This ongoing national cross-sectional survey

allows us to examine the high prevalence of child malnutrition since 1992 and has had four rounds (1992–1993 (NFHS-1), 1998–1999 (NFHS-2), 2005–2006 (NFHS-3), and 2015–2016 (NFHS-4) (IIPS 1995, 2000, 2007, 2017; Pathak and Singh 2011). Data collected by NFHS includes, but is not limited to, information on state and national level estimates for nutrition, health, and healthcare (Pathak and Singh 2011). NFHS surveys indicate that the overall prevalence of malnutrition in Indian children under-5 has declined during the first two rounds of the survey, has remained stagnant during the third round, and has further declined between 2006 and 2016 (NFHS-4) (Singh et al. 2011; IIPS 2017). Three important nutritional indices that affect children's susceptibility to disease and survival are exemplified in the graph below (Fig. 1).

The data from 1992 to 2016 shows that there has been a steady decrease in stunting (58–38.4%) (IIPS 2000, 2007, 2017). Some factors that may have contributed to this decline include rapid economic growth, provision of national primary health care, and implementation of preventative nutrition programs such as Integrated Child Development Services Scheme and the National Rural Health Mission (Pathak and Singh 2011). Data on wasting for the first two rounds was not available for NFHS-1 and was only collected on children under the age of 3 years for NFHS-2 (IIPS 2000). However, NFHS-1 indicates that one in six children in India were wasted at the time of the survey (1992–1993) (IIPS 1995). Moreover, NFHS-2 indicates that approximately 16% of children under the age of 3 were wasted (IIPS 2000). In addition, during the last two rounds of NFHS, wasting has increased (19.8–21.0%) suggesting that wasting has been a persistent problem for children under-5 within this subcontinent over the past few decades (IIPS 2007, 2017). Underweight status in Indian children under-5 showed the greatest decline between NHFS-3 and NFHS-4 (IIPS 2007, 2017). Significant declines also occurred in the

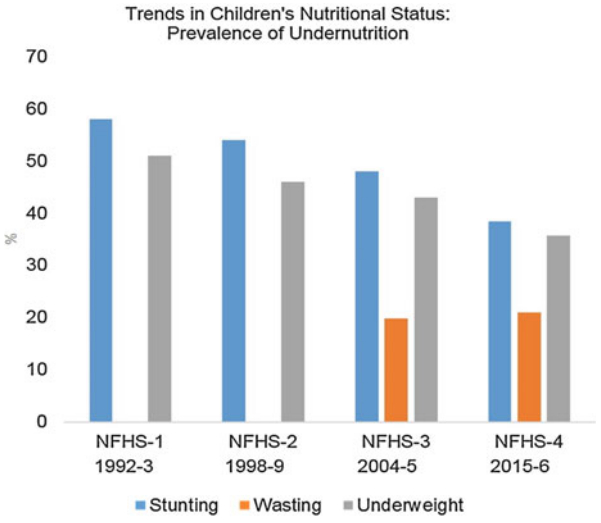

Fig. 1 Prevalence of undernutrition. Data from NFHS for percentage of children under the age of 5 who are malnourished in India from 1992 to 2016. Key: NFHS=National Family Health Survey (please note that NFHS 1 and 2 had focused on children under 3 and 4 years of age, respectively and hence the trends may not be exactly comparable)

first two rounds of the NFHS, which has often been attributed to the rapid economic growth in the 1990s (Kumar et al. 2015).

Regional differences in child malnutrition are evident from 1992 to 1998 and from 1998 to 2006. During 1992–1993, 50–60% of children in central, eastern, and western regions of India were found to be malnourished (Pathak and Singh 2011). Small declines in the prevalence of malnutrition were noted from 1992 to 1998 within different regions. In this timeframe, declines in child malnutrition were observed in most of the southern, northern, eastern, and northeastern states. During 1998–2006, several states within the western, central, eastern, and northern portions of India made significant progress towards reducing the burden of underweight children from 50–59% to 40–49%. These findings are significant as national averages from this timeframe did not depict any of these major shifts in child malnutrition (Pathak and Singh 2011). For example, certain parts of India such as the central and eastern regions have had minimal reductions in child malnutrition since 1992–2006 (IIPS 2007; Pathak and Singh 2011). Between 2006 and 2016, states progressed in remarkably different ways in stunting reduction. Analyses of publicly available summary data from the NFHS-4 (Menon et al. 2017) indicate that most states in India progressed faster than the national average, which is affected strongly by larger states with high prevalence, large under-5 populations, and slow progress. Notable progress in stunting reduction was seen in states such as Chhattisgarh, Arunachal Pradesh, and Gujarat; the limited progress in populous states like Uttar Pradesh and Bihar contributes to India's overall burden (Fig. 2).

An important opportunity offered by the NFHS-4 survey is the ability to examine the spatial distribution of malnutrition by district and not just by state. The NFHS-4 focus on district representativeness now allows national- and state-level attention to the districts that contribute the most to the high burden of malnutrition. It is notable, however, that the districts that face a high stunting burden are not the same as districts that face high wasting burdens.

Rapid urbanization in India over the past few decades is likely to pose a challenge to addressing nutritional status in children. Factors such as poor living conditions, income constraints, and higher costs of food are likely to be significant risks looking forward. The prevalence of stunting, wasting, and underweight status has mostly declined from 1992 to 2016 for urban children in India but this is not necessarily seen in their rural counterparts. Data from NFHS indicates a decline in the prevalence of stunting in children in urban areas from 40% to 36% to 31% in the first three rounds of this survey (Kumar et al. 2015). In NFHS-4, the prevalence of stunting remained at 31% indicating almost no change in stunting in urban children from 2005 to 2016 (IIPS 2017). By comparison, stunting in rural areas from 2005 to 2006 showed a greater decline (IIPS 2007). The prevalence of underweight children in urban India declined from 44%, 38%, and 37% to 29.1%, while declines in rural areas were comparatively lower (Kumar et al. 2015; IIPS 2017). In addition, current statistics from the NFHS-4 indicate that the percentage of underweight children is higher in rural areas (38.3%) than urban areas (29.1%) (IIPS 2017). Wasting had declined from 18% to 13% in the first two rounds of NFHS before increasing to 17% in the third round and 20% in the fourth (Kumar et al. 2015;

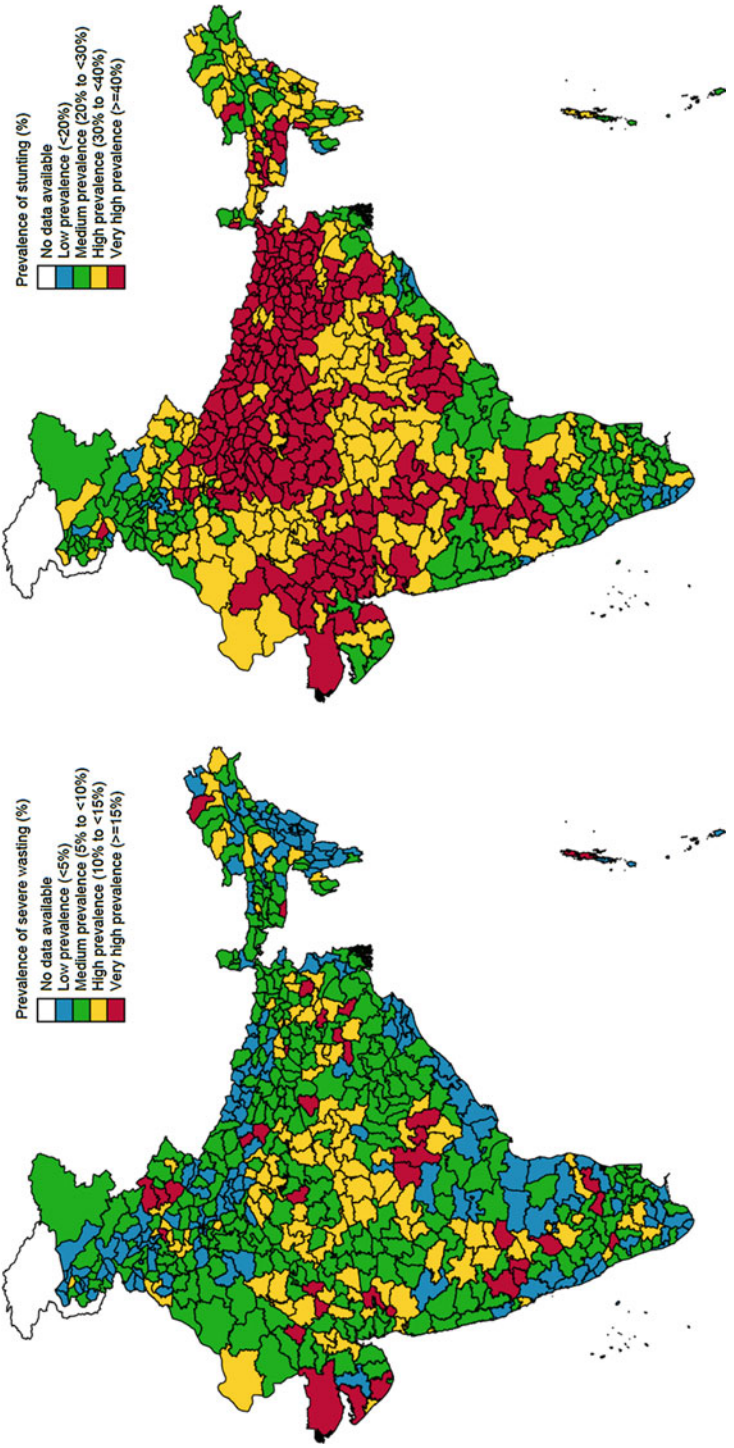

Fig. 2 **Subnational patterns of wasting and stunting for India** (Menon et al. 2017)

IIPS 2017). These increases may be attributed to population migration and urban slums (IIPS 2007, 2017). Similarly, there are trend data on linear growth and stunting from the baseline and final surveys of National Nutrition Monitoring Bureau from 1975–1979 ($N = 6043$) to 2012–2013 ($N = 11{,}910$) on anthropometry from birth to 18 years from seven states in households of rural India (Mamidi et al. 2016). The increments in height of 18+ were highest for both boys (7.4 cm) and girls (4.8 cm) in the state of Kerala followed by Tamil Nadu (boys, 7.3 cm and girls, 3.8 cm). Under-5 stunting rate reduced from 82% in the baseline survey to 45.7% in the final survey at 1.35% per year in the pooled states and was similar in both boys and girls. The recovery in stunting was highest in Tamil Nadu (1.63% per year) followed by Kerala (1.46% per year) (Mamidi et al. 2016).

Determinants of Malnutrition in India

The determinants of malnutrition among children range from immediate determinants like poor child feeding and childhood illness to underlying determinants such as the health, economic and educational status of women, the economic status of households, and sanitation and food environments (Black et al. 2013). In India, these determinants play out in different ways across the country. In recent years, several studies based on the NFHS and other data sets from India have focused on identifying the major determinants of poor nutrition. Studies have focused on the role of infant and young child feeding, especially complementary feeding (Menon et al. 2014), on sanitation (Hammer and Spears 2016), on gender and women's roles (Bose 2011; Coffey et al. 2017), and on the role of income and growth (Subramanian et al. 2016). Over two decades ago, Ramalingaswami and colleagues had identified the important role that female empowerment had played in determining high rates of low birth weight in India (Ramalingaswami et al. 1996). These associations of malnutrition with women's living conditions and empowerment have been underscored in a range of studies from various settings in India (Sethuraman et al. 2006; Ghosh-Jerath et al. 2013; Kshatriya and Acharya 2016), and the impact of various grass root nutrition education interventions at impacting outcomes has also been shown to affect women's empowerment and participation (Kadiyala et al. 2016).

The data from NFHS-4 suggest an uneven spread of these determinants across the country, as well as uneven change in several determinants over time and by geography (Menon et al. 2017). Among the determinants of most concern are complementary feeding, and issues surrounding the status and health of women (early marriage, poor women's nutrition, uneven and inadequate access to antenatal care during pregnancy), and sanitation. Indeed, there is now an increasing understanding (also articulated in India's new nutrition strategy) that action on malnutrition must address these multiple determinants in a localized fashion – district-by-district and state-by-state (NITI Aayog 2017).

Poor complementary feeding has been recognized as an important correlate of undernutrition in India. Patel et al. (2012) reviewed data on 15,028 last-born children aged 6–23 months from the National Family Health Survey 2005–2006.

They examined inappropriate complementary feeding indicators against a set of child, parental, household, health service, and community-level characteristics. The prevalence of timely introduction of complementary feeding among infants aged 6–8 months was 55%. Among children aged 6–23 months, minimum dietary diversity rate was 15.2%, minimum meal frequency was 41.5%, and minimum acceptable diet was 9.2%. Children in northern and western geographical regions of India had higher odds for inappropriate complementary feeding indicators than in other geographical regions. Richest households were less likely to delay introduction of complementary foods than other households. Other determinants of not meeting minimum dietary diversity and minimum acceptable diet were: no maternal education, lower maternal body mass index (BMI) (<18.5 kg/m(2)), lower wealth index, less frequent (<7) antenatal clinic visits, lack of postnatal visits, and poor exposure to media (Patel et al. 2012).

Economic status of households is a major determinant of children's nutritional status as indicated by differences between wealth quintiles in NFHS surveys over the last few decades where the rate of malnutrition has been shown to be higher among the poorest quintiles (Pathak and Singh 2011; Kumar et al. 2015). Although the national prevalence of child malnutrition has declined from 1992 to 2006, inequality has grown and children from the poorest wealth quintile do not seem to have fared as well as their counterparts in wealthier quintiles. Child malnutrition in the poorest wealth quintile has declined by an average of 6% compared to an average 27% reduction among the wealthier quintiles – a gap that indicates widening economic inequality with respect to child malnutrition. In addition, the poor-rich ratio increased from 1992 to 1998 (1:8 to 2:4) and remained at 2:4 ratio from 1998 to 2006. These wide ratios indicate that there is a significant income gap and infer that food security inequalities remain in India (Pathak and Singh 2011).

Consequences of Malnutrition

Undernutrition impacts children's survival, susceptibility to disease, physical and cognitive development, as well as the country's economic productivity. Although, the prevalence of undernutrition has decreased over the past decade, it remains a persistent problem in India. The impact of undernutrition can be divided into short- and long-term consequences. In the short-term, children are at increased risk for mortality, morbidity, and disability. In the long-term, children do not develop to their full potential. Thus, they may become stunted, have impaired cognition, and women may have increased risk for poor pregnancy outcomes. Poor cognitive development can lead to poor school performance, less schooling, and reduced economic productivity and earning potential. Additionally, these children are at increased risk of becoming overweight and developing noncommunicable diseases (NCDs), such as hypertension and cardiovascular disease (UNICEF 2015). Thus, it is important to address the nutrient needs of children within the first 1,000 days of life as many of these risk factors can be potentially irreversible (Black et al. 2013; UNICEF 2015).

In the context of India, the relationship of early childhood and adolescent nutrition with long-term outcomes and the risks of NCDs has been underscored in several settings with gradual equalization between urban and rural populations (Tripathy et al. 2016). These risks have been specifically underscored among poor adolescents in South India (Panuganti et al. 2017) and have also been the subject of food policy analysis for reducing the double burden of malnutrition (Thow et al. 2016).

Mortality

Under-5 mortality in children worldwide was 6.9 million in 2011. One-third of these deaths were related to undernutrition (Bhutta and Salam 2012). Almost half of these deaths were found in India, Pakistan, China, Nigeria, and the Democratic Republic of Congo. Most of these deaths were preventable. In 2015, over 5.9 million children died before their fifth birthday. The majority of these deaths occurred within Sub-Saharan Africa and South Asia (Liu et al. 2016). The most current national statistics from India (NFHS-4) estimates that the rate of mortality for children under the age of 5 to be as high as 50% (IIPS 2017).

The most common causes of mortality among children growing up in India are: pneumonia, preterm birth complications, diarrhea, intrapartum-related complications, and malaria. Targeting the main causes of under-5 mortality includes treating disease states and taking measures to promote healthy pregnancies in expectant mothers. Addressing the underlying risk factors of mortality such as undernutrition is key to helping reduce mortality rates in children under-5 in India (Caulfield et al. 2004).

Morbidity

Children who are stunted, underweight, or wasted have impaired immunity and are at increased risk for infectious diseases including measles, pneumonia, meningitis, and malaria (Black et al. 2008). Infection, in turn, further aggravates undernutrition – a cycle that increases the likelihood of mortality for a child (Ramachandran and Gopalan 2009; Ahmed et al. 2012). Immune system impairment is particularly problematic when an undernourished child suffers from repeated infections and is unable to meet their nutrient needs as repeated exposure can have a negative impact on a child's ability to meet their growth needs for their age or even regain a normal growth pattern at a later stage. Persistent exposure to infection can even lead to death (Ahmed et al. 2012). In addition, many infections such as measles or helminthic infection increase a body's demand for proteins and calories (Black et al. 2008; Ahmed et al. 2012). The increased macronutrient demand only further impairs growth and development in malnourished children as well as their susceptibility to other infections.

In particular, malnourished children are at increased risk for developing diarrhea which can further affect the nutritional status of a child. Persistent diarrhea can damage the lining of the small intestines and negatively impact absorption and

utilization of nutrients needed for healthy development and growth in undernourished children. As this process persists, the infected child becomes increasingly malnourished and increasingly susceptible to other diseases as even deficiencies in micronutrients such as, iron, vitamin A, zinc, and iodine can have serious consequences. Iron is needed for hemoglobin synthesis, oxygen delivery to tissues, brain and motor development, and protection against infections like malaria (IIPS 2007; Ahmed et al. 2012; John et al. 2017). A diet low in vitamin A can increase susceptibility to infection, cause preventable diseases, such as measles and diarrheal diseases, and slow one's ability to heal from illness (IIPS 2007; Ahmed et al. 2012; Black et al. 2013). Severe deficiency in vitamin A can also lead to permanent eye damage. Iodine deficiency can impair psychomotor development, speech, and hearing. It also decreases the amount of energy available to developing children and can cause goiter and mental retardation, both of which are preventable (IIPS 2007; Ahmed et al. 2012; John et al. 2017). Other micronutrient deficiencies such as zinc can lead to increased risk of diarrhea, pneumonia, malaria, dermatitis, retarded growth, mental disturbance, delayed sexual maturation, and recurrent infections (Ahmed et al. 2012). In light of all this, NHFS data indicating 58% of Indian children are anemic (NHFS-4) and almost 71 million people suffer from iodine deficiency (NFHS-3) is alarming (IIPS 2007, 2017). Not meeting micronutrient needs during critical years of development decreases an individual's immune response and decreases linear growth (Black et al. 2013). All of which combined, increases morbidity and mortality (Singh et al. 2011; Bhutta and Salam 2012).

Risks of Noncommunicable Diseases

Alongside the increased risk of infection, undernutrition can lead to inappropriate weight gain and susceptibility to noncommunicable disease. Undernutrition prevents children from meeting their weight- and height-for-age. Normally, weight gains within the first 1000 days of life are associated with the development of adult lean mass. Weight gains after the first 1000 days are associated with the development of adult fat mass. Undernourishment early in life prevents children from meeting their length-for-age and therefore leads to stunted growth. Thus, undernourished children have less lean body mass and shorter stature (Black et al. 2013). Not meeting nutrient needs early in life puts children at increased risk of being overweight later in life (Ahmed et al. 2012; Black et al. 2013). As a consequence to not meeting nutrient needs and carrying excess fat mass, these children have increased susceptibility to noncommunicable diseases, such as diabetes, metabolic syndrome, cardiovascular disease, and obesity (Black et al. 2013; UNICEF 2015).

Obesity in low- and middle-income countries has increased from 4.2% to 6.7% from the early 1990s to 2010 (Black and Dewey 2014). It is expected to continue to increase as children in India still are unable to meet their nutrient needs during critical times of growth and development. In addition, most nutrition interventions are not focused on preventing obesity but instead focus on undernutrition and stunting. Many of these programs target availability, accessibility, and acceptability

of food and nutrients from conception to early childhood. Healthy portion sizes, key nutrients, and healthier food choices are not directly incorporated into integrated interventions - all of which could help prevent and proactively treat overweight/obesity in Indian children (Black and Dewey 2014).

Developmental Outcomes and Economic Productivity

In the first few years of life, children undergo rapid brain development. Development in children can be broken down into several domains: sensory-motor, cognitive, and social-emotional. Poor health, nutrition, and disease can lead to poor brain development in the short- and long-term (Grantham-McGregor et al. 2007; Black and Dewey 2014; Prado and Dewey 2014).

Children develop crucial neuronal connections and have high nutritional needs, which are critical to cognitive development. Not only do these changes occur at a fast rate but continue to build on each other as the child grows. Inability to form these connections impacts the brain's structure and functional capacity. As the child develops, these deficits become more pronounced (Grantham-McGregor et al. 2007; Black and Dewey 2014; Prado and Dewey 2014).

Poor cognitive development also perpetuates the child into a cycle where diminished learning ability leads to poor school achievement, delayed school entry, early school termination, and diminished ability to continue education, which limits employment opportunities and earning potential later in life (Grantham-McGregor et al. 2007; Black and Dewey 2014). Studies from over 51 countries indicate that every year of schooling leads to a 9% difference in wages (Grantham-McGregor et al. 2007). Thus, on a societal level, there is a significant economic cost associated with malnutrition's impact on children's developmental outcomes. Not meeting the nutrient needs of Indian children handicaps a future generation and impacts national development.

Implications for Policies and Interventions

India's malnutrition burden affects the world's malnutrition burden. More importantly, it affects millions of children, who are India's future. In recent years, there has been an increasing understanding of the scale and scope of India's malnutrition burden, and this is reflected in India's new nutrition strategy (NITI Aayog 2017). India's policy environment for nutrition has been robust for many years, however, with large-scale delivery platforms that include most evidence-based nutrition-specific interventions (Avula et al. 2017) and several social welfare programs that address the underlying determinants of malnutrition – including those related to food security, poverty, gender issues, and sanitation. Nevertheless, given the diversity in context and capacity across India, implementation and quality of programs are India's most pressing challenges. Despite improvements in the coverage of both delivery platforms and interventions in the last decade, many gaps persist, especially

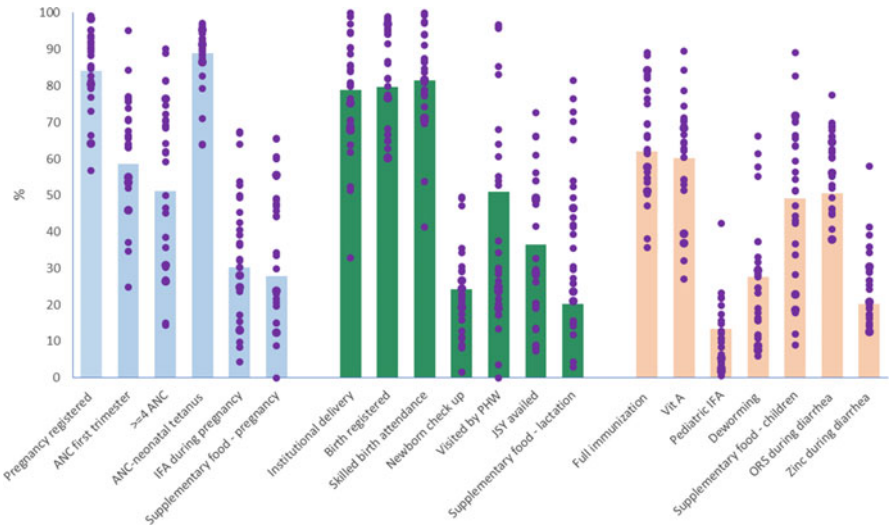

Fig. 3 Comparison of nutrition-specific intervention coverage in India. Data presented as median coverage with each dot representing a state (Menon et al. 2017)

in relation to health and nutrition services for children (Fig. 3), and there are wide differences between states.

What is encouraging is that some poor states (like Odisha and Chhatisgarh) have been exemplars for scaling up health and nutrition services in recent years (Kohli et al. 2017 for Odisha) and thus set the tone for what is possible within India's existing policy instruments. However, much more is needed to address further issues of quality of services and commodities within the health system and the ICDS.

Looking forward, addressing India' nutrition challenges in the future will require a close look at the health and nutritional status of adolescents – both boys and girls. Although these groups are recognized as being vulnerable, as well as offering a window of opportunity to intervene, there is limited data on the health and nutritional status of adolescents, and of the reach of interventions to these groups. Investments will be needed, therefore, to close some of these gaps and to explore the potential of programs like the Midday Meal Scheme to deliver more nutrition interventions to school-based children. In addition, given India's growing challenges of overweight and obesity, engaging and working with school-age children to strengthen healthy diets and physical activity will be essential to secure the health of future generations.

Conclusions

Undernutrition has a significant effect on a child's survival and development. Undernutrition in all of its forms is associated with almost 45% of the current burden of under-5 child deaths (Black et al. 2013). In countries like India, the prevalence of

stunting, wasting, and micronutrient deficiencies is very high. Progress has been made in addressing malnutrition concerns such as stunting; however, many children continue to not meet their nutrient needs for growth and development. Not only is undernutrition substantially high in India, it differs in populations affected throughout the subcontinent. For example, the prevalence of stunting varies according to region, is higher among rural areas compared to urban areas, and disproportionately affects the poorest population quintiles. Risk factors associated with undernutrition can lead to significant consequences for children. Risks include mortality, morbidity, poor growth and development, and economic inequality. This impact is evident in a child's physical development, mental development, educational attainment, and economic productivity later in life. These consequences have a significant impact on affected individuals and families – impacts that persist within families from one generation to the next and leave large numbers of our next generation unable to meet the nation's developmental and workforce needs. Meeting nutrient needs of children within the first 2 years of life is crucial. Meeting nutrient needs not only benefits a person's health and development but has a positive impact on a person's cognitive abilities and economic opportunities later in life. Investing in child nutrition is vital to the health of India and its future generations (Grantham-McGregor et al. 2007).

Summary Points

- There is a particularly high burden of child malnutrition in India.
- 28% of newborns in India are low birth weight.
- 21% of children under-5 have moderate or severe wasting.
- 38% of children under-5 have stunting.
- Micronutrient deficiencies, particularly vitamin A, iron, iodine, zinc, and folic acid, are common and contribute to child malnutrition.
- Malnutrition in children varies according to region and is impacted by rapid urbanization and economic status within households.
- Undernutrition increases the risk of infectious diseases.
- Undernutrition impacts growth and development in children.
- Malnutrition affects the economic productivity of individuals and the growing population in India.
- Despite several programs, rate of progress is relatively slow with much national disparities.

Effects of Famine

The Effects of Prenatal Exposure to the Dutch Famine 1944–1945 on Health Across the Lifecourse

8

Tessa J. Roseboom

Contents

Abstract

Poor nutrition during critical periods of early human development has lasting negative consequences for growth, development, and health. This chapter summarizes the evidence from studies investigating the effects of prenatal exposure to the Dutch famine on later mental and physical health. The Dutch famine was remarkable in several ways, and its unique features have contributed to the fact that it has most often been used in studies examining the long-term consequences of prenatal undernutrition. The Dutch famine was an acute period of undernutrition that was clearly circumscribed in time and place; it had an abrupt beginning

and end and struck a population that was previously and subsequently well nourished. Also, the administration was well organized and records were kept allowing researchers to investigate the consequences of starvation in the decades that followed. All these characteristics make the Dutch famine uniquely suited for such studies, and allow researchers to take a quasi-experimental design to address a question that would otherwise be impossible to answer in a human setting.

The effects of famine depended on its timing during gestation and the organs and tissues undergoing critical periods of development at that time. Early gestation appeared to be the most vulnerable period which may not be surprising considering the fact that all organs are laid down within 12 weeks after fertilization. The effects of famine were widespread and affected structure and function of organs and tissues, resulted in altered behavior and increased disease risks, which in turn led to reduced participation in the labor market and increased mortality. The effects of famine were apparent in the absence of any effects on size at birth. Some effects of prenatal undernutrition were more pronounced or even limited to one sex, but generally the effects applied to both men and women. There is preliminary evidence to suggest that the effects of famine may not to be limited to those affected prenatally, but were passed on to the next generation, both through the maternal and paternal line.

Studies in other settings show similar effects and suggest that the findings are not uniquely linked to the characteristics and setting of the Dutch famine, but reflect biologically fundamental processes that describe human plasticity. We expect that adequately feeding women before and during pregnancy will allow future generations to reach their full potential and lead healthier and more productive lives, ultimately leading to healthier and more equal future.

Introduction: Hunger in an Age of Plenty

Good nutrition is fundamentally important for maintenance, growth, development, reproduction, and health. Poor diets, due to insufficient, imbalanced, or excessive intakes of nutrients, can impair growth and development and induce disease.

Today the world faces a double burden of malnutrition that includes both undernutrition and overnutrition. Never before in history have there been so many people with hunger worldwide. It is estimated that nearly one billion people worldwide go hungry each day. While at the same time more than one billion people are overweight or obese. Malnutrition – in any form – poses threats to health. Counterintuitive as it may seem, both undernutrition and overnutrition are reducing the health of millions of individuals around the globe. Hunger and inadequate nutrition contribute to early deaths for mothers, infants, and young children and account for more losses of life than AIDS, malaria, and tuberculosis combined (WHO nutrition facts). Deficiencies in the diets of children can impair growth and development and lead to stunting and wasting in childhood, while deficiencies in adulthood can lead to blindness, scurvy, or anemia. Such cases are most often seen in developing countries, while in developed countries the consequences of imbalanced or excessive diets lead to obesity, diabetes, and cardiovascular diseases.

The evidence presented in this chapter indicates that the consequences of undernutrition may not be limited to the individuals suffering from undernutrition, but that the offspring, especially if they have been exposed to undernutrition while in their mothers' womb may be negatively affected as well. These consequences are apparent throughout the lifecourse and might even extend into the following generation. Similarly, imbalances in prenatal nutrition caused by maternal obesity and gestational diabetes are known to negatively affect offspring's health.

The Long-Term Consequences of Poor Diets in Early Life

Studies across the world have consistently shown that babies who were small at birth have increased rates of chronic degenerative diseases. These associations cannot be explained by prematurity, but rather reflect variations in early growth to be associated with later disease risk. This led to the hypothesis that a limited supply of nutrients to the developing fetus leads to adaptations that increase its chances of survival in the short term but increase its risk of disease in later life. This is thought to reflect developmental programming: early environmental cues induce anatomical, physiological, and biochemical changes that have lasting consequences for the structure and function of organs and tissues and permanently affect the physiology. Although the adaptations may be beneficial for short-term survival, the adaptations may come at a cost in later life, especially if the environment into which the individual is born is very different from the environment in which the individual developed. The greater the degree of mismatch between the prenatal environment and the environment in adult life, the greater the disease risk associated with it. This hypothesis is known as the Developmental Origins of Health and Disease hypothesis (DOHaD).

The Dutch Famine as a Model to Test the DOHaD Hypothesis

The DOHAD hypothesis suggests that undernutrition in utero permanently changes the body's structure, function, and metabolism in ways that lead to chronic degenerative disease in later life. The hypothesis was formulated based on epidemiological studies, which have subsequently been confirmed in populations across the world. These observational studies in humans consistently showed that small size at birth was linked to greater disease risk in later life. Small size at birth was taken as an indication of reduced fetal growth due to limited supply of nutrients to the fetus. Animal studies have experimentally shown that restriction of fetal nutrition indeed induces adaptations that lead to altered structure and function of organs, increased rates of disease, and shortened lifespan. But the experimental evidence for the DOHAD hypothesis in humans is impossible to obtain.

While famine is sadly not uncommon in many parts of the world, studying effects of undernutrition during pregnancy is hampered by the fact that undernutrition is usually not restricted to pregnancy alone, and effects of chronic undernutrition and accompanying problems of infection complicate the situation. The tragic circumstances of the Dutch famine of 1944–1945 created a unique opportunity to assess the effects of prenatal famine exposure on health in later life. The Dutch famine has been used by various investigators as an equivalent to an experimental setup to investigate the effects of prenatal undernutrition in humans. What is unusual about the Dutch famine is that the famine was imposed on a previously well-nourished population; there was a sudden onset and relief from the famine; and, despite the adversities of the war, midwives and doctors continued to offer professional obstetric care and kept detailed records of the course of pregnancy, the delivery, and the size and health of the baby at birth. Furthermore, detailed information is available on the weekly rations provided during the famine, and in several inflicted cities birth records were kept which allowed researchers to trace those born around the time of the famine and thus to study the long-term effects of prenatal famine exposure (Figs. 1 and 2).

The Historical Course of Events That Led to the Dutch Famine 1944–1945

After the invasion of the Allied forces on the 6th of June 1944, a few weeks of heavy fights followed. Then, the Allied forces finally broke through German lines. Quickly, the Allied troops took possession of France, Luxembourg, and Belgium. By the 4th of September 1944 the Allies had the strategic city of Antwerp in their hands, and on the 14th they entered the Netherlands. The Dutch expected that the German occupation would soon be over, and so did the commanders of the Allied forces. Hoping to capture strategic bridges across the river Rhine to open a pathway for rapid invasion into Germany, the Allied forces launched a parachute attack behind the Nazi forces near the city of Arnhem. However, the operation failed with major losses. Operation Market Garden had failed. Subsequently, the Dutch government called for a strike of the Dutch railways in order to support the Allied offensive. As a

Fig. 2 Ration provided to adults in Amsterdam, the Netherlands April 1944, consisting of 2 slices of bread, 2 potatoes, and half a sugar beet

reprisal, the Germans banned all food transports. The food situation in the western part of the Netherlands worsened dramatically. Food stocks ran out rapidly, and soon rations for adults dropped to below 1000 calories a day. The embargo on food transports was lifted in early November 1944, when food transport across water was permitted again. But because most canals and waterways were frozen due to the early and extremely severe winter, it had become impossible to bring in food from

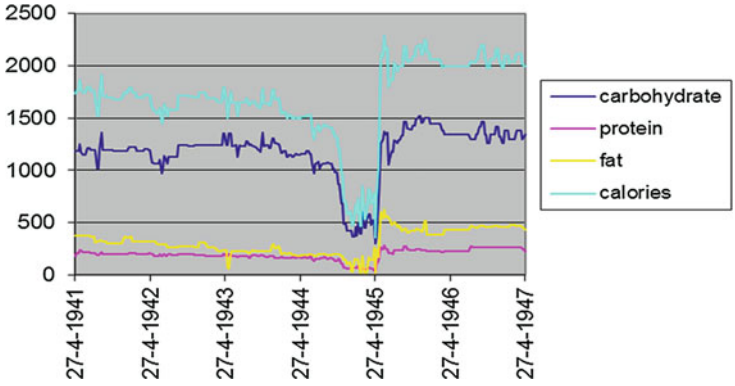

Fig. 4 Official rations for adults in Amsterdam over time

the rural east to the urban west of the Netherlands. Food rations declined to extremely low levels between February and May 1945, with daily rations varying between 400 and 800 calories a day. During the famine, infants were relatively protected, because their official daily rations never fell below 1000 calories. Pregnant and lactating women were entitled to an extra amount of food, but at the peak of the famine these extra supplies could not be provided anymore. Also, extra food came from the black market, central kitchens, church organizations, and foraging trips to the countryside. The period of famine ceased in early May 1945 immediately after the final surrender of the Germans. The food situation quickly improved and within a month rations were above 2000 calories (Figs. 3 and 4).

In addition to the immediate provision of food after the war, medical aid was a top priority for the Netherlands. The famine had a profound effect on the general health of the population. In Amsterdam, the mortality rate in 1945 had more than doubled compared to 1939, and it is very likely that most of this increase in mortality was attributable to undernutrition. Doctors from the UK and USA were sent to survey

medical needs. Clement Smith from Harvard Medical School was among the first to witness the effects of the famine on the health of the Dutch population. He immediately saw the opportunity to obtain information that would help resolve important questions on how poor maternal nutrition affects pregnancy and the development of the fetus before birth. Using obstetric records from Rotterdam and The Hague, he studied effects of prenatal exposure to famine on pregnancy and the fetus which he described in his paper "*The effect of famine on pregnancy and its product*" (Smith et al. 1947). This paper describes that babies born during the famine were lighter at birth.

Since the Dutch famine lasted 5–6 months (from late November 1944 until early May 1945), investigators have been able to not only assess effects of prenatal undernutrition per se but also to differentiate between effects of undernutrition according to its timing during gestation and the organs and tissues developing at that time. Although the exact definitions differ between studies, all studies assessing effects of prenatal famine exposure have differentiated between effects of famine in early, mid, or late gestation (Fig. 5).

In general, the Dutch famine studies have provided support for the fetal origins hypothesis. Studies in different cohorts and with different setups have shown differences in outcomes between those who had been exposed to the Dutch famine during gestation and those who had not been exposed to famine. The effects of famine depend on its timing during gestation and the organs and tissues developing at that time.

Consequences of Prenatal Famine Exposure

In general, the Dutch famine studies have provided support for the fetal origins hypothesis. Studies in different cohorts and with different setups have shown that those who had been exposed to the Dutch famine during any stage of gestation were found to have raised glucose levels as adults. One study found increased blood pressures and rates of hypertension among those who had been exposed to famine during any stage of gestation (Stein et al. 2006), while another study could not confirm effects of famine on blood pressure (Roseboom et al. 1999). Glucose problems and diabetes are more common among individuals in their 1950s who were exposed, for any gestational stage of exposure.

Early Gestation

Studies on the long-term consequences of prenatal exposure to famine on later health started with the landmark studies of Stein and Susser performed in the early 1970s following the increasing awareness in the late 1960s that early nutritional deprivation might cause irreversible damage to the brain (Stein and Susser). This study among military conscripts did not demonstrate any effect of undernutrition during gestation on the adult mental performance. Those exposed in early gestation had a twofold increase in risk of schizophrenia (Neugebauer et al. 1999) and antisocial personality disorder (Hoek et al. 1996), as well as increased rates of addiction in later life (Franzek et al. 2008). Prenatal famine exposure has also been associated with affective psychoses and depression, though not all studies replicated this finding (Stein et al. 2007; de Rooij et al. 2008). Some studies have found indications of effects of exposure to famine in early gestation on cognition (De Rooij et al. 2010) though other studies did not detect such effects (Stein and Susser; Stein et al.). Imaging studies of the brains have shown lasting effects of famine exposure on brain size and structure (De Rooij et al. 2016; Hulshoff Pol et al. 2000). Men who had been exposed to famine in early gestation had smaller intracortical volumes and total brain volumes than unexposed men. They also had smaller volumes of total cortical gray matter, white matter, cerebellar gray matter, thalamus, caudate nuclear, and accumbens area and a large number of more specific cortical white and gray matter areas. The overall reduction in brain size after prenatal famine exposure was ~5%. A decreased intracortocal volume was also reported in a smaller study of schizophrenic patients (Hulshoff Poll et al. 2000), which suggests that prenatal undernutrition has lasting effects on brain size and structure.

Stein and Sussers landmark study found that 19-year-old conscripts exposed to famine in early gestation were more likely to be obese (Ravelli et al. 1976). These effects on obesity were also found in two other studies which examined effects on anthropometry in adulthood (Ravelli et al. 1999; Stein et al. 2007) with the effects being more pronounced among women than men. Women who had been exposed to famine in early gestation had higher BMI and appeared to be more centrally obese than those who had not been exposed to famine prenatally. These differences in

adiposity could at least in part be mediated by differences in food preferences and food intake as there are indications that those exposed to famine in early gestation had higher energy intakes, higher protein intakes, and higher intakes of fat (Lussana et al. 2008; Stein et al. 2009). They also had more atherogenic lipid profiles, with higher LDL and lower HDL cholesterol levels (Roseboom et al. 2000c; Lumey et al. 2009), again the effects being more pronounced in women than in men. There were indications that those exposed to famine in early gestation more often had disturbed blood coagulation (Roseboom et al. 2000b) and were more responsive to stress (Painter et al. 2008). Exposure to famine in early gestation was furthermore associated with increased rates of cardiovascular disease (Roseboom et al. 2000), which occurred at an earlier age (Painter et al. 2006) and led to increased mortality (Ekamper et al. 2014; van Abeelen et al. 2012).

Although based on small numbers, there is evidence to suggest that women exposed to famine in early gestation have increased rates of breast cancer (Painter et al.). Analyses of mortality data suggest that those exposed to famine in early gestation have increased mortality, which is mainly found in women and mostly due to cardiovascular causes and cancer. The famine affected mortality in the short term and also increased childhood mortality. Subsequent studies initially did not detect any effects of famine exposure on mortality before the age of 50 and 58 years (Roseboom et al. 2000; Painter et al. 2006). More recently, studies with longer follow-up have shown that exposure to the Dutch famine in early gestation is associated with increased mortality (Van Abeelen et al. 2012; Ekamper et al. 2014). Uniquely, Ekamper used a large national birth cohort to assess effects on mortality up to age 63 years and found a 12% increase in mortality among those who had been exposed to famine in early gestation.

The effects of famine exposure in early gestation are not limited to health but appear to have economic consequences too. The most striking finding was that the probability of being employed was significantly lower among those who had been exposed to famine in early gestation (Scholte et al. 2015). This result fits with findings of poorer performance on cognitive tasks in men who had been exposed to famine in early gestation. It seems that the effects of famine on employment are at least partly explained by effects on cognition. Mental disorders such as schizophrenia and antisocial personality disorders which were more common after exposure to famine in early gestation may contribute to this, as well as the physical health. It could be argued that the effects of famine exposure on health reduced individual productivity and hence employability.

Mid Gestation

Exposure to famine in mid-gestation was linked to an increase in occurrence of microalbuminurea in adulthood and a decrease in creatinine clearance (Painter et al. 2005). It may be that mid-gestational exposure to famine – the period of rapid increase in nephron number – may prevent formation of sufficient glomeruli and thus increase the risk for microalbuminurea and deteriorated renal function in

adulthood. This supports the concept that intrauterine conditions during distinct, organ-specific periods of sensitivity may permanently determine health outcome in later life. Another example of this phenomenon is the finding in the same study that people who had been exposed to famine in mid-gestation had an increased prevalence of obstructive airways disease (Lopuhaa et al. 2000). These observations were not paralleled by reduced lung function or increased serum concentrations of IgE. This suggests that the increased prevalence of symptoms and disease may be attributable to increased bronchial reactivity rather than to irreversible airflow obstruction or atopic disease. Because the bronchial tree grows most rapidly in mid-gestation, our findings support the hypothesis that fetal undernutrition permanently affects the structure and physiology of the airways during "critical periods" of development that coincide with periods of rapid growth.

Late Gestation

One study found an association between prenatal exposure to famine and later hypertension,[22]

which may be due to an insulin secretion defect.[16]

These findings provide further evidence that the timing of exposure in relation to the stage of pregnancy may be of critical importance for determining health outcomes.

Epigenetics

The Dutch famine families study provided the first direct evidence for epigenetic programming through prenatal famine exposure. Men and women who had been exposed to the famine periconceptionally had less methylation of the IGF2 gene compared with their unexposed same-sex siblings (Heijmans et al. 2008). Further studies from the same group provided additional evidence that the early gestation period is a critical time window during which the prenatal environment may affect the human methylome, with direct evidence for effects in blood, which may suggest that other tissues are effected as well (Tobi et al. 2009). The functional implications of these findings need further exploration. The studies do suggest that the effects of famine exposure on methylation are specific – i.e., are present in some genes but absent in others. The mechanisms underlying DNA methylation differences from prenatal exposure await elucidation but the observed timing-specific associations in blood may hint at an intrinsic sensitivity of newly developing tissues.

Conclusions

Findings from the Dutch famine studies – despite slight differences in individual findings between the different studies – in general suggest that maternal nutrition before and during pregnancy play an important role in later disease susceptibility.

They have shown that maternal undernutrition during gestation has lasting negative consequences for the offspring's health. Many chronic diseases that plague our society may originate in the womb. The effects seem to be large and depend on the timing during gestation and the organs and tissues developing at that time. Also, the effects are independent of the size of the baby at birth. Most notably, those exposed to famine in early gestation did not have lower birth weights than those who were not exposed to famine prenatally, but did have worst health outcomes as adults. This may imply that adaptations that enable the fetus to continue to grow may nevertheless have adverse consequences for health in later life. Chronic degenerative disease may be viewed as the price paid for adaptations made to an adverse intrauterine environment.

These findings confirm experimental evidence from studies in animals showing that undernutrition during gestation permanently affects the structure and function of organs, thereby affecting behavior as well as disease risk, and ultimately shortening lifespan (Ozanne et al. 2004). Moreover, the findings from the studies of the long-term consequences of the Dutch famine have now been replicated in other settings in which the effects of famine have been examined. Studies in other settings of famines with different durations and severity affecting different populations support these findings and suggest that the results of studies on the Dutch famine are not uniquely linked to the characteristics and setting of the Dutch famine, but rather reflect biologically fundamental processes that describe human plasticity . A study in Nigeria showed that prenatal undernutrition also affects later health in African populations (Hult et al. 2010). People who had been exposed to the Biafran famine during the Nigerian civil war (1967–1970) in utero were found that have increased rates of hypertension and type 2 diabetes at the age of 40 compared to those who had not been exposed to the Biafran famine in utero. Similarly, studies of people exposed to the Great Leap Forward famine in China have shown similar effects of prenatal famine exposure in later life risk of diabetes, hypertension, and schizophrenia. Undernutrition in early life contributes significantly to the increasing prevalence of hypertension and glucose intolerance. Therefore, prevention of fetal and infant undernutrition should be given high priority in national health, education, and economic agendas to limit the increase of noncommunicable diseases in many developing countries.

Policies and Protocols

The knowledge presented here has been taken up into policy actions.

Evidence for the importance of early nutrition for later health has come from many cohort studies across the globe. Pooled analyses of several cohorts from low and middle income countries have shown that not only are babies who were larger at birth more likely to be healthy, they are also more likely to complete secondary school (Adair et al. 2013). These findings have clear implications for public health policy and nutrition interventions. A focus on improvement in nutrition in pregnancy and the first 2 years after birth could lead to substantial reductions in stunting and

improved survival (Bhutta et al. 2008). These improvements form the basis for the emphasis on the first 1000 days of life. The 1000 days between a woman's pregnancy and her child's second birthday offer a unique window of opportunity to shape healthier and more prosperous future. The right nutrition and care during this 1000 day window can have a profound impact on a child's ability to grow, learn, and rise out of poverty. It can also shape a society's long-term health, stability, and prosperity. The 1000 Days Initiative was born in 2010 in response to groundbreaking scientific evidence that identified a powerful window of opportunity from a woman's pregnancy to a child's 2nd birthday when nutrition had a long-term impact on the future health and development of both children and societies. With the backing of the US Government, the Government of Ireland, the Bill & Melinda Gates Foundation, and several nonprofit organizations, 1000 Days began its work as a partnership to drive greater action and investment to improve nutrition for women and young children throughout the world.

Investing in the early years is one of the smartest investments a country can make to break the cycle of poverty, address inequality, and boost productivity later in life. Today, millions of young children are not reaching their full potential because of inadequate nutrition, lack of early stimulation and learning, and exposure to stress. Investments in the physical, mental, and emotional development of children – from before birth until they enter primary school – are critical for the future productivity of individuals and for the economic competitiveness of nations.

Hunger is caused by poverty and inequality, not scarcity. For the past two decades, the rate of global food production has increased faster than the rate of global population growth. The world already produces more than enough food to feed everyone on the planet. We should prioritize a more equal distribution of food across the world so that both the consequences of poor diets due to undernutrition and overnutrition will be prevented. Priority should be given to women of reproductive age. Based on the findings of the Dutch famine studies, we expect that adequately feeding women before and during pregnancy will allow future generations to reach their potential and lead healthier and more productive lives, ultimately leading to healthier and more equal future. Breaking the vicious cycle of poverty and undernutrition will most likely succeed if we provide women with sufficient food to provide their children a good start in life.

Malnutrition kills millions of children every year and robs millions more of the opportunity to reach their full potential. This global crisis requires global action in order to give every child a fair start to life. In 2012, world leaders committed to reaching six global nutrition targets by 2025. Yet, reaching these targets in the next decade will require increased investment. World leaders must act now to fulfill their promises and save millions of lives. Attempts to divide the available food around the world in a more equal manner seem a very important issue to address. Giving women of reproductive age priority in allocating food in times of food shortage seems important to try and break the vicious cycle of undernutrition and poverty. In recognition of this, WHO and UN policies have prioritized nutrition during the first 1000 days of life, from conception to the 2nd birthday as one of the most important investments we can make in human development and in the health of future generations.

Dictionary of Terms

- **Prenatal undernutrition** – undernutrition before birth
- **Plasticity** – the ability of living organisms to adapt to the environment
- **Programming** – nutrition and other environmental factors acting in early life permanently affect the way in which the organism grows and develops with lasting consequences for later health.
- **Epigenetics** – refers to changes in/regulation of the expression of genes without alterations to the DNA sequence. These changes in expression of genes have consequences for phenotype and explain why one genotype can result in various phenotypes.

Summary Points

- Poor nutrition during critical periods of early human development has lasting negative consequences for growth, development, and health.
- The effects of prenatal famine exposure depend on its timing during gestation and the organs and tissues undergoing critical periods of development at that time.
- Early gestation seems to be the most vulnerable period.
- The effects of prenatal undernutrition are widespread and affect structure and function of organs and tissues, result in altered behavior and increased disease risks, which in turn increases mortality.
- The effects of famine exposure are apparent in the absence of any effects on size at birth.
- Some effects of prenatal undernutrition are more pronounced or even limited to one sex, but generally the effects apply to men and women.
- The effects of famine pass on to the next generation, both through the maternal and paternal line. This is likely to involve epigenetic regulation mechanisms.

Abstract

Evidence has shown that growth patterns in early life are associated with the diseases risk in adulthood. This reflects the concept of programming in which environmental factors generate long-lasting variability in phenotype for individual to adapt to an adverse environment. Low birth weight (BW) and poor growth rate are associated with obesity, diabetes, and cardiovascular disease in later life. Animal and epidemiological studies have linked BW and growth rate with the changes in body composition. Prenatal and early postnatal undernutrition can affect fat distribution, reduced bone mineral content, and muscle mass in later life in animals. Individuals who were exposed to the Dutch Famine, the Great Leap Famine in China, World War II, or Nazi occupation have a higher body weight, poor grip strength, and physical performance, and/or poor bone density and higher risk of osteoporosis. Epidemiological studies also show that infants with lower BW or poor growth rate were associated with changes in body composition. Recent animal studies, however, demonstrate that this developmental programming is potentially reversible. Nevertheless with the current evidence, appropriate dietary advice can be given to promote optimal fetal and infant growth and lower diseases risk in the offspring in later life.

Introduction

Poor accessibility of food and insufficient caloric intake could result in starvation. About 800 million people in the world were suffering from chronic undernourishment in 2014–2016 (Kueper et al. 2015). Famine can be declared when mortality, malnutrition, and hunger are not met. It is defined as at least 20% of households in a particular area facing extreme food shortages with a limited ability to cope, acute malnutrition rates exceeding 30%, and the death rate exceeds two persons per day per 10,000 persons (UN 2017). Children are the most

vulnerable victims in famine. Globally 161 million under 5 years old were estimated to be stunted in 2013 (World Hunger 2017).

Famine is known to affect the nutritional status at gestation and postnatal period. Fetal origins hypothesis proposes that the exposure to poor nutritional conditions in utero and/or during postnatal life leads to alterations in the development of vital organs, tissues, and body systems. These alternations are advantageous for survival in short term but may permanently predispose the fetus to structural, physiological, and metabolic adaptations, and lead to an increased risk of chronic degenerative diseases in later life (Barker et al. 2002). Various studies suggested the association between impaired intrauterine and early postnatal growth and increased risk of development of obesity, diabetes, and cardiovascular disease at adult life (Barker et al. 2002). There is also evidence showing that early life nutrition can affect the process of aging, frailty, and ultimately life span (Bleker et al. 2016).

Several animal studies and case series studies have examined the effect of famine during prenatal and postnatal period on adult health. Epidemiological studies on the impact of low BW and adult health have also been reported. This article aims to summarize the impact of famine in childhood on adult health with a focus on the changes in body composition including fat, muscle, and bone mass.

Evidence from Animal Model Regarding the Effect of Famine In Utero and during Early Life on Body Composition

Animal studies have examined the effect of prenatal and early postnatal undernutrition on body composition in later life. The results are summarized in Table 1. These studies provide insights that early life environment is critical for optimal health and ameliorates chronic diseases in adulthood.

Fat Mass

Development of adipocyte is highly influenced by the nutritional environment at prenatal and early postnatal life (Eleftheriades et al. 2016). The fat cell size in later life was increased in female and male rats who were born from mothers that were undernourished for the first 2 weeks of gestation. Female rats did not become obese, while male rats became hyperphagic and obese in adults (Jones and Friedman 1982). Such gender-specific changes have also demonstrated in Engelbregt et al. (2004). Intrauterine growth retardation was induced by ligation of the uterine arteries from day 17 of gestation to mimic prenatal malnutrition. Rats were postnatally starved by litter enlargement to 20 pups per mother from day two after birth until weaning. The total fat mass in female rats at 6 months old in either prenatal or postnatal starvation groups did not differ from the control group. However, significant result was found in male postnatal starvation rats when compared with the control. Starved male rats had a lower total fat mass and body fat percentage while a higher lean mass percentage.

Table 1 Summary of animal studies on early life undernutrition and its effect on body composition in later life

Outcome studied	Exposure to undernutrition	Effect of early life undernutrition on body composition in later life
Fat mass	Prenatal	- male offspring became hyperphagic and obese; increased fat cells in both female and male offspring as adults (Jones and Friedman 1982) - rat offspring born heavier at birth showed greater value of abdominal and total fat than offspring born with a lighter birth weight at 26 days old (Eleftheriades et al. 2016)
	Postnatal	- Total fat mass for male rats was significantly lower compared to the control group at 6 months old (Engelbregt et al. 2004)
	Prenatal and postnatal	- no difference was observed in abdominal and total fat in offspring that were born with a heavier birth weight compared to the control group at 26 days old (Eleftheriades et al. 2016)
Bone health	Prenatal	- lower TBBMC compared to rats fed with a normal pre or postnatal diet at day 26 of life (Eleftheriades et al. 2016) - TBBMC was significantly lower in both male and female rats compared to controls at the age of 6 months; reduced in trabecular bone and cortical content in both male and female offspring at 6 months old. Trabecular bone density was found to be lower in female rats only (Engelbregt et al. 2004) - maternal protein restriction resulted in reduced bone area and BMC in the offspring later in life (Mehta et al. 2002)
	Postnatal	- lower TBBMC in male rats compared to the control but no such difference in female rats at the age of 6 months (Engelbregt et al. 2004)
Muscle mass	Prenatal	- reduced muscle fiber numbers at term guinea pig fetus (Dwyer et al. 1995) and in near-term ewes fetus (Demirtaş and Özcan 2012)
	Postnatal	- percentage of lean mass in male rats at the age of 6 months was significantly higher compared to control (Engelbregt et al. 2004)

Another study found that prenatal food restriction had a significant impact on abdominal adiposity later in life (Eleftheriades et al. 2016). Pregnant rats were randomized to control diet or 50% of normal diet throughout gestation. The prenatally starved offspring were further divided into two groups based on BW, either with a heavier BW (a mean BW at or above two SD of the control group that received standard prenatal diet) or a lower BW (less than two SD of the control) and lactated by either mother with standard prenatal diet or restricted diet. Heavier offspring in the prenatal starved groups fed with a standard postnatal diet resulted in a greater value of abdominal and total fat than those with a lower BW and those in control group at 26 days old. However, this difference was not observed when the prenatally starved rats were continuously postnatally starved. These observations indicated that BW can be a factor contributing to the increased adipose tissue in rats that had suffered in utero undernutrition.

Bone Health

Several animal studies have demonstrated that prenatal and postnatal undernutrition affect fetal bone development and body mineral content (BMC) in adulthood. Eleftheriades et al. (2016) found that rats fed with standard prenatal and postnatal diet had a significant higher total BMC when compared to prenatal growth restricted rats at day 26 of life. In another study, adult rats exposed to either prenatal or postnatal malnutrition resulted in persistent growth retardation in terms of body weight and total body bone mineral content (TBBMC) at age of 6 months (Engelbregt et al. 2004). TBBMC was significantly lower in both male and female rats that had experienced prenatal malnutrition compared to control ($p < 0.01$ and $p < 0.05$). When these rats experienced postnatal food restriction, TBBMC was found significantly lower in male rats ($p < 0.01$) whereas no such difference was observed in female rats (Engelbregt et al. 2004).

Romano et al. (2010) used bilateral uterine vessel ligation in pregnant rats to induce uteroplacental insufficiency and found that both male and female rats were born 14% lighter compared to the control group ($p < 0.05$) and remained smaller at 6 months of age ($p < 0.05$). Trabecular bone and cortical content was reduced when compared to the control in both male and female rats. Trabecular bone density was found to be lower in growth restricted female rats ($p < 0.05$). When the rats were fed with a constant high calcium diet since adolescence, there was an increased in cortical bone mineral density (BMD) in both sexes ($p < 0.05$). However, it was not sufficient enough to recover bone content and strength even with calcium supplementation when compared with rats that did not suffer from in utero undernutrition. Adequate protein intake may also contribute to bone health development. Mehta et al. (2002) demonstrated that maternal protein restriction resulted in reduced bone area and BMC in offspring later in life.

Muscle Mass and Strength

Prenatal undernutrition is associated with reduced neonatal muscle weight in sheep and a reduction of postnatal muscle fiber in pig (Dwyer et al. 1994; Greenwood et al. 2000). In a guinea pig experiment, a 40% restriction in maternal feed intake through gestation resulted in reduction of fetal body weight and a 20–25% reduction in muscle fiber number at term (Dwyer et al. 1995). Furthermore, early gestational undernutrition that lasted for the first 25 days of gestation did not affect muscle fiber number development of the placenta, whereas gestational undernutrition period that extended to 25 days and longer affected development of secondary fibers (Dwyer et al. 1995). The results indicated that the stages of undernourishment during gestation had different effects on muscle fiber development.

Demirtaş and Özcan (2012) investigated the effect of mild and severe nutrient restriction during early gestation on fetal muscle development in ewes. Ewes from the mild group received 85% of daily nutritional requirement and ewes from the severe group received 50% of daily nutritional requirement from the first day of

gestation and throughout the gestational period. The total number of muscle fibers, primary and secondary fiber numbers had decreased in ewes with either mild or severe undernutrition during early gestation. Moreover, the more severe the nutrient restriction during in utero, the greater decrease in the total fiber numbers (Demirtaş and Özcan 2012). Skeletal muscle is vulnerable to the availability of nutrients during particular period in fetal development.

Evidence from Case Series Studies and Epidemiological Studies Regarding the Effect of Famine during Childhood on Body Composition

The Dutch Famine

The Dutch Famine took place in the winter of 1944–1945 in the western Netherlands. The general daily calorie intake of the inhabitants decreased gradually from about 1800 calories to 1000 calories and further to a daily intake between 400 and 800 calories. It liberated after 6 months and the daily intakes increased to more than 2000 calories. The famine had a profound effect on the health of the population. The mortality rate was more than doubled compared with 1939 (Roseboom et al. 2001). The effects of exposure to the Dutch Famine during gestation on health in later life are summarized in Table 2.

Higher chronic diseases risk and impaired physical function have been found in individuals exposed to the Dutch Famine. Women who had been exposed to the Dutch Famine aged 0–9 years had 25% higher risk of being overweight (95% CI 1.05–1.50), higher BMI by 0.48 kg/m^2 (95% CI 0.13–0.83), and 1.02 cm more of waist circumference (95% CI 0.17–1.88) compared to unexposed women after adjustment for potential confounders (van Abeelen et al. 2012). Men exposed to prenatal undernutrition during the Dutch Famine had lower grip strength

Table 2 Summary of disease risk associated with the Dutch Famine (Painter et al. 2005; Portrait et al. 2007; Roseboom et al. 2000, 2001, 2006, 2011)

Period of starvation	Effects
Famine in early gestation	- more atherogenic lipid profile - higher fibrinogen concentrations and reduced plasma concentrations of factor VII - higher BMI - higher risk of coronary heart disease, dyslipidemia, more stress responsive - increased risk of schizophrenia and antisocial personality disorder
Famine in mid gestation	- increased prevalence of obstructive airways disease - greater prevalence of microalbuminuria - reduced glucose tolerance - decreased in creatinine clearance
Famine in late gestation	- reduced glucose tolerance - highest mortality rate

($\beta = -5.0$ kg; 95% CI -9.2 to -0.8, $p < 0.05$) and physical performance score ($\beta = -0.8$ points; 95% CI -1.6 to 0.0, $p < 0.05$) than unexposed men after adjusted for BMI, birth weight, socioeconomic status (SES), and various lifestyle factors (Bleker et al. 2016). These studies provide evidence that poor nutritional status in prenatal and early postnatal is a predictor of various health outcomes.

During the World war II

During World War II, Japanese women who experienced low nutrient intake when they were 5 years old showed a significantly lower BMD than unexposed women. By comparing women aged 50–54 years in 1992–1993 and women who reached the same age in 1999–2002, the older women group was relatively shorter and had significantly lower BMD (0.86 ± 0.15 g/cm^2 vs. 1.02 ± 0.16 g/cm^2) ($p < 0.001$) (Yoshimura et al. 2005).

Chinese adults who suffered from famine during this period showed a poor bone health. Chinese adults aged 65 years and above who had experienced famine (defined as a caloric restriction for at least 1 year) were shorter (OR 0.92; 95% CI 0.89–0.99), had a higher BMI (OR 1.11; 95% CI 1.03–1.19), and higher prevalence of recurrent falls (defined as two or more falls in the previous 12 months) (OR 1.67; 95% CI 1.17–2.37) (Woo et al. 2010). Women who were exposed to famine also had higher rate of developing osteoporosis ($p = 0.049$), lower femoral neck BMC ($p = 0.031$), and lower femoral neck BMD ($p = 0.034$). In addition, women who had experienced famine had a higher loss in femoral neck BMD (percentage change -1.38; 95% CI -2.72 to -0.03) than those who had not been affected (Chan et al. 2007). However, these associations were attenuated when education was entered into the analysis model. Famine exposure had little impact on BMC, BMD, and osteoporosis status in men (Chan et al. 2007). These studies showed that poor growth during infancy and childhood has impact on bone health and the effect may be gender-specific.

Holocaust Survivors

The incidence of osteoporosis and osteopenia was found to be high in Holocaust survivors. Holocaust survivors are those who were in Europe under Nazi occupation during the years 1939–1945 and were constrained in concentration camp, ghetto, labor camp, or in a children's institution. Female Holocaust survivors were significantly associated with greater likelihood of osteoporosis (OR 1.39; 95% CI 1.00–1.93, $p = 0.03$) (Werner 2003). In addition, female survivors at age 60 years or older had 2.88 times higher risk of osteoporosis than those in the control group after adjustment for various covariates ($p = 0.014$) (Marcus and Menczel 2007). The incidence of osteoporosis and osteopenia was significantly higher in those who exposed to unfavorable condition at 17 years old or younger. They showed a 3.47 higher risk of having osteoporosis than the control group ($p = 0.019$). In contrast,

the lack of difference in the osteoporosis risk was seen among those exposed at age of 17 years and/or older and the control (Marcus and Menczel 2007). These observations further support the period of nutrients restriction is a determinant of bone health later in life.

Great Leap Famine in China

The Great Leap Famine (Great Chinese Famine) that occurred in 1959–1961 resulted in death and malnutrition of millions of people including babies. It had been estimated that the daily per capita availability of food energy during 1959–1961 decreased dramatically to 1500 calories and this level was well below the average food energy requirement of about 2100 calories (Ashton et al. 1984; Chen and Zhou 2007).

The health impacts of the Great Chinese Famine are summarized in Table 3. Studies showed that early life exposure to famine was associated with increased risk of overweight later in adult life (Luo et al. 2006). Yang et al. (2008) compared BMI data based on 2012 China Health National Survey of rural residents born during the famine years of 1959–1961 with those born after the famine, 1964 (control group). The mean BMI and the prevalence of overweight of the women who were born during the famine years were significantly higher compared to the controls ($p < 0.01$). Yang et al. (2008) concluded that higher risk of overweight and obesity in women were caused by malnutrition in fetal life. However, this difference was not observed in men. Similarly, Wang et al. (2010) found that the effect of famine and body weight in adulthood might be gender-specific. Wang et al. (2010) examined the body weight and height of adults who had suffered from famine either as a toddler or during gestational stage in the Chongqing region. Fifty years after exposed to famine, those female exposed to famine during toddler or gestational showed an increase in weight, consequently, leading to overweight and obesity compared to the control. However, males that were exposed to the famine as a toddler showed a decreased in body weight in adulthood and did not affect the males that were exposed to the famine during gestation.

In addition, bone health may also be affected as a consequent of this famine. Chen et al. (2016) found that male survivors of the Great Chinese Famine who were born in 1961 (i.e., those with fetal development in the most severe period of the famine) had a highest risk of developing osteoporosis in adulthood compared to males that did not suffer from the famine (control).

Association of Growth Patterns in Early Life on the Body Composition

Substantial evidence has suggested an association of growth patterns during early life with later health outcomes. The changes of body composition in response to the early environmental conditions may be the determinants of the increasing prevalence

Table 3 Study outcomes of the Great Chinese Famine

Publication	Study data/ population	Study outcome	Famine exposure (birth year)[a]	Age at examination (years)[a]	Results
Chen et al. 2016	2013 health examination at a health screening center of a hospital in Chongqing	Osteoporosis	Exposed to famine (1959–1962); Mean age 0–3 years Control (1956–1958) and (1963–1962) combined as control	48–57	Male survivors of the great Chinese famine who were born in 1961 had a highest risk of developing osteoporosis in adulthood compared to males that did not suffer from the famine (control)
Luo et al. 2006	The China health and nutrition Survey 1991, 1993, 1997, and 2000	Overweight	Famine group (1959–1962); Mean age 0–3 years Control (1963–1966)	–	The probability of being overweight was higher in the provinces that experienced more severe famine compared to provinces that were less severely affected. Such differences were more pronounced in women

			0–2 years Control (1962–1964)		and gestational stage ($p < 0.05$ vs. control) Male subjects: Exposure to famine during toddler stage reduced body weight ($p < 0.05$ vs. control). No impact on the adulthood male body weight during gestational stage
Yang et al. 2008	2002 Chinese nutrition and health Survey	BMI	Faming group (1959–1961); mean age 0–2 years Control (1964)	38–43	The mean BMI of rural residents born during the famine years 1959–1961 were significantly higher than the control group ($p < 0.01$)

[a]approximate age estimation

of obesity, sarcopenia, and osteoporosis (Sayer and Cooper 2005). Epidemiological studies have investigated the association between BW and lean mass or fat mass in adult (Table 4). Studies suggest that BW or weight at 1 year old is associated to adult weight. Three studies have further examined the association between BW and body composition at young adult and elderly subjects. BW was associated with thigh muscle and bone area in young adults (Kahn et al. 2000) and total lean mass and muscle mass in elderly group (Gale et al. 2001; Kensara et al. 2005; Patel et al. 2011). More body fat and more central distribution of fat with a greater trunk to limb fat ratios was found in low BW group ($\leq$3.18 kg) at the age above 64 years old (Kensara et al. 2005). These studies suggest a positive association between BW and subsequent lean body mass and a negative association between BW and relative adiposity.

Table 4 Association between weights measured at birth and at infancy with fat mass and/or muscle mass

Number of subjects	Study population	Assessment age	Results
153 women	Resident in Bath UK	21	No significant association between BW and adult weight Weight at 1 year old was a significant predictor of adult weight ($r = 0.35$, $p < 0.001$) (Cooper et al. 1995)
224 men, 189 women	Born in Hertfordshire	63–73	BW was associated with adult weight in men only ($p < 0.001$) Weight at 1 year old was associated with adult weight in both sexes ($p < 0.001$) (Cooper et al. 1997)
102 men, 41 women	Living in Sheffield	70–75	BW was negatively associated with whole body total fat (23.09 kg for BW $\leq$ 3.15 kg vs. 21.03 kg for BW $\geq$ 3.64 kg, $p = 0.03$) BW was positively associated with whole body total lean mass (45.02 kg for BW $\leq$ 3.15 kg vs. 46.88 kg for BW $\geq$ 3.64 kg, $p = 0.002$) Data adjusted for age, sex, height, and weight (Gale et al. 2001)
192 men	White and black male for military service	17–22	For every kg increment in BW, BMI increased by 1.66 units ($p < 0.001$), thigh muscle and bone area increased by 16 cm^2 ($p = 0.0029$), waist circumference increased by 3.9 cm ($p = 0.0014$) No significant association with thigh subcutaneous fat area (log_{10} of cm^2) ($p = 0.086$) Data adjusted for race and height (Kahn et al. 2000)
32 men	Born in Hertfordshire	64–72	Low BW group ($\leq$3.18 kg) had a higher percentage of body fat (29.31% vs. 25.33% in high BW group ($\geq$3.86 kg), $p = 0.029$), fat mass (24.49 kg vs. 21.67 kg, $p = 0.039$) but a lower fat free mass (59.12 kg vs. 61.95 kg, $p = 0.039$) and muscle mass (27.23 kg vs. 29.22 kg, $p = 0.022$) Data adjusted for weight and height (Kensara et al. 2005)
105 men	Born in Hertfordshire	68–76	Low BW group ($\leq$3.18 kg) has a lower total lean mass ($p = 0.04$). However, results attenuated after adjustment for age, height, and physical activity ($p = 0.06$) (Patel et al. 2011)

Table 5 Association between weights at birth and at infancy and skeletal status

Number of subjects	Study population	Age	Results
153 women	Resident in Bath UK	21	BW and weight at 1 year old were not associated to BMD Weight at 1 year old was positively correlated with lumbar spine BMC ($r = 0.32$, $p < 0.01$) and femoral neck BMC ($r = 0.26$, $p < 0.01$) (Cooper et al. 1995)
224 men, 189 women	Born in Hertfordshire	63–73	BW and weight at 1 year old were not associated with BMD in both sexes Weight at 1 year old was associated with BMC in men at lumbar spine ($p = 0.03$), in women at lumbar spine ($p = 0.01$), and at femoral neck ($p = 0.01$) Data remained significant after adjusting for age, SES, smoking, alcohol consumption, calcium intake, activity level, and years since menopause (Cooper et al.1997)
55 men, 57 women	Resident in Finland	71	Poor growth rate was associated with hip fracture risk. The risk was 1.9 times higher in the lowest quartile in the growth rate of height ($p = 0.006$) and 1.7 times higher in the lowest quartile in the growth rate of weight ($p = 0.009$) (Cooper et al. 2001)
498 men, 468 women	Resident in Hertfordshire	60–75	BW was associated with BMC in men (proximal femur: $r = 0.16$, $p = 0.003$; lumbar spine $r = 0.10$, $p = 0.03$) and women (proximal femur $r = 0.16$, $p = 0.0008$; lumbar spine $r = 0.11$, $p = 0.03$) Weight at 1 year old also associated with BMC in men (lumbar spine $r = 0.17$, $p = 0.0001$; proximal femur $r = 0.22$, $p < 0.0001$) and women (lumbar spine $r = 0.13$ $p = 0.01$; proximal femur $r = 0.14$ $p = 0.002$) Data remained significant after adjusted for age, BMI, cigarette, alcohol consumption, physical activity, social class, years since menopause, and the use of hormone replacement therapy in women BW was associated with BMD in men in proximal femur only ($r = 0.10$, $p = 0.03$) Weight at 1 year old was associated with BMD in men in lumbar spine only ($r = 0.11$, $p = 0.01$) (Dennison et al. 2005)
102 men, 41 women	Living in Sheffield	70–75	BW and BMC was associated in men at lumbar spine (69.61 g for BW $\leq$ 3.15 kg vs. 78.23 g for BW $\geq$ 3.64 kg) ($p = 0.012$) and femoral neck (4.4 g for BW $\leq$ 3.15 kg vs. 4.73 g for BW $\geq$ 3.64 kg) ($p = 0.024$). No association with BMD BW and BMC was associated in women at lumbar spine (46.52 g for BW $\leq$ 3.15 kg vs. 56.41 g for BW $\geq$ 3.64 kg) ($p = 0.003$) and femoral neck (3.14 g for BW $\leq$ 3.15 kg vs. 3.72 g for BW $\geq$ 3.64 kg) ($p = 0.004$)

(*continued*)

Table 5 (continued)

Number of subjects	Study population	Age	Results
			BW was associated with BMD in women at lumbar spine (0.84 g/cm^2 for BW $\leq$ 3.15 kg vs. 0.96 g/cm^2 for BW $\geq$ 3.64 kg) ($p = 0.004$) and femoral neck (0.65 g/cm^2 for BW $\leq$ 3.15 kg vs. 0.75 g/cm^2 for BW $\geq$ 3.64 kg) ($p = 0.011$) Data adjusted for age (Gale et al. 2001)
866 men, 1282 women	Born in Hertfordshire	59–73	Men who have a fall history had a lower weight at 1 year old ($p = 0.04$) and poor conditional infant growth ($p = 0.02$) Poor conditional infant growth was associated with fall history in men only (OR 1.27, 95% CI 1.04–1.56 $p = 0.02$). Results attenuated after adjustment for adult grip strength, height, age, walking speed. No association was found in women (Sayer et al. 2006)

Osteoporosis is a skeletal disorder characterized by low bone mass and strength, deterioration of bony tissues, and increase risk of fracture. BW and weight at 1 year old as well as a poor growth rate are correlated with decreased BMC and increased risk of hip fractures in later life (Table 5). BW was associated with BMC in men and women at lumbar spine and femur neck (Dennison et al. 2005; Gale et al. 2001). Associations were also found with infant weight at 1 year old (Cooper et al. 1995, 1997; Dennison et al. 2005; Gale et al. 2001). However, the correlation between BW and BMD was less prominent in these studies. Low childhood growth rate in weight and height was associated with an increased hazard ratio for hip fracture at older age (Cooper et al. 2001) and it is usually found in men who had fall history in past years (Sayer et al. 2006). The strong association of BW with BMC suggests that there are prenatal and postnatal programmed factors in determining bone mineralization and risk of osteoporosis in later life (Dennison et al. 2005).

Muscle strength has a major impact on the age-related decline in physical performance and independence. It is generally studied by using hand grip strength (Kuh et al. 2002). The association of BW and grip strength in later life was studied (Table 6). Lowest BW ($\leq$2.5 kg) was associated with reduced grip strength (28.5 kg vs. 32.4 kg in the highest BW group, $p = 0.01$) (Sayer et al. 1998). Similarly, lowest weight at 1 year old was also associated with reduced grip strength ($p = 0.02$) (Sayer et al. 1998). In another study in which grip strength was assessed at age 53 years old, there was a positive relation between BW and adult grip strength in both sexes. For a 1 kg increase in BW, there was an estimated mean increase in grip strength of 1.83 kg in men (95% CI 0.52–3.19, $p < 0.01$) and 1.2 kg in women (95% CI 0.29–2.11, $p < 0.01$) when adjusted for adult body size, weight, and height (Kuh et al. 2002). These data suggested that children born into an adverse environment in which they had not gained weight in infancy would result in persisting consequences through later adult and such poor adult environment could possibly lead to more rapid aging as well (Sayer et al. 1998).

Table 6 Association between weights at birth and at infancy and grip strength

Number of subjects	Study population	Age	Results
1371 men, 1404 women	Birth in England, Scotland, Wales	53	Lower BW had a lower grip strength in men (45.9 kg at BW $\leq$ 3.06 kg vs. 50.6 kg at BW $\geq$ 3.87 kg p < 0.001) and in women (26.9 kg at BW $\leq$ 2.95 kg vs. 29.5 kg at BW $\geq$ 3.65 kg, $p < 0.001$) BW was associated with grip strength in both sexes. An extra kg of birth weight was associated with 1.83 kg difference in men and 1.27 kg difference in women ($p < 0.01$) Data adjusted for adult body size, body weight, and height (Kuh et al. 2002)
411 men, 306 women	Birth in Hertfordshire	65–74	BW was associated with grip strength (28.5 kg at BW $\leq$ 2.5 kg vs. 32.4 kg at BW $\geq$ 4.31 kg, $p = 0.01$) Weight at 1 year old was associated with grip strength (29.8 kg at weight $\leq$ 8.16 kg vs. 34.2 kg at weight $\geq$ 11.79 kg, $p = 0.02$) Data adjusted for age, sex, current social class, SES at birth, and height (Sayer et al. 1998)

Potential Mechanisms Linking the Effect of Famine during Childhood to the Body Composition

Phenotypic "plasticity" enables one's genotype to give rise to a range of different physiological or morphological states in response to different environmental conditions (Barker et al. 2002). It enables the production of phenotypes that are better matched to the environment. The mechanisms underlying the changes are still unknown. It has been postulated that genetic, physiological, behavioral, and environmental factors influence permanently in the cell proliferation and differentiations, heritable changes in gene expression, and alter the neuroendocrine systems which are crucial in the regulation of the body composition and physiological processes (Vickers 2011).

When the food intake is limited, the amount of glucose utilized by the body is reduced to a minimum since brain, kidney, and erythrocytes require glucose for their metabolism. The metabolic rate of the cells decreases significantly to allow for the subsistence of the organism as a whole (Kueper et al. 2015). Both the reduction of the basal metabolic rate and the nutrient deficiency contribute to the stunted growth. In addition, lower muscle mass resulted in reduced ability to metabolize calories and more likely to have positive calorie balance (Kahn et al. 2000). Stunted children had impaired fat oxidation and preferential oxidation of carbohydrate. The tendency to store fat was enhanced with this adaptation (Kulkarni et al. 2014) and permanently altered the number of adipocytes in the body (Sayer and Cooper 2005).

Furthermore, there are leading hypotheses that changes in stress hormones which could result in changing body composition (Kulkarni et al. 2014). Undernutrition is a powerful stimulator of stress leading to a reduction in growth hormones, insulin-like

growth factor-1, and thyroid hormones, resulting in impaired growth, lower energy expenditure, and a higher risk of positive energy balance (Fall et al. 1998; Kulkarni et al. 2014). These also alter the protective effect of bone health, reduce bone mineralization, and predispose an individual to an accelerated rate of bone loss during life (Cooper et al. 2002). The poor protein intake during famine could also reduce the intestinal calcium absorption as the results of secondary hyperparathyroidism and lead to a lower BMC (Matinolli et al. 2015).

Poor growth in early life is associated to lower muscle mass and poor muscle strength later in life and may lead to sarcopenia. The alteration of skeletal muscle morphology including the decrease in muscle fiber score and myofiber density may explain this association (Patel et al. 2011). Moreover, low BW was associated with increased proportion of type IIX fibers and deceased type IIA fiber. The increased in type IIX fiber may influence the whole body and muscle glucose metabolism, a situation which is similarly observed among patients with diabetes (Jensen et al. 2007).

Reversibility of the Developmental Programming

Fetal origins hypothesis proposes that alternations in fetal and postnatal nutrition and endocrine status result in the developmental adaptation that permanently predisposes the individual to higher diseases risk in adulthood (Barker et al. 2002). However, recent animal studies have suggested that developmental programming is potentially reversible by nutritional or targeted therapeutic interventions and may be able to ameliorate or reverse the consequences associated with developmental programming (Vickers 2011). Administration of leptin to rats that were undernourished in utero reversed the metabolic phenotype of insulin resistance and obesity that would otherwise develop in these animals (Guilloteau et al. 2009). Leptin given orally in rats resulted in lower body weight, lower fat content, and consumed fewer calories than their untreated controls at 6 months of age (Guilloteau et al. 2009). Another study in adult female rats also showed that IGF-I infusion led to a complete normalization of adiposity, fasting plasma insulin, and leptin concentration in the offspring (Vickers 2011). Furthermore, the effects of hyperleptinemia and increased fat mass development in rat were completely ameliorated by a diet high in omega-3 (Wyrwoll et al. 2006). These animal studies provide evidence for the possibilities of dietary manipulation on exacerbating programming effects. However, more research is needed to translate these animal studies to human settings.

Implementation

Animal studies and epidemiologic studies of human cohorts showed an association between undernutrition during gestation and at postnatal stages and future adult health. The process of adaptation that enables the infants to continue to grow may have adverse consequences for their health in later life. This association is likely to be reversed as demonstrated in animal studies recently. More work is needed to elucidate the mechanisms and identify the potential biomarkers responsible for the

adaptation process. With this information, it is useful to identify susceptible patients for dietary or nutritional interventions. A public health approach to promote optimal fetal and infant development through providing appropriate dietary advice is necessary. Reinforcing the awareness of health should be considered in terms of maternal and neonatal health, the growth of infant, their health as an adult, and even the health of subsequent generations (Gluckman et al. 2008). In addition, preventive strategies against obesity, osteoporotic fractures, and sarcopenia may be implemented at early life to improve BW and allow linear growth in children, and to promote optimal body composition and muscle strength, and minimize the potential loss (Kulkarni et al. 2014).

Conclusion

Evidence has shown that early nutrition factors may influence the long-term health and consequently the aging process. Under condition of suboptimal postnatal nutrition, infant must adapt to its environment and survive through such poor condition. However, such adaptations can lead to poorer muscle mass and higher fat mass (Gale et al. 2001, Kensara et al. 2005); lower grip strength (Kuh et al. 2002; Sayer et al. 1998), reduced BMC (Cooper et al. 1995, 1997; Dennison et al. 2005; Gale et al. 2001), and higher bone fracture and fall risk (Cooper et al. 2001; Sayer et al. 2006). Case studies on individuals in the Dutch Famine, the Great Leap Famine, and Holocaust survivors also supported the findings. The mechanisms for these adaptive changes are still unknown but it has been postulated that they are related to genetic, physiological, behavioral, and environmental factors (Vickers 2011). Recent findings on animals showed that the adverse consequences can be reversed by nutritional and pharmacological interventions. More research is needed to elucidate the underlying mechanisms for these adaptations and to identify the critical window period to reduce the associated diseases risk later in life.

Policies and Protocols

This chapter highlights the importance of early life nutrition on adult health, in particular the impact of famine in childhood on adult health with a focus on the changes in body composition including fat, muscle, and bone mass. In this chapter, we have described that BW and growth rate are both associated with the changes of body composition and skeletal status. We have also summarized that malnutrition or undernutrition in infants and early childhood leads to a disturbance in energy balance. Such energy imbalance could interact with the genome and lead to complex mechanisms which result in reduced body size and muscle mass, lower BMC and higher fat store. These changes can persist into aging which increase the risk of fall, osteoporosis, sarcopenia, and poor quality of life. To promote healthy aging, one should not only focus on the health status at mid-age adult but also the nutritional status at early ages. Therefore, nutrition intervention programs during

pregnancy and lactation are undoubtedly important to optimize the intrauterine environment and postnatal nutritional status from the public health perspective. However, current evidence is still lacking to justify any changes in dietary guidelines and dietary recommendations in these groups. More studies are needed to identify the factors that are associated with the delivery of nutrients in placenta, infant's adaption to a limited nutrient supply environment, and the possible mechanisms of this adaptive change on gene expression, body structure, and physiology. Further advances in this field may be able to reduce the prevalence of age-related diseases which represent the major healthcare issues in the aging population.

Dictionary of Terms

- **Aging** – Aging results in changes in body composition including increased total and abdominal fat accumulation, decreased lean muscle mass and bone mineral density. These changes predispose individuals to higher diseases risk, such as diabetes, heart disease, sarcopenia, and osteoporosis.
- **Famine** – Famine is a scarcity of food leading to malnutrition, starvation, and increased in mortality. Pregnancy and the first few years of life require adequate amount of food intake to support the growth and development of the infant. Limited food availability may lead to poor pregnancy outcomes and poor growth rate and may cause adverse health effects of the offspring in adulthood.
- **Fetal origins hypothesis** – It proposes that the period of gestation and early life has great impact on individual's development and health outcomes.
- **Optimal nutritional status** – It is a result by taking adequate amount and various types of nutrients so that the body can achieve the best performance and possibly a good health in lifetime.
- **Sarcopenia** – It is the loss of muscle mass, quality, and strength due to aging. It leads to higher risks of falls, mobility limitations, disability, and fractures. Exercise, in particular the resistant exercise is currently considered to be the best approach to delay its onset.

Summary Points

- Fetal origin hypothesis proposes that fetal growth condition is associated to the health outcome in adulthood. Epidemiological studies have shown that low birth weight and poor growth rate increase risk of obesity, diabetes, and cardiovascular diseases, possibly mediated through the changes in body composition.
- Evidence from animal model suggests that in utero or early life exposure to malnutrition affect body composition later in life including altered fat distribution, and reduced bone mineral content and muscle mass. However, translating such evidence to human setting is still difficult.
- People who were exposed to the Dutch Famine, the Great Leap Famine, World War II, or Nazi occupation generally showed higher body weight, poorer grip

strength, and physical performance, and/or lower bone density and higher risk of osteoporosis.

- Epidemiological studies support a link between infant weight and adult weight. Lower birth weight is associated with decreased lean muscle mass and increased fat mass.
- Infant weight is an important determinant of later bone health. Weight at 1 year old was associated with bone mineral content in women. Poor growth rate was related to a history of fall or hip fracture risk in individuals age 60 and above.
- Infant weight can influence the muscle strength in midlife which is associated with quality of life and independency in aging.
- Evidence of animal studies suggests that the developmental programming is potentially reversible.
- Dietary interventions for pregnant and lactating women allow optimal fetal growth and hence could lower the diseases risk in offspring in later life.

Abstract

Throughout history, populations have been exposed to periods of severe food shortage, famine, and starvation. Famine continues to be a major world health issue today with an estimated 794.6 million people (10.9% of the world's population) undernourished in the 2012–2014 period. Historical episodes of famine have sometimes allowed the effects on subsequent health to be studied in detail. For instance, during WWII, the studies of starved children in the Warsaw Ghetto documented bone softening, osteoporosis, and osteomalacia. Histologically the bone marrow was replaced with connective tissue and few myelocytes or chondrocytes were visible. Infants born to women who experienced famine during pregnancy may have increased risk for certain health conditions and there is evidence that musculoskeletal conditions may originate in the intrauterine period. Fetal programming is likely to increase the risk of osteoporosis when the environment during pregnancy is lacking in essential minerals and vitamins. The interplay between the three most important components of bone metabolic health, calcium, vitamin D, and vitamin K, often occur together in communities affected by hunger. Lack of adequate nutrition and vitamin D may lead to Rickets in children. Vitamin K deficiency can lead to intrauterine epiphyseal ossification and adolescent osteoporosis. Folic acid deficiency during pregnancy is also a key factor in neural tube anomaly development. Lathyrism due to famine-related dietary restriction to predominantly one food type, the lathyrus legume species, can lead to osteolathyrism. Symptoms include bone tissue hemorrhage, collagen disease causing bone softening, osteoporosis, and frequent fractures. Famine osteopathy is a conglomerate of metabolic aberrations resulting from nutritional deprivation. Developed countries that welcome immigrants and refugees from famine hit regions should make provision for screening and early detection of metabolic deficiencies such as osteoporosis.

WWII	World War II

Historical Background

Famine as a socioeconomic phenomenon was known in antiquity and the Latin term *famina* evolved later on in history into the French and English term famine. The quote by Zweig, a pacifist and pan-European writer, applies to both the ideological and social aspects of famine. In the twentieth century food production reached an all-time high, with sufficient levels for the entire world population. It is in this century that the unnecessary occurrence of famines is *one of terrible and inexcusable failure* (Devereux 1988). Despite high economic achievement *it is this century's shame* that over 75 million people perished during the twentieth century as a result of nutritional deprivation (Devereux 1988).

Developmentally, famine may be either acute or chronic. The syndrome of famine can also be categorized according to intensity into three distinct types: (i) mild, namely hunger; (ii) moderate, also called destitution or inanition; or (iii) extreme famine, leading to mortality. Howe and Devereux (2004) have called for a scale for famine rather than a binary, famine or no famine, categorization (Howe and Devereux 2004). The staggering figure of 75 million deaths due to famine in the twentieth century can be attributed to natural disasters, such as flood, drought, or earthquake; government or societal repression of populations; political or military invasion; or genocide.

Both World War I and II resulted in widespread destitution due in part to the destruction of crops and farmland. There was famine in Europe during WWI, and in Russia millions of people were victims of the 1917 October Revolution. There was the catastrophic Soviet food confiscation that led to over 6 million Ukrainian deaths between 1932 and 1934 (Davies et al. 2004). Famine also emerged in Europe following WWII and in Asia hunger spread to include India (3 million victims), Southeast Asia, Bangladesh (1.5 million victims), and Cambodia (2 million). Later on, famine was documented in Eastern and Central African countries such as Ethiopia (with 1 million victims) and Somalia and the Sudan (each with 0.5 million). However, by far the most catastrophic figures were revealed by China later in the century with as many as 33 million deaths due to the "Great Leap Forward" between 1959 and 1961. More recently there has also been famine in North Korea with a reported 3.5 million deaths between 1995 and 1999 (Goodkind and West 2001; Owen-Davies 2001). Famine remains a major world health issue today with an

estimated 794.6 million people undernourished in the period 2012–2014, accounting for approximately 10.9% of the world's population (World Hunger News 2016).

Pathology of Famine

The literature on socioeconomic aspects of famine is voluminous. Apart from widespread mortality, famine may also result in clinical sequelae for survivors. In the young and very old, the effect of famine on the immune system leads to vulnerability to infectious diseases, further increasing the risk of mortality (Barbosa-Saldivar and Van Itallie 1979). Famine may also lead to delayed symptomatology in the early adult lives of survivors.

Following the Siege of Leningrad (1939–1943), the population was exposed to prolonged famine; however, the wider world did not learn the full extent of the hardship until sometime later. During World War II the invading German army instituted a siege around Leningrad from September 1941 to January 1944 which lead to a reported 830,000 deaths as a result of the causes related to the population-wide famine. The population of Leningrad (now St Petersburg, Russia) at that time was 2.9 million of which 0.5 million were children (Sparen et al. 2004). Infection was often the main complication with diseases such as tuberculosis, dysentery, scarlet fever, and pneumonia the prevalent cause of death (Brozek et al. 1946). During the siege, severely restricted diets during pregnancy resulted in an estimated daily sustenance of only 300–800 calories. The rate of premature births was as high as 41.2%, with neonatal mortality rates of 9% for full-term births and 30.8% for premature births (Antonov 1947).

Some 40 years after the Siege of Leningrad, epidemiological studies of children born at the time of the siege were conducted at Stockholm's Karolinska Institute (Sparen et al. 2004). The authors concluded that:

> *Starvation, or accompanying chronic stress, particularly at the onset of or during puberty, may increase vulnerability to later cardiovascular disease.*

Figure 1 illustrates the increase in risk of cardiovascular mortality for males who were children during the siege compared to controls not exposed to famine.

Earlier studies had reported that adults who had been exposed to malnutrition or starvation *in utero* during the siege did not appear to be at increased risk of glucose intolerance, dyslipidemia, or cardiovascular disease, yet they were more likely to have endocrine dysfunction, and high blood pressure, if obese (Stanner et al. 1997). However, it is well-established that restricted growth *in utero* increases the risk of Type II diabetes, coronary heart disease, and hypertension in adult life (Barker 1998).

In November 1944, as a reprisal for an anti-German railway bridge strike, the occupying army instituted a food embargo over the western Netherlands. By April 1945, nutrition had been gradually reduced to 400 calories a day, with a reported 18,000 deaths in the Dutch famine (known as the "Hongerwinter") (van der Zee 1998; Susser and Stein 1994).

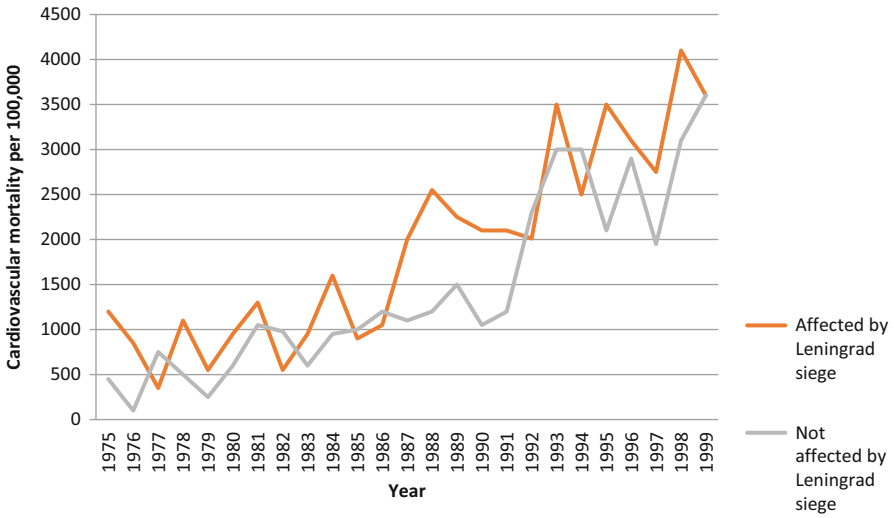

Fig. 1 Cardiovascular mortality in males exposed to famine during the Leningrad siege versus controls (Adapted from Sparen et al. 2004)

Records, studied some 40 years later at Amsterdam University, showed that small size and low birth weight were related to metabolic aberrations (in glucose and lipid levels), obesity, and increased mortality rate (Roseboom et al. 2006). Changes in reproductive function, early menopause, and increased breast and colon malignancy were also observed, all related to nutritional deprivation in pregnant women (Dirx et al. 2003; Elias et al. 2004).

During World War II, there was also severe food shortage on the Channel Islands, including Guernsey and Jersey, when they were demilitarized by the British in 1940 and then occupied by the German military. The invasion of Normandy in 1944 cut off the food supply to the 60,000 inhabitants of the five Channel Islands. Only a fifth of the population was evacuated, but those that remained endured a five-year long critical food shortage and famine. Islanders exposed to malnutrition as infants were later found to have increased cardiovascular morbidity, delayed puberty, and an increase in breast cancer, although statistically nonsignificant (Fentiman et al. 2007; Head et al. 2008).

Pathogenesis of Famine-Induced Metabolic Bone Disease

The concept of trimester-based intrauterine development has become essential for an understanding of fetal programming, including the programming of bone development.

Intrauterine conditions during the first trimester (the embryonic period) affect neuronal and mesenchymal-cartilaginous tissue development. The following 6 months of pregnancy, namely the second and third trimesters, are critical to the multiplication and growth of existing cells (Weisz and Albury 2014).

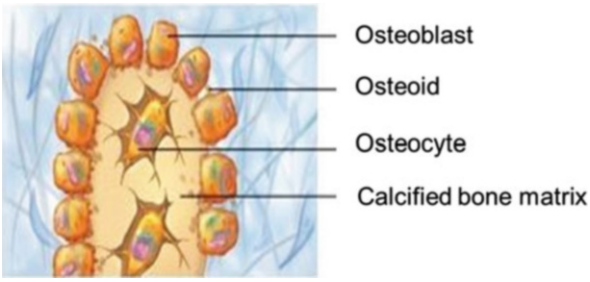

Fig. 2 Bone matrix, or osteoid, is secreted by the osteoblasts which then become calcified and develop into osteocytes

The second trimester is the time when the fetus is most sensitive to maternal metabolic status and dietary intake; direct effects on fetal adipose, muscle and bone formation have been observed. In the third trimester glucose and cortisol levels are critical, exerting effects on kidney formation, birthweight, limb length, and head circumference at birth, as well as postpartum maternal weight changes (Weisz and Albury 2014).

Maternal and fetal nutrition are in delicate balance and the state of maternal nutrition influences the fetal state by enforcing functional changes. Studies have shown that the second trimester is the most strongly affected by maternal metabolic intake. At this time, the adipose, muscle, and bone tissue formation takes place. An adaptation or reprogramming to the food shortage is applied: the number of cells formed is adjusted down; oxygen and nutrition are deviated toward the vital organs (brain, heart, arteries). The baby is at increased risk of being small in size with low birthweight and the foundation is laid for potential future neonatal, childhood, or adult diseases (Fig. 2).

Effect of Famine on Bone Metabolism

At this stage it is necessary to review normal fetal osteogenesis (Fig. 3).

The recognition of intrauterine starvation and its effect on bone metabolism followed on from studies on general metabolism. Numerous studies have observed that intrauterine skeletal development is under hormonal control, as well as dependent upon the availability of minerals and the vitamins D, B9 (Folate), and K (Weisz and Albury 2013).

Bone formation, or osteogenesis, is already evident by the fourth week of the embryonic period, but the bone is still a soft structure. In the developing fetus, mesenchymal cells are transformed into osteoblasts, and eventually further into osteoclasts, with two types of ossification: intramembranous axial ossification (skull, mandible, clavicle, ribs, and sternum genesis), or endochondral appendicular ossification (long bones, pelvis, and vertebrae) (Fig. 4). During the second and third trimesters, limb development continues with nonmineralized bone matrix being secreted by osteoblasts and then transformed into osteocytes.

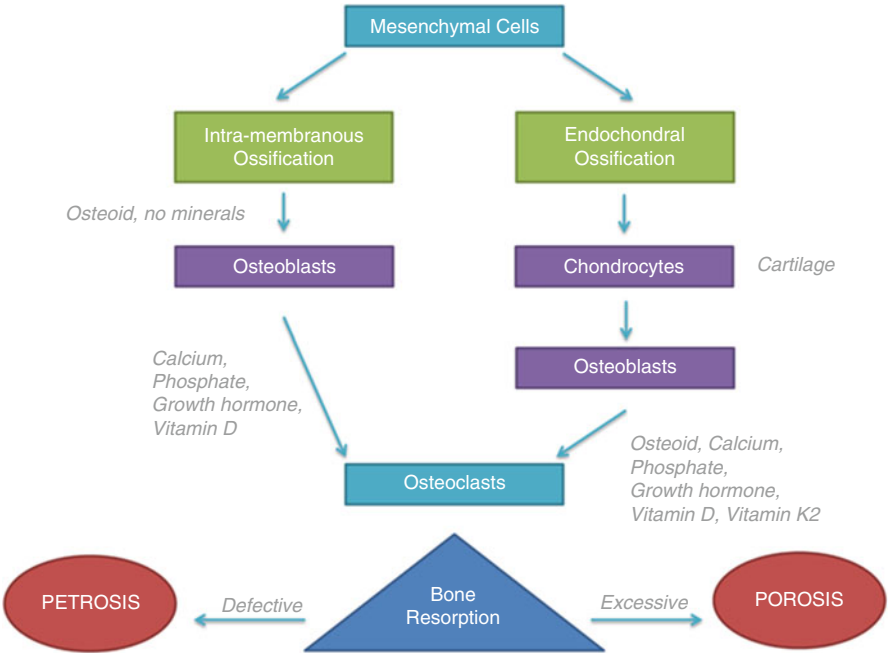

Fig. 3 Normal and pathological bone formation in the developing fetus (designed by author, G.M.W). Mesenchymal cells are pluripotent cells capable of differentiating into various cell types including osteoblasts, chondrocytes, myocytes, and adipocytes.

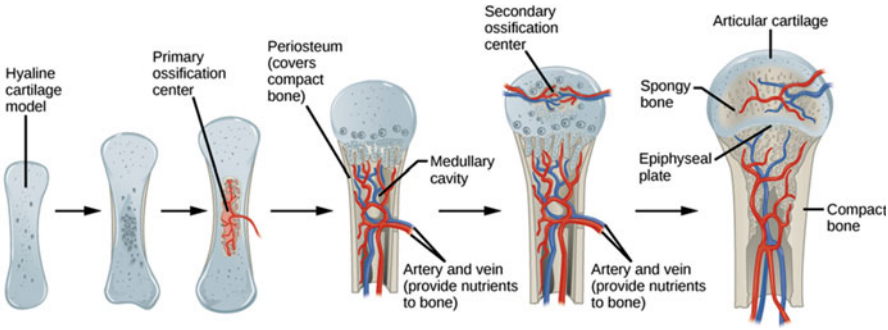

Fig. 4 Bone development [adapted from copyright free image http://cnx.org/contents/qmrJu64i@3/Bone (Accessed 21 Mar 2017)

In the bone marrow, the osteoblasts contribute to destruction of the central bone matrix. The matrix continues to absorb calcium, and the central bone space is emptied, while the bone grows externally toward the cortex/periosteum (Gilbert 2000).

A balance is maintained between osteoblast and osteoclast activities, under the influence of minerals (sulfur, calcium, phosphates, magnesium, selenium, strontium,

and zinc) and the vitamins D, B9, and K. This balance is also regulated by hormones (including pituitary, growth and parathyroid hormones); as well as glucose, cortisol, and the important osteoproteins. Vascularization of the bone leads to the blast/clast equilibrium, producing normal bone architecture. A disturbance in the blast/clast equilibrium can lead to osteopenia or osteoporosis if there is excessive osteoclastic activity, while reduced osteoclastic activity can lead to osteopetrosis.

Pathology of Famine Osteopathy

The effects of famine could result in either cortex trabecular decalcification or diminished osteoid/matrix formation, which then leads to rickets in children or osteomalacia in adults.

The Acute Effect of Famine on Bone Metabolism

The acute clinical signs of famine were detected in most tragic circumstances during WWII in the Warsaw Ghetto where over 200,000 people were incarcerated, with decreasing food supply which progressively diminished.

Teaching was considered unnecessary and was forbidden by the occupying authorities, but permission was given for a *Medics Course for Prevention of Epidemics*, which was transformed into a clandestine Medical School, conducted within the confining walls of the Ghetto. The faculty was comprised of 27 detained professors from various Polish universities. They conducted the teaching of medicine and also research into hunger. The preclinical studies were conducted in makeshift laboratories, while the clinical studies were conducted within six hospitals with mainly nocturnal lectures. The results of the research on hunger physiology were recorded with remarkable accuracy given the circumstances, and were smuggled out or buried in metal containers. These "archived" records were recovered after the war by the five surviving teachers, formulated into a book and published initially in Polish then in French, and finally in the USA, with commentaries by the Columbia University staff in New York (Winick 2005).

The researchers commented on the effects of hunger on metabolic pathways, as well as on cardiac, renal, pulmonary, and hormonal activities. They also described the softening and bowing of bones and the loss of bone fracture healing, making surgery impractical. Osteomalacia and osteoporosis were documented on autopsies performed on swollen, edematous children, abandoned and left dying on the streets. This was a rather rapid effect of inanition, the second effect of famine, which often progressed to the third effect – fatality. Histology obtained from autopsies showed the replacement of bone marrow with connective tissue, with a few myelocytes and chondrocytes remaining.

> *"Scientifically it still remains the most detailed study of semi-starvation ever carried out. It has had a profound influence on the way we treat this disease."* Winick 2005

The Chronic Effect of Famine on Bone Metabolism

According to the 1962 classification of Casuccio, which is still applicable today, osteoporosis develops in several ways (Casuccio 1962). These are:

(i) Primary osteoblastic deficiency, which may be congenital (*osteogenesis imperfecta*)
(ii) Reduced osteoblastic activity in the absence of trophic stimuli (inactivity, ovarian agenesis, testicular agenesis, menopause)
(iii) Reduced osteoblastic activity from inhibitory stimuli (Cushing's disease, excess adrenocorticotrophic hormone (ACTH), thyrotoxicosis)
(iv) Normal osteoblastic activity, but insufficient bone construction material (due to malnutrition, disturbances of the digestive system, insufficiency of vitamin C, diabetes, thyrotoxicosis, cortisone, ACTH, stress, Cushing's disease)
In view of recent developments in the late twentieth century, the above classification requires an additional category, namely:
(v) Fetal programming as a mechanism of osteoporosis development

Development of the Theory of Fetal Programming

The relationship of the theory of fetal programming to adult metabolic disease was first identified in the 1980s, after initially being analyzed from a pediatric perspective. The theory of fetal programming is often referred to as "The Barker Hypothesis" as the epidemiologist Dr David Barker initially identified a direct link between prenatal nutrition and late-onset coronary heart disease in poor areas of England (Barker and Osmond 1986). This theory has since been expanded to include additional conditions, with evidence of increased risk of stroke, hypertension, and diabetes due to impaired growth and development during fetal life and infancy (Barker et al. 2009; Barker 1997). Soon, the theory was extended to include skeletal pathology, with the risk of developing osteoporosis later in life being linked to undernutrition in fetal or early postnatal life (Cooper et al. 2000). The use of rat models showed the effect of altered nutrition *in utero* on bone biochemistry and strength, supporting the importance of the intrauterine environment on skeletal growth and later disease incidence (Lanham et al. 2008a, b).

Intrauterine Starvation and Bone Metabolism

It is unknown at what point in development the effect of starvation influences adult human development. However, epidemiological reviews have provided evidence that adult musculoskeletal conditions may be founded in the intrauterine period (Blyth et al. 2009). There is also evidence that epigenetic changes may affect placental transfer of nutrients, including calcium and vitamin D (Bocheva and Boyadjieva 2011).

In the 1990s, Cooper and associates developed the theory that compromise of the early stages of bone development due to reduced provision of nutrition, minerals,

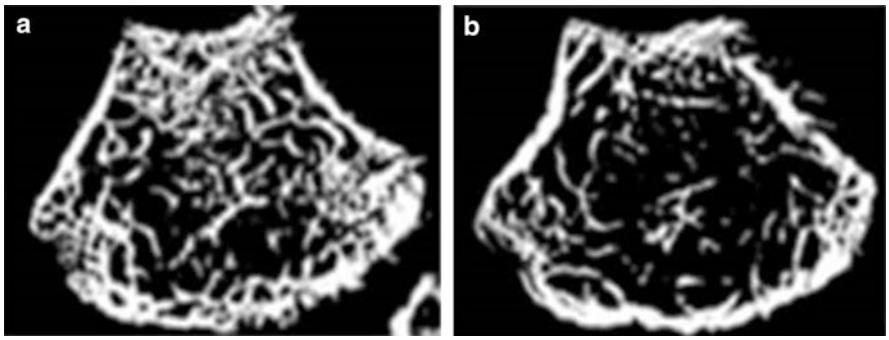

Fig. 5 Bone architecture seen in transverse cross-section (**a**) normal bone architecture. (**b**) osteoporotic bone. Note scarcity of bone trabeculi (computer design by author, GMW)

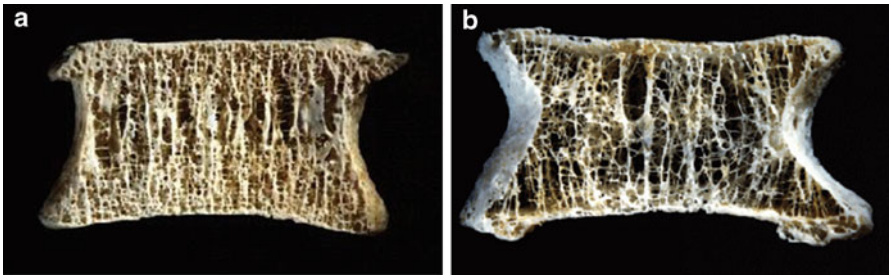

Fig. 6 Histology of normal and porotic bone

and growth factors could lead to changes in bone metabolism in adults.(Fall et al. 1998; Gale et al. 2001) The pathogenesis of osteoporosis was determined and a role was attributed to intrauterine programming (Cooper et al. 2000).

Further descriptions were published giving clear confirmation of the bone metabolic aberrations that result from intrauterine macro- and micronutritional deprivation (Weisz and Albury 2014, 2016). It was proven that even with the "catch-up phenomenon," whereby normal nutrition is achieved, not all bones achieve normal developmental growth (Weisz and Albury 2013; Weisz et al. 2012). Regardless of the mechanism, the end result is low bone tissue density, i.e., osteoporosis (Figs. 5 and 6). Famine therefore affects neonates, children, adolescents, and early adult life.

The Famine-Related Metabolic Bone Diseases

Rickets and Osteomalacia

The childhood form of osteomalacia, or rickets, is a condition resulting from a lack of vitamin D, which is essential for calcium absorption and bone mineralization. It is the result of a lack of ultraviolet sun ray exposure and of malnutrition. Vitamin D is

present in an inactive form in the skin and is partially activated by ultraviolet rays, a process completed in the liver and essential for the absorption of calcium and phosphates in the small intestine. Vitamin D, calcium, and phosphate are all necessary for calcification of the osteoid matrix of the bone tissue. Paradoxically, during starvation it has been observed that bone marrow adipose tissue increases and contributes to the weakening and softening of the bone and the lack of ability for fractures to heal (Devlin 2011).

Nutritional rickets may result from a lack of ingestion of eggs, fish oil, milk, or margarine; none of which are available in famine-affected areas, in squalors or natural disaster areas, and in prisons, ghettos, or concentration camps. The effect in childhood is on the epiphyseal growth area of the bones, which becomes low or completely devoid of matrix calcification, and the bone has no lateral expansion. In rickets, joint pain and swelling is clinically apparent, most evident at the wrist and ankle. Also apparent is the obvious lack of growth of long bones, spinal deformities, and bowing of long bones with fractures at the ends. Radiology of the lower ends of the radius and ulna shows cupping and fraying of the metaphysical regions. Blood tests reveal low levels of vitamin D and calcium. Histologically, unmineralized areas of matrix, surrounded by mineralized trabeculae, are detectable.

Osteomalacia, the adult form of induced-metabolic bone disease, resulting from lack of vitamin D has similar clinical joint signs. The histology is also similar, namely islands of unmineralized osteoid areas (Fig. 7).

Vitamin K Deficiency

Vitamin K was discovered incidentally in 1929 by Henry Dam in Denmark and was published as the K-oagulation vitamin in 1934 ("K" is derived from the German word "koagulation"); it was further chemically identified by E.A. Doisy. Both scientists were awarded Nobel Prizes in 1943, which were collected postwar in 1946.

Vitamin K consists of a group of three protein components:

(i) Vitamin K2, the most potent, has subtypes MK4 and MK7 (menaquinones). While absorbing calcium, MK4, and MK7 activate the osteoid in the matrix of bone by enzymatic carboxylation.
(ii) Vitamin K1 (or Matrix Gla protein) is protective against arterial wall calcification and cartilage ossification.
(iii) Vitamin K3 (or Protein S) promotes coagulation and its deficiency leads to childhood osteopenia and vertebral osteoporosis (Figs. 8 and 9).

Vitamin K deficiency leads to early intrauterine or early postnatal epiphyseal ossification (detectable by ultrasound), which may cause adolescent osteoporosis of the long bones and vertebrae, and also lead to early adult arterial wall calcifications. The early adult arterial wall calcification is paradoxically paralleled by osteoporosis.

The syndrome of vitamin K osteopathy is due to either malnutrition or malabsorption. This hemorrhagic syndrome, catastrophic during the early fetal intrauterine

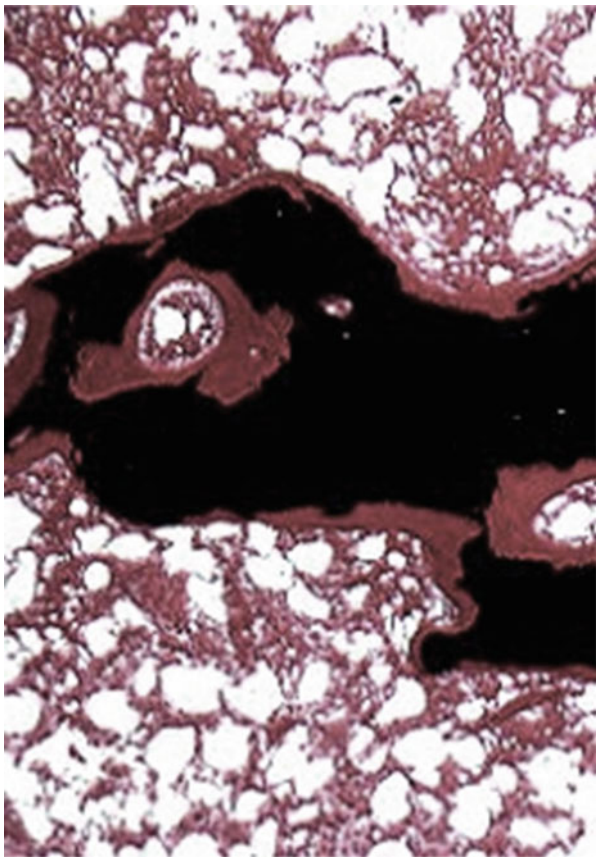

Fig. 7 Histopathology of osteomalacia showing islands of noncalcified bone

Fig. 8 Osteogenesis – the roles of Vitamin K and D in bone formation (Prepared by author, G. M. Weisz)

period, is at times also present in adults. Although vitamin K was discovered in 1929–1930, the osteopathic syndrome was only described in the late twentieth century and in more detail in the twenty-first century.

The condition is a famine-related syndrome that is typically found in regions affected by famine. The interplay between the three most important components of bone metabolic health: calcium, vitamin D, and vitamin K often occur together in communities affected by hunger (Dam 1946; Zetterstrom 2006).

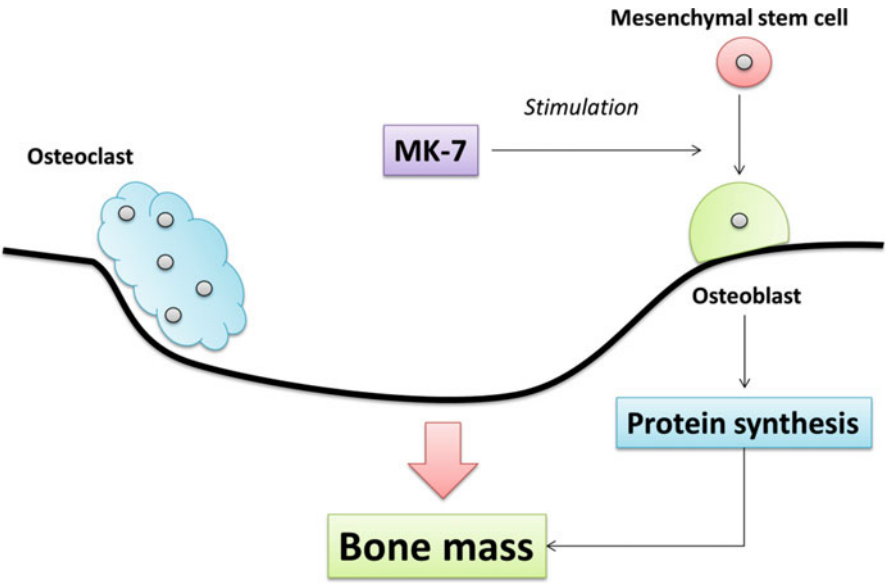

Fig. 9 The role of menaquinone 7 (MK-7) in bone formation (Prepared by author, G. M. Weisz)

Folic Acid Deficiency and Skeletal Malformations

Nutritional deficiency of folic acid leading to anemia was studied in 1930 by Lucy Wills in the subcontinent of India. Wills observed the high frequency of neural tube anomalies (NTA): spina bifida, meningocele, myelomeningocele, and also cranial abnormalities such as facial split, hydrocephalus, and anencephaly (Hoffbrand and Weir 2001).

Perhaps the geographical distance of the publication (in the Indian Journal of Medical Research) caused the considerable delay in recognition of this important observation in Western Medicine. Indeed, it was not until the late twentieth century that research in the UK, Europe, and the USA was directed towards understanding the interdependence of folate and NTA.

Numerous publications described the correlation without being definitive about a direct causal relationship (Smithells et al. 1976, 1977). It was in 1988, in Western Australia, that Bower and Stanley established a definite causal relationship (Bower and Stanley 1989). In the 1980s, it was the contribution of Wilson (Wilson et al. 2003), Smithells (Smithells et al. 1980), Schorach (Schorah et al. 1983), Laurence (Laurence and Campbell 1981; Laurence et al. 1981), and others that raised awareness of the relationship between folate (vitamin B9) and NTA. This was followed by an authoritative editorial in The Lancet in 1991 (MRC Vitamin Study Research Group 1991), further reinforced in a detailed monograph by Bannister (Bannister and Tew 1991). In 1996, the mechanism of pathogenesis resulting from folic acid deficiency and the parallel increase in homocysteine was suggested by Rosenquist (Rosenquist et al. 1996). In 1998, the Academy of Pediatrics, USA, determined the

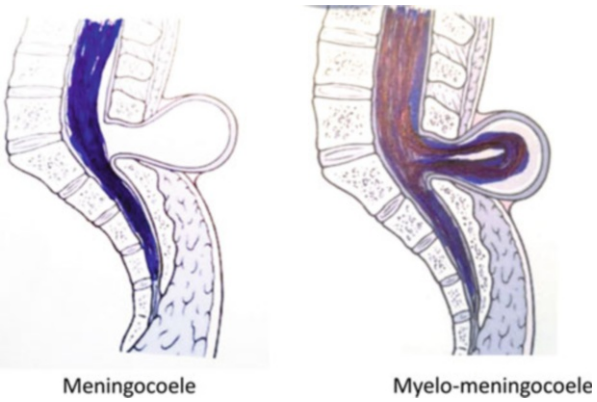

Fig. 10 Spina bifida meningocele and myelomeningocele (Drawn by author, G. M. Weisz)

prophylactic, preconception, primary, and secondary treatment for recurrent cases and this was further reinforced by the Royal College of Obstetricians & Gynaecologists, UK, in 2004 (Clarke 2004; Evans et al. 2004).

The pathology of folate deficiency is anemia, fatigue, gastrointestinal disturbances, hearing loss, and cardiac anomalies. The impact on development of the central nervous system ranges from asymptomatic, to moderate, to catastrophic. The neural canal, an invagination of the ectoderm, develops into the spinal canal to be closed posteriorly by pedicles and laminae. This will form a tube containing the dural (neural) sac, with the spinal cord, from the base of the skull to lumbar two vertebral level and containing the cauda equina nerve conglomerate down to the sacral canal.

Failed closure of the tube leaves the L4-5 and sacral areas open most frequently, exposing the nerves to external pressure. This spina bifida is not infrequent, is mostly asymptomatic, discovered incidentally, and at times covered by a hairy formation over the regional skin area. A more serious cystic bulging may emerge externally, the meningocele and occasionally with nerve content, the myelomeningocele. Surgical correction is possible at times leaving neurological signs of paresis, paralysis, sphincter incontinence, and erectile dysfunction (Fig. 10).

Nutritional folate deficiency is almost inexistent in developed countries, except perhaps due to malabsorption following surgical excision. However nutritional deficiency is present in famine hit areas of sub-Saharan and the East-Asian desert regions.

Metabolic Bone Disease due to Famine-Imposed Lathyrus Ingestion

Mesenchymal membrane changes leading to osteoblastic malfunction and ending in disturbed bone metabolism have been observed following the ingestion of toxic substances, in a similar way to the teratogenic effect of thalidomide on limb development and the effect of alcohol on the development of the corpus callosum in the brain.

The toxic effect of grass pea variants of *Lathyrus sativus* or *Lathyrus odoratus* was known to Hippocrates and was also described by Ramazini in seventeenth century

Modena. In Bavaria, it was forbidden to consume Lathyrus by the Duke of Wittenberg in the eighteenth century, its availability was widespread in India in the nineteenth century. Lathyrism was a condition reported in Spain during the Civil War in the 1930s.

During WWII, the ingestion of grass pea was imposed by the Romanian authorities as the sole source of food in the Vapniarca concentration camp (Transnistria, Ukraine) on a population of some 100,000 incarcerated people (Weisz 2016). On observing the symptoms, an ingenious prisoner physician, Dr Arthur Kessler (1903–2000), unlikely to have had any former knowledge of this historical condition which did not exist in Europe at that time, recorded some 1,800 patients with various degrees of paralytic signs. This eventually forced the authorities to allow access to alternative food types. Two hundred survivors of this camp were examined after the war in Tel Aviv's Ichiloff University Hospital (Cohn and Streifler 1981a, b, 1983) and together with the prisoner physician's notes, the condition was revived in the literature.

It was a group of Belgian researchers, led by Lambein, who eventually discovered that the toxic compound in the grass pea was ODAP (L-amino acid alanine derivative), and was the cause of what became known as the complex condition **neurovasculo-osteo-lathyrism** (Haque et al. 1996; Ngudi et al. 2012; Riepe et al. 1995).

The Pathology of Lathyrism

Neurolathyrism, a motor neuron disease of the thoracic spine, demyelination, and degeneration of the anterior horn cells, was described clinically and reproduced experimentally (Getahun et al. 2002; Belanger 1959). Changes were localized to the thoracic cord using MRI studies. Neurolathyrism was characterized by symptoms including wobbling, scissor walk, collapsing gait, spastic paralysis of the legs, and incontinence.

Vasculo-lathyrism is characterized by fragility of blood vessels and connective tissue, thrombosis, gangrene of lower limbs, and development of aortic aneurism.

Osteolathyrism results from ingestion of both lathyrus legume species, but mostly *L. odoratus*, which influences bone turnover, softening the bone due to collagen disease. Hemorrhage in the bone tissue is also observed, due to fragility of arterioli, eventually developing into osteoporosis and frequent fractures. These symptoms occur as a result of the second identified toxic amino acid (beta-amino-propio-nitrite), promoting the formation of exostosis and development of kyphoscoliosis.

As an aside, it is interesting to recall the Spanish painter, Francesco Goya's graphic illustration of the crippled woman lying on the floor, in an early nineteenth-century print, with the title of *Gracias a la almorta* (Fig. 11).

Famine Osteopathy and the Medical and Legal Implications

Famine osteopathy is a conglomerate of metabolic aberrations resulting from nutritional deprivation with a clear clinical symptomatology and distinct histopathological features. The pathogenesis is clearly established. The outcome in general is

Fig. 11 'Thanks to the millet (grass pea flour)', ca. 1810, aquatint print by Francisco Goya [public domain]

described as a benign, nonfatal condition, except for embryonic vitamin K deficiency and lathyrism. The main malignant complication of the bone disease is major fractures and their consequences.

In developed countries accepting immigrants and refugees from famine-hit countries, the medical community has an obligation to facilitate early detection of metabolic deficiencies. The diagnosis should be based on clinical examination and serum analysis for early detection of metabolic deficiencies, testing that (in the Australian healthcare system) would cost less than $50.The respective health authorities also have an obligation to expedite treatment of any diagnosed conditions, particularly in light of the fact that all diseases, except lathyrism, are curable. Similarly, all the discussed metabolic bone diseases are preventable.

Hypocalcemia and Osteomalacia

The famine osteopathy induced by hypocalcemia, namely osteoporosis, is curable with calcium supplementation or calcium-rich diet. Calcium is present in food such as meat, eggs, and dairy products. The daily recommended intake is between 700 mg and 1200 mg a day (as recommended by the National Institutes of Health, USA) a dosage also accepted by the British Health Authorities and the Australian Dietary Guidelines of the Department of Health, 2013. See Appendix A.1.

Rickets and Osteomalacia

In rickets and osteomalacia, mineral homeostasis can be achieved with double or triple doses of vitamin D, namely up to 1000–2000 IU per day. It is a preventable and treatable metabolic bone disease. The treatment is successful with the daily

requirement of 50 nmol per litre and is obtained from ultraviolet skin exposure and consuming milk products, meat, fish, and eggs (Munns et al. 2016).

Vitamin K Deficiency

Vitamin K deficiency requires consumption of 1 mg per day of vitamin K, although less is required in childhood (around 90 mcg a day). Apart from bone health, supply of the vitamin is beneficial in blood clotting and in prevention of arterial wall calcifications. It is available from foods such as greens (turnip, spinach broccoli, kale, etc.). It is also found in meat (chicken, beef), butter, and cheese, which is unlikely to be available in the famine-ravaged regions. Deficiencies caused by malabsorption and malnutrition are curable and preventable.

Folate Deficiency

The recommended dosages differ according to the severity of the pre-existing condition. For those in the low-risk category (no prior case of neural tube defect in the family of either parent), 0.4 mg folic acid a day starting 2 months preconception (in a planned pregnancy) to be continued until the end of lactation is recommended. In those with a moderate risk (with history of prior incident in either of the parent's family), the recommended daily dose increases to 1 mg a day, starting at three months preconception and lasting until the end of lactation. For those at high risk (previous child with NTA born to the same parents), the recommended dosage is 4 mg for the same period of time. Folates are readily present in meat, milk, and liver, which are all rarely available in famine ravaged regions. Folates are also found in green leaves, spinach, beans, turnips, etc.

Lathyrism

Lathyrism requires palliative treatment for instability, immobility, and/or incontinence. Prophylactic measures were outlined at the "Workshop on toxiconutritional neurodegenerations konzo and lathyrism," held at Ghent University in September 2009. Various dilutions of the legumes by water bleaching reduce the toxicity of ODAP. Combining grass pea with grain reduces the frequency of the condition. Lathyrism is an incurable condition. However, the condition is preventable and requires education of often illiterate and/or poorly educated people living in famine-ravaged regions of Asia (India, Nepal, Bangladesh) and in the Horn and Sub-Saharan regions of Africa (Ethiopia, Sudan, etc.). Australian researchers intend to improve the quality of grass pea crops by reducing ODAP toxin levels, thus making this highly drought resistant and nutritious crop safe for human consumption in drought-ravaged areas of the globe (Dixit et al. 2016).

Policies and Protocols

Clinical examination and serum analysis for early detection of metabolic deficiencies should be considered, particularly in immigrants and refugees who have been exposed to famine.

Vitamin and mineral supplementation that could be considered in famine-exposed areas, for prevention of deficiencies resulting in bone disease:

- **Calcium** (daily recommended intake is between 700 mg and 1200 mg)
- **Vitamin D** (1000–2000 IU per day)
- **Vitamin K** (1 mg per day)
- **Folic Acid** (0.4 mg per day during pregnancy and 2 months prior to conception)

Dictionary of Terms

- **Lathyrism** – Osteolathyrism occurs during times of famine when the diet is predominantly reliant on Lathyrus species of legume (grass pea). Symptoms include neurological symptoms and collagen cross-linking abnormalities leading to weak bones and frequent fractures.
- **Neural tube anomaly** – Neural tube anomalies, including spina bifida and anencephaly, may result from a diet deficient in folic acid during pregnancy. This deficiency can affect the development of the brain and spinal cord.
- **Osteoblast** – Osteoblasts are cells which produce bone.
- **Osteomalacia** – Osteomalacia is a deficiency in the bone-building process resulting in bone softening. Osteomalacia is usually a result of calcium or vitamin D deficiency.
- **Osteoporosis** – Osteoporosis is a condition in which bones become more brittle and less dense due to a loss in minerals such as calcium. People with osteoporosis have an increased risk of fractures.
- **Rickets** – Rickets is a bone disease occurring in infants and children usually caused by a lack of vitamin D. Rickets results in soft, weak bones and may lead to skeletal deformities, muscle weakness, and delayed growth.

Summary Points

- Famine affects an estimated 794.6 million people worldwide (2012–2014), accounting for approximately 10.9% of the world's population.
- Throughout history there have been opportunities to study the effect of starvation and famine on populations including the Leningrad siege, the Dutch Hongerwinter, and the Warsaw ghetto.
- In the Warsaw ghetto, one of the most detailed studies of starvation was conducted by a group of imprisoned physicians. Severe food restriction led to bowing of bones, osteomalacia, and osteoporosis in children with histological evidence of bone marrow being replaced with connective tissue.

- The risk of developing osteoporosis in later life has also been linked to undernutrition during the fetal period.
- During periods of famine, there is evidence that maternal epigenetic changes may affect placental transfer of essential nutrients for bone development including calcium and vitamin D.
- Osteomalacia, or rickets, is a condition resulting from a lack of vitamin D. Vitamin D is essential for calcium absorption and bone mineralization, and its deficiency may occur due to a lack of ultraviolet sun ray exposure or malnutrition.
- The interplay between the three most important components of bone metabolic health, being calcium, vitamin D, and vitamin K, often occur together in communities affected by famine.
- Vitamin K deficiency can lead to intrauterine epiphyseal ossification and adolescent osteoporosis.
- Folic acid deficiency during pregnancy is a key risk factor for neural tube anomaly development.
- Lathyrism due to famine-related dietary restriction to predominantly one food type, the lathyrus legume species, can lead to osteolathyrism. Symptoms include bone tissue hemorrhage, collagen disease causing bone softening, osteoporosis, and frequent fractures.

All Metabolic Bone Disorders Resulting from Malnutrition Are Preventable and All Osteopathies, Except Lathyrism, Are Curable

Daily Requirements (Nat Inst Health USA)

Life stage group	Calcium recommended dietary allowance (mg/day)	Vitamin D recommended dietary allowance (IU/day)
0–6 months	a	b
6–12 months	a	b
1–3 years old	700	600
4–8 years old	1,000	600
9–13 years old	1,300	600
14–18 years old	1,300	600
19–30 years old	1,000	600
31–50 years old	1,000	600
51–70 years old	1,000	600
51–70 year old females	1,200	600
71+ years old	1,200	800

[a]For infants, Adequate Intake is 200 mg/day for 0 to 6 months of age and 260 mg/day for 6 to 12 months of age

[b]For infants, Adequate Intake is 400 IU/day for 0 to 6 months of age and 400 IU/day for 6 to 12 months of age

Suffering the Great Hunger: Scurvy and Tuberculosis as Reflected in Skeletons of Victims of the Great Irish Famine (1845–1852)

11

Jonny Geber

Contents

Abstract

The Great Famine in Ireland between 1845 and 1852 was one of the worst health calamities of the nineteenth century. In recent years, palaeopathological analyses of human skeletal remains from archaeologically excavated famine mass burials from Ireland have revealed the physical impact of health deprivation due to starvation and infectious disease. Vitamin C deficiency and tuberculosis were two conditions that caused immense suffering during this period, and which are observable in the skeletal remains of the victims of the Famine. The manifestations of these reveal aspects of physical exhaustion but also that of recovery. Bioarchaeology – which is the study of human remains from archaeological contexts – provides a unique insight how the human experienced famines in the past. In the context of the Great Famine, it has provided means to acknowledge

Introduction

Health conditions in human populations change with societal transformations. This occurred, for instance, alongside and following the agricultural transition about 10,000 years ago (Cohen and Armelagos 2013). An increasing dependency on agricultural produce made populations more vulnerable to crop failures with famines occurring as a consequence. Famines and human starvation are mentioned in some of the most ancient literary sources in the world, such as, for instance, the *Epic of Gilgamesh* dating to c. 2000–1400 BC (Geber 2015a). In addition to written sources, archaeology also provides the means to study how these conditions may have been expressed in past societies. A particularly valuable insight is gained from direct studies of the people themselves, by assessing the evidence of disease and starvation through bioarchaeological analyses of human bones and teeth. Using the most commonly accepted definition, bioarchaeology is the study of human skeletons from archaeological contexts in a broad anthropological sense that takes the social and cultural context in which they lived into account (Buikstra 2006). By investigating how the skeleton adapts to social, cultural, and ecological environments, bioarchaeology enables a unique and direct insight into the living conditions people experienced. This insight is yielded in particular from palaeopathological research, which aims to assess and describe the evidence and consequence of disease in past societies.

While bioarchaeology and palaeopathology have the means to detect the effects and consequences of famine and starvation in past societies, it is only in recent years that these topics have been studied (e.g., Beaumont and Montgomery 2016; Geber 2015b; Yaussy et al. 2016). A characteristic feature of famine, in general terms, is an excess death rate that is leaning towards particular age groups and social levels of a given population – namely, the weakest and most vulnerable such as the young, the old, and the poor (Ó Gráda 2009). This pattern is potentially discernable from a contextual analysis of archaeological burial grounds and by assessing the mortality profile of the dead (based on the estimated age-at-death) who were interred therein (see Chamberlain 2006; Margerison and Knüsel 2002). The human skeletal response to starvation is potentially detectable by observing elevated nitrogen levels ($\delta^{15}N$) in bone and teeth collagen as a consequence of a prolonged period of severe malnutrition that has resulted in the body attempting to regain energy by obtaining it from its own protein tissue (Beaumont and Montgomery 2016). Likewise, sudden dietary shifts due to the consumption of so-called "famine foods" may also be detectable in stable isotope analysis of skeletal tissue (Beaumont and Montgomery 2016).

In addition, the bone remodeling process might become altered and result in decreased bone mass and osteopenia (Brickley and Ives 2008; Ortner 2003). However, in general death by famine and starvation is analogous with death by disease, in particular, infectious ailments, but also metabolic diseases due to malnutrition. Most infectious and metabolic conditions will not manifest skeletally, but when observed in the human remains they provide the most tangible insight into the nature of suffering disease for the people who lived before the advent of antibiotics.

Death by Famine: The Kilkenny and Clones Union Workhouse Mass Burials

An intense level of suffering is evident from the skeletal remains of victims of the notorious Great Famine in Ireland (1845–1852) that have been discovered during archaeological excavations in recent years. Two such important discoveries are the mass burial grounds at the former workhouse institutions in Kilkenny City in County Kilkenny (Geber 2015b; O'Meara 2006) and Clones in County Monaghan (O'Donovan 2012; Fig. 1). In both of these cases, the local awareness or archival records relating to these mass burial grounds did not exist and they appear to have been intentionally repressed from communal memory in the years and decades that followed the Famine. A total of 970 skeletons were unearthed from the Kilkenny mass burials and 35 individuals from Clones (Fig. 2). They constitute the remains of individuals on the lowest rank of the social scale who were incarcerated in institutions that through their very function exposed them to further demeaning treatment. Although there are physical testimonies to a horrid period in Irish history, the analysis and study of the remains has been able to bring some humanity and dignity back to these people who were treated extremely badly in life, by telling their story and acknowledging their lives and what they experienced in the final months leading up to their deaths.

The Great Famine in Ireland – also known as the Great Hunger or *An Gorta Mór* – has been described as "the greatest social disaster of nineteenth-century Europe" (Eagleton 1995, 22). It is in terms of relative mortality outcome one of the worst subsistence crises in human history (Ó Gráda 2007). The Famine was the result of a potato blight *(Phytophthora infestans)* that arrived in Ireland in the late summer of 1845 and then quickly spread across the country (Zadoks 2008). A vast proportion of the population, who were completely dependent on the potato crop for their subsistence, suffered famine as a consequence. The estimated numbers of famine deaths have ranged from about 800,000 to one million, which comprised over 10% of the total population of Ireland at the time (Boyle and Ó Gráda 1986; Cousens 1960). A great proportion of these, about 20% (c. 200,000), took place in the notorious workhouse institutions (Guinnane and Ó Gráda 2002). These establishments (Fig. 3a), which were operating on the notion that only those "deserving" of relief (i.e., the most desperate, impaired, and critically ill) would be allowed access, were operating under severe financial and logistical strains during the Famine period (O'Connor 1995, 121–143). Originally intended to provide accommodation for

Fig. 1 County map of Ireland, with the geographic locations of Kilkenny and Clones. Based on template by Alan O'Rourke (©www.toodle.com), used by permission

80,000–100,000 people across all of Ireland (Kinealy 2006; O'Connor 1995), by September 1849, about 250,000 were dependent on indoor relief (Donnelly 2001). Overcrowded conditions meant that the spread of infectious disease became rampant and the mortality rates were exceptionally high. This, in turn, resulted in considerable logistic (and economic) difficulties relating to the burial of the dead, who in many places were interred in non-consecrated grounds, in mass burials, with no ceremony (Geber 2012).

The Kilkenny Union Workhouse (Fig. 3b) opened in April 1842 and was built to accommodate 1,300 inmates. During the Famine, however, the institution became severely overcrowded, developed into a hotspot for infectious disease, and there

Fig. 2 In-situ photographs of skeletons of victims of the Great Irish Famine at the Kilkenny and Clones Union workhouses. (**a**) The remains of a 2–3 year-old-child (left) and an older adult (≥46 years) female (right) buried at the Kilkenny Union Workhouse (Photo: Margaret Gowen & Co. Ltd). (**b**) The skeleton of an adolescent aged approximately 13 years at the time of death from Kilkenny (Photo: Margaret Gowen & Co. Ltd). (**c**) The burial of an older adult (≥46 years) female from Clones Union Workhouse (Photo: Edmond O'Donovan & Associates)

were mass deaths as a result. Between August 1847 and March 1851, inmates were buried in mass burials within the grounds of the workhouse at the back of the establishment, a short distance from the infirmary block (Geber 2015b). A similar situation appears to have taken place at the union workhouse in Clones. Mass burials adjacent to where the boundary wall and the mortuary building of the institution once stood were discovered in 2012, and the dead had, just as in Kilkenny, been interred by being placed in the graves on top of each other (O'Donovan 2012). The workhouse in Clones first opened in February 1843 and was constructed to provide relief for 600 inmates (O'Connor 1995). In June 1849, however, over 1,600 people were dependent on indoor relief in Clones, and hundreds of people were housed at auxiliaries at various locations in the town and its vicinity (MacDonald 2000).

Suffering the Great Irish Famine: The Palaeopathological Evidence

It is not possible to determine the direct cause of death of the individuals who were interred in the Kilkenny and Clones mass burials from their skeletons, but the historical sources reveal that it was most likely due to infectious disease (Census of Ireland Commission 1856). These were generally described as "famine fever" and

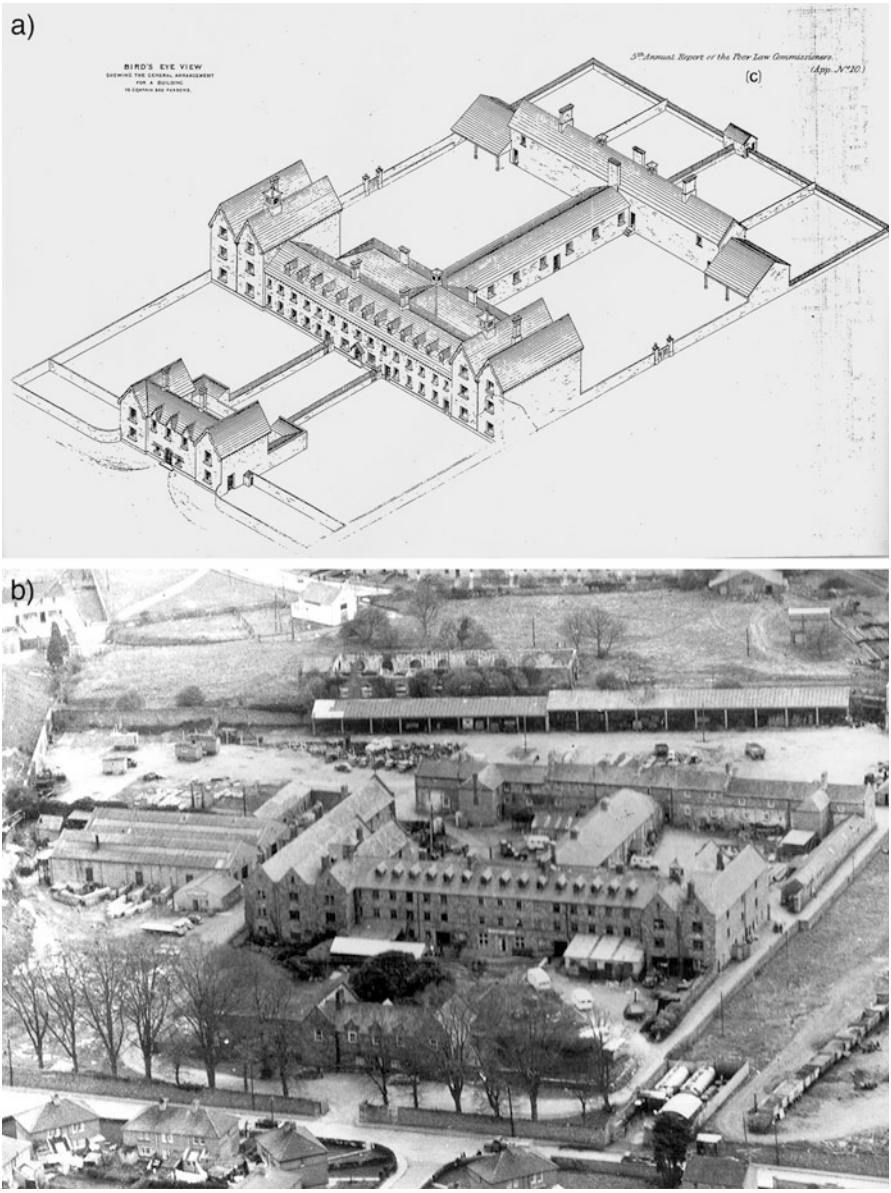

Fig. 3 (**a**) The general layout of the typical Irish union workhouse institution, as designed by the English architect George Wilkinson (1814–1890) (Source: *5th Annual Report of the Poor Law Commissioners, Appendix no. 10*). (**b**) Aerial photograph of the Kilkenny Union Workhouse, when the buildings functioned as a depot for the Kilkenny County Council during the 1960s (Source: Kilkenny County Library, Local Studies, courtesy of Karyn Deegan)

would have included conditions such as typhoid, typhus, and relapsing fever (Mokyr and Ó Gráda 2002). Infectious diseases spread quickly across Ireland during these

years, as the population was weakened by severe malnutrition and starvation. The highest famine-induced mortality was seen in the winter of 1846 and 1847 when an epidemic of typhus – and other diseases – tragically resulted in the deaths of an estimated 400,000 men, women, and children (Kinealy 1997, 79). The year 1847, which would later be called "Black '47," was the year when the highest relative numbers of excess deaths were recorded in both County Kilkenny and County Monaghan, as well as most of Ireland (Cousens 1960). It was during 1847 that the intramural burial ground in Kilkenny was taken in use, and it is likely that the mass burials discovered at Clones include interments of inmates who perished during this specific period of mass mortality.

Vitamin C Deficiency

Pathological changes in the Kilkenny and Clones skeletons reveal that they suffered from severe metabolic stress in the period leading up to their deaths. The most evident of these were the widespread manifestation of osseous lesions indicative of Vitamin C deficiency or scurvy. This debilitating and often extremely painful disease became very common in Ireland following the destruction of the potato crop in the 1840s, and it would have been synonymous with the physical experience of the Famine for those who suffered the most. Prior to the blight, the required daily amount of Vitamin C that is required to sustain good health would have been more than plentifully provided for by the potato (Crawford 1988). Scurvy was therefore rarely encountered amongst the agricultural populace in Ireland prior to the blight, and in the early years of the Famine it was often misdiagnosed (ibid.). To diagnose scurvy in skeletal tissue is not straightforward, as many of the lesions it produces are nonspecific and can occur in other conditions (Brickley and Ives 2008). What is considered a virtually pathognomonic skeletal marker of scurvy is the manifestation of porotic lesions at the site of the attachments of the masticatory muscles on the temples of the skull (Fig. 4) and of the lower jaw, as well as abnormal porosity around the sockets of the teeth (Fig. 5) and of the hard palate (Ortner et al. 2001; Ortner et al. 1999). Layers of new bone may also form at the site of muscle attachments elsewhere on the skeleton, i.e., the shafts of the long bones and on the scapulae (shoulder blades) (Brickley and Ives 2008). These manifestations are the result of hemorrhage, which in turn is linked to micro-trauma of soft and hard tissues that is weakened due to impaired collagen formation in the body and the skeleton (Ortner 2003).

Nearly 52% of all skeletons from Kilkenny and 29% from Clones showed evidence suggestive of scurvy (Table 1). This is an exceptionally high rate in comparison to other bioarchaeological samples that have rarely revealed crude prevalence rates exceeding 5% (Mays 2014). The true rate of individuals suffering from the disease in Kilkenny and Clones cannot be ascertained however; the skeletal manifestation of Vitamin C deficiency is a paradox as it is only evident once some Vitamin C has been reintroduced to the system. Without the vitamin, the osseous lesions from which the disease is diagnosed skeletally cannot form (Brickley and Ives 2008). The high rate of scurvy in both the Kilkenny and Clones is instead a

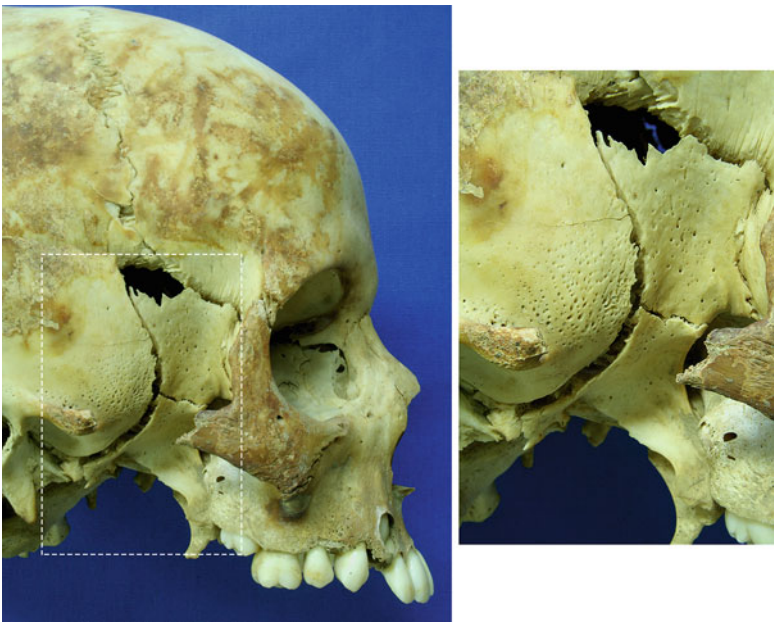

Fig. 4 Porotic lesions on the ectocranial surface of the greater wing of the sphenoid and the anterior portion of the temporal bone on the right side of the skull of a 10–11-year-old child from the Kilkenny Union workhouse mass burials. The lesions are indicative of micro-trauma affecting the mastication musculature which in turn would have been a consequence of scurvy that affected this child (Photo: Jonny Geber)

reflection of the desperately poor state of health these individuals would have suffered prior to having been granted access to the workhouse institutions. They evidently recovered from their scurvy – some Vitamin C would have been provided from the daily meal rations in the workhouse – but due to a weakened immune system they had little chance of surviving once they entered institutions ridden with infectious disease (Geber and Murphy 2012). The skeletons are therefore a physical testimony to the reality faced by many in Ireland during the Famine to either seek admission in the union workhouses and risk death from infectious disease or avoid it and risk death by starvation (Fig. 6). The social shame of entering the workhouse would have forced many to the latter action. In other accounts, it was said that people who had avoided the workhouses would ultimately seek relief when they were nearing death. They might then, at least, be buried in a coffin (Cohen 2002, 125).

The manifestation of scurvy in these samples have allowed for a comparison of how the disease is likely to have affected different sections of the population. Palaeopathological scurvy is easier to diagnose in children, as the manifestations of the disease are more evident in the growing skeleton. In adults, the changes are more subtle and less evident, which explains why the adult prevalence is substantially lower than the non-adult rate in both the Kilkenny and Clones samples. In the

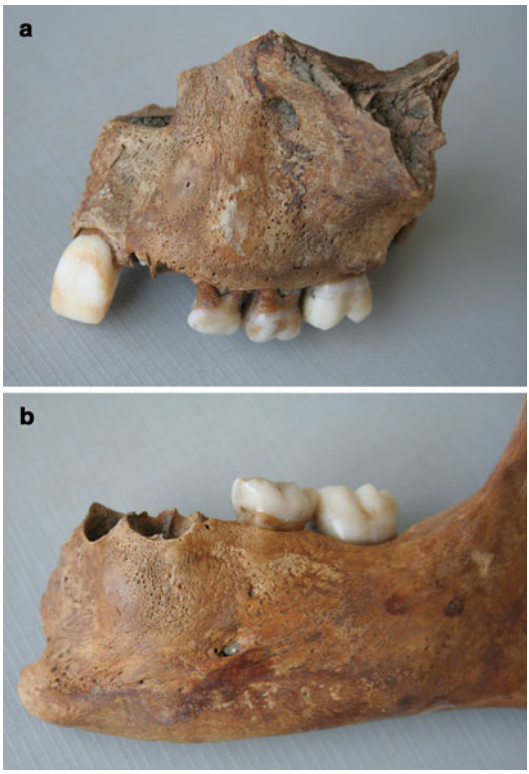

Fig. 5 Porous and porotic lesions on the left maxilla (**a**) and mandible (**b**), and around the alveolar margins, of an approximately 9-year-old child from Clones Union Workhouse, indicative of scurvy (Photo: Jonny Geber)

Table 1 Prevalence rates of scurvy, diagnosed skeletally in victims of the Great Irish Famine from the Kilkenny and Clones Union workhouses

	Kilkenny Union Workhouse		Clones Union Workhouse	
	Non-adults	Adults	Non-adults	Adults
Vitamin C deficiency[a]	60.8% [330/543]	40.1% [169/421]	41.2% [7/17]	16.7% [3/18]

[a]See Geber and Murphy (2012) for information on how the diagnoses were quantified

child sample, lesions suggestive of scurvy are present in all the age groups, from infants (<1 year) to adolescents (13–18 years). In adults (>18 years), it was most commonly observed in the skeletons of males (Table 2), and in particular those of taller stature (Table 3). This is an interesting observation, as it does indicate that physical build and sex were factors that influenced the ability to cope with famine stress. During the Irish Famine, it is estimated that the excess death ratio between males and females was 1.1:1, and that about 37,000 more males than females died (Boyle and Ó Gráda 1986). The discrepancy in the rates of scurvy between the sexes would imply that the Vitamin C deficiency in males was more pronounced than females during the Famine, at least for the section of the population that were admitted into the workhouse institutions. As stated above, scorbutic lesions in the

Table 2 The prevalence rate of lesions indicative of scurvy in skeletons of adult males and females from the Kilkenny Union Workhouse mass burials

	Males	Females
Vitamin C deficiency[a]	50.9% [107/210]	29.6% [58/196]

[a] $\chi^2(1) = 19.175$, p = <0.001

Table 3 The difference in estimated living statures (mean) in scorbutic and non-scorbutic male and female adults skeletons from the Kilkenny Union Workhouse mass burials

	Scorbutic	Non-scorbutic
Male statures (cm) (n = 186)[a]	172.23 (SD = 5.48)	170.43 (SD = 6.16)
Female statures (cm) (n = 159)[b]	159.00 (SD = 6.30)	157.88 (SD = 5.26)

[a] $t(184) = -2.290$, $p = 0.023$
[b] $t(157) = -1.176$, $p = 0.241$

skeleton will only be apparent once Vitamin C has been reintroduced to the diet, which would have been the case once inmates had access to the diet provided for them in the workhouse. At the Kilkenny institution, the quantities of the food rations were the same for both males and females, and the higher nutritional requirement of males was not taken into consideration. This may explain why the male rates were higher. It would also explain why the taller built individuals in this sample appear to have been more affected, as those of shorter stature would have had a lesser biological requirement of the vitamin to sustain an adequate health status (see FAO 2001). Recent research has also suggested that Irish males are genetically

predisposed to develop scurvy compared to other populations (Delanghe et al. 2013), and this possibility further highlights the complexity of the range of factors that determined the outcome for those who suffered during the Great Famine.

Tuberculosis

While typhus, dysentery, and cholera were some of the infectious diseases that were the main cause of death during the Irish Famine (Kennedy et al. 1999), they leave no markers on bones. Other "famine diseases" on the other hand, such as typhoid fever, small pox, and tuberculosis, are potentially manifested in the skeleton (see Aufderheide and Rodríguez-Martín 1998; Ortner 2003), although it is only the latter that leaves specific osseous changes. In the context of a famine, the likelihood of detecting skeletal markers of these conditions is reduced due to the immediate death and demise of those who are most affected; it is only in its most chronic state that infectious disease affects the skeleton, and then in individuals who were "strong" enough to survive the disease to such an advanced stage (this notion is generally referred to as the "osteological paradox," see Wood et al. 1992). The skeletal manifestations of the infectious diseases that were observed in the victims from Kilkenny highlight the extent of this suffering for only a few, but it indirectly suggest the agony these diseases would have caused to thousands of people suffering the Famine in Ireland in the middle of the nineteenth century.

Of the seven cases diagnosed as tuberculosis in the Kilkenny sample, six were active at the time of death (Geber 2015b). Of these, three adults displayed vertebral involvement, which was manifested as characteristic psoas abscesses of the vertebral bodies in the lumbar spine. This pathological change, which is a typical skeletal manifestation of the disease, can potentially result in severe back pain and eventually spinal deformity with further negative health consequences (Garg and Somvanshi 2011). Two children, aged five to 6 years and 9 years, were affected by cranial tuberculosis, which had resulted in large lytic lesions on their cranial vaults and mandible. One adolescent female, aged between 14 and 17 years, was affected by a severe active infection of the left hip joint, which was probably due to tuberculosis. This is a common joint affected by the disease, especially in young individuals, and can result in a considerable painful disability (Tuli 2016, 71–115). In addition, there were 32 adults and 29 children from Kilkenny and Clones that displayed lesions on the visceral surface (facing the lungs) of their ribs (Table 4). This is indicative of a pulmonary infection and may potentially relate to tuberculosis (Kelley and Micozzi

Table 4 Crude prevalence rates of active cases of tuberculosis and rib lesions diagnosed skeletally in victims of the Great Irish Famine from the Kilkenny and Clones Union workhouses

	Kilkenny Union Workhouse		Clones Union Workhouse	
	Non-adults	Adults	Non-adults	Adults
Tuberculosis	0.6% [3/545]	0.7% [3/425]	0.0% [0/17]	0.0% [0/18]
Rib lesions	5.8% [28/479]	9.3% [32/343]	12.5% [1/8]	0.0% [0/7]

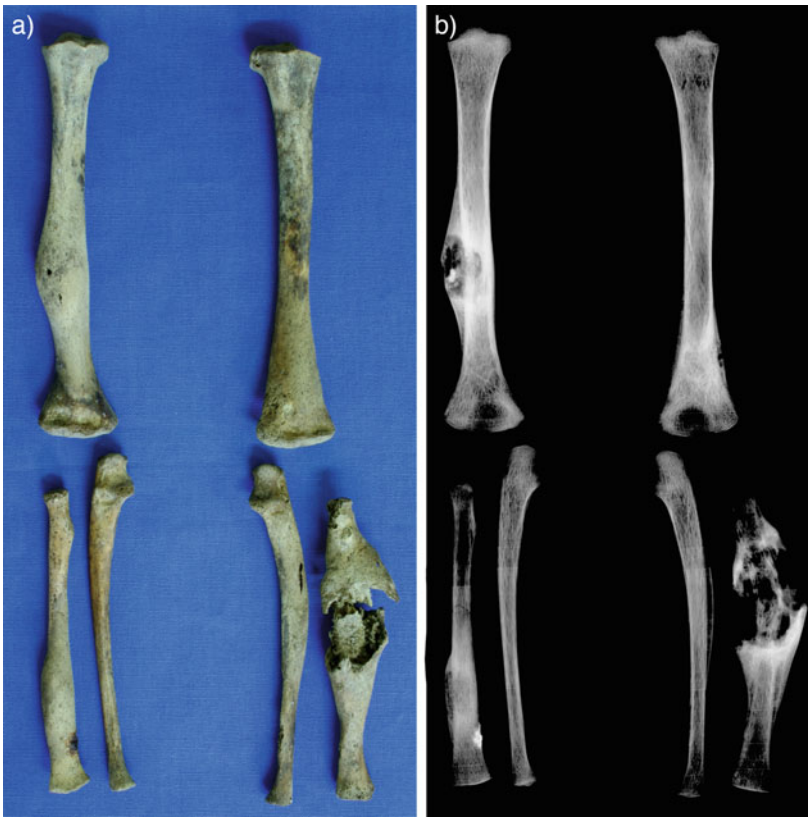

Fig. 7 Photograph (**a**) and radiograph (**b**) of the arm bones of a 5–6-year-old child from the Kilkenny Union Workhouse. The bones are severely affected by osteomyelitis caused by tuberculosis

1984; Roberts et al. 1998), although a definite diagnosis based on these osseous lesions alone is not possible (Mays et al. 2001; Rogers and Waldron 1989).

Tuberculosis in children has a different skeletal manifestation than in adults. One gross deformity which is more commonly observed in their skeletons in chronic cases of tuberculosis is osteomyelitis. This condition, which is a severe infection that affects the bone marrow and bone cortex, was observed in a 5- to 6-year-old child (Fig. 7). This individual also displayed evidence of a bilateral pulmonary infection (probably tuberculous) and Vitamin C deficiency. Osteomyelitis is, however, not exclusively associated with tuberculosis, and in the context of these skeletons, typhoid fever is a condition that also needs to be considered. Typhoid osteomyelitis is generally more common in children than in adults, with a multifocal manifestation that often attacks the ribs, tibiae, and spine (Adler 2000, 154; Aufderheide and Rodríguez-Martín 1998, 191). This possibility highlights the likelihood that the experience of famine and starvation in Ireland during the 1840s and early 1850s

involved comorbidity of conditions, and whatever ailment that ultimately caused the death of those who died was only one of the many illnesses suffered at the time.

According to Steinbock (1976, 175), tuberculosis is only detectable in the bones and joints of approximately 5–7% of those who suffer the disease, and it would then only appear when it has reached a chronic stage. Other authors have suggested that the percentage is much lower, from 1% to 3–5% (see Roberts and Buikstra 2003, 89). The skeletal evidence, as observed in the bones of the workhouse inmates assessed in this study, is, therefore, likely to be a drastic underrepresentation of the true prevalence of the disease in these two population samples. Tuberculosis was not an uncommon disease in Ireland before the Famine, far from it (see Breathnach and Moynihan 2011; Jones 2001). As in most parts of the world, the disease was associated with poverty and poor living conditions (Roberts and Buikstra 2003). The deteriorating health conditions due to malnutrition and living conditions during the Famine, however, meant that the disease took hold on a much broader level, and it caused approximately 107,200 deaths in Ireland between January 1846 and the end of March 1851 (Census of Ireland Commission 1856, 661). According to the 1851 Census, it was the fifth most common cause of death (excluding natural causes due to old age) in the Irish union workhouses between January 1846 and the end of March 1851, with 10,377 individually recorded deaths attributed to the disease (ibid., 116–117).

Perceiving of the Impact of the Great Irish Famine

Between 1841 and 1851 Ireland saw a population loss of almost 20% (Kennedy et al. 1999) that was approximately equal parts the result of famine-related deaths and emigration. It is a tantalizing thought to consider what Ireland was like immediately after the subsistence crisis had ended, and how people coped with adjusting to a post-Famine society. In some places, whole local communities had been destroyed (Kinealy 1997). Expressions of rural Irish folk culture, such as the use of Irish language, which at the time was viewed as an expression of inferior and of low social status, declined more rapidly than it had done previously, and it would eventually be largely lost as a consequence (Hindley 1990). The Irish rural landscape must have been perceived as completely desolate in places; an emptiness and silence that marked a striking contrast to what had been before. There does also appear to have been a silence in terms of what experiences and witness accounts were preserved in communal memory (see Ó Gráda 1999, 194–225; Ó Gráda 2001). It is clear that selective memories were in place – much of it was probably relating to the social shame of poverty, and that some stories were never told or passed on to the following generations. This evidently occurred at Kilkenny and Clones, where the location and awareness of the mass burials adjacent to the workhouse institution were eventually forgotten.

There is a vast collection of contemporaneous written sources relating to the Famine, from government reports and newspaper articles to recorded witness accounts and folklore. But these sources also have limitations, and they rarely give

an ample insight into the experience of the Famine from the perspective of those who were worse off and of those who vanished. While these people may not be that visible in the written records, the traces of their lives are present in the archaeological record – in the Irish landscape itself through the environment in which they lived and the fields in which they worked, to the remains of the cabins in which they lived. And they are physically present in the burial record, which occasionally is discovered in Ireland during archaeological excavations prior to road or building developments (Geber 2015b, 1–10). The potential of using archaeology to expose this dark period in Irish history has been recognized for a long time (see O'Sullivan 1997; Orser 1996), but it still remains a largely unexplored research topic. Ireland's Famine heritage is of international significance; it tells not only the story of Ireland and the nations to which hundreds of thousands of people were forced to flee to, but it is also the story of the ultimate consequence of a strictly hierarchical society and social injustice in nineteenth-century Europe and elsewhere. The people who died in the Irish Famine were primarily those who had lived on the social margins, and they tend – as a consequence – to be largely invisible in the historical records.

One of the most invisible population subgroups in the historical sources are the children. However, in the bioarchaeological record from this period they are the most apparent, particularly in Kilkenny where 56.2% of all 970 individuals interred in the mass burials were aged less than approximately 18 years. The largest age group of these comprised of young children (n = 239) aged between 1 and 5 years of age at the time of death (Geber 2015b). This fact highlights an aspect of Famine history which tends to be forgotten: the impact it had on the youngest generation. While it is well-known that children would have comprised over half of all the victims of the Great Irish Famine (see Boyle and Ó Gráda 1986), their story is still largely untold (see Geber 2014, 2016a, b; Jordan 1998). Even for those who survived, the long-term consequences of having experienced a childhood during the Famine should not be underestimated (see Galler and Barrett 2001; Lumey et al. 2011). For a child (and even fetus) to have experienced malnutrition and severe health deprivation would have resulted in a negative effect on their physical growth and eventually physical health as an adult, as well as possibly their cognitive and behavioral development (see Walsh 2012, for a discussion on the potential increase in schizophrenia during the second half of the nineteenth century in Ireland, as a consequence of in utero stress during the Great Famine). In that sense, the Famine may have affected the Irish population beyond the substantial social, political, economic, and cultural consequences that have been discussed by numerous historians and other famine scholars (e.g., Ell et al. 2014; O'Rourke 1994; Smith 1993; Stout 1996; Whelan 1995).

Acknowledging Lives Lost

The human reality of the Great Hunger, as indicated from the bioarchaeology of its victims, gives a direct insight into the calamity which is unique in famine studies. The extensive manifestation of skeletal lesions indicative of Vitamin C deficiency and scurvy does not only confirm the historical accounts of the period of the

widespread occurrence of a painful and debilitating disease, it also allows an insight into how the condition affected different sections and members of the population. The extent and severity of the skeletal lesions caused by tuberculosis give a similar insight. Death by famine in Ireland during the second half of the 1840s and early 1850s would have been extremely painful. Those who perished experienced levels of suffering and privation that are probably too difficult to fully comprehend today. The archaeological discovery of the mass burials at Kilkenny and Clones have provided a poignant reminder of a very dark period in the relatively recent history of Ireland, which not only relates to the apparent hardship that people endured during the Famine but also the demeaning manner in which the poor and the lowest social strata were treated by contemporaneous Victorian society. In both Kilkenny and Clones the local community expressed a sincere concern and wish for the remains to be returned to their parish and respectfully reinterred after the scientific analysis of the skeletons had been completed. These reburials took place in May 2010 and March 2014, respectively. In Kilkenny and Clones, the rediscovery of these burials have enabled the story of these people to be told, their lives to be acknowledged, and for them to have finally been given dignified treatment in death.

Policies and protocols

The skeleton adapts and responds to biological, environmental and cultural factors (Larsen 2015). Bioarchaeology assess morphological features in the skeleton and employ metrics to determine and estimate sex, age at death, physical built and assess evidence of disease and trauma in ancient human remains. With this information, and interpreted in the cultural and social context the once living population the human remains derive from, the discipline attempts to reconstruct how life was experienced by the people who lived in the past. The historical records relating to the Great Irish Famine of the 1840s and early 1850s are extensive, however, it often lacks to provide insight of those who suffered most from this catastrophe. Recent bioarchaeological research of the Great Irish Famine has enabled a unique historical perspective of the human experience of famine and starvation. While the historical and archival records—almost all written by the societal élite or middle classes—enable historians to gain a detailed insight into the social construct of mid-nineteenth-century Ireland, the skeletons of the people of the labouring "lower" classes who lived during this time are able to tell their stories from their perspective. The physical experience of disease, malnutrition and physiological stress can be discerned from their bones and teeth. The high prevalence of skeletal evidence of scurvy has, for instance, revealed the great level of suffering endured before people were granted access to the notorious workhouse institutions. Males suffered from scurvy to a greater degree than females, possibly due to a relatively lesser and inadequate intake of nutrients as they biologically required. Infectious diseases, such as tuberculosis, are likely to have been much more prevalent than what the skeletal evidence suggests. Few people who experienced famine and starvation would have survived an infectious

disease long enough for it to manifest itself on bone tissue. Social and cultural context is therefore of essential importance when studying famine and starvation from human skeletal tissue, in both past and present societies. The archaeological research of the famine-period mass burials at Kilkenny and Clones has highlighted the importance of recognising human skeletons from archaeological contexts as remains of people, of individuals; men, women and children with names and personalities who lived and worked in the very landscape that people and communities call home today. Archaeological discoveries such as these enable communities to make an emotive connection to a very poignant and difficult past. This was a past that for a very long time was ignored, not talked about and eventually forgotten. About one million people are believed to have perished as a consequence of the Great Irish Famine. The bioarchaeology of the Kilkenny and Clones Union Workhouse mass burials has enabled the stories of some of these people to be told.

Dictionary of Terms

- **Bioarchaeology** – The study of ancient or historic human remains from archaeological contexts, which takes social, historical, and cultural frameworks into account.
- **Mass burials** – Multiple interments of corpses within a single grave, which are generally occurring during catastrophic mass mortality events.
- **Osteological paradox** – The idea that the skeletal evidence of disease and health in bioarchaeological samples represent a paradox, as pathological conditions in bones may only be evident in "healthy" individuals who have survived long enough for these manifestations to occur. As a consequence, the skeletons of "unhealthy" individuals who died during the early onset of an infection may display no evidence of disease at all.
- **Palaeopathology** – The study of disease in the past from the analysis of ancient or historic human remains.
- **Victorian** – A term relating to the historical era between 1837 and 1901 which is defined by the reign of Victoria (1819–1901), Queen of the United Kingdom of Great Britain and Ireland.
- **Workhouse** – A house of industry, which in Britain and Ireland related to social policies deriving from the enactment of the British and Irish Poor Law Acts of 1834 and 1838, where government-aided relief to the poor in terms of basic shelter and food were given in exchange of hard and often degrading labor. The living conditions in these institutions were notoriously harsh and intentionally kept to a low standard to "encourage" those in need of help to avoid seeking "indoor relief" and thereby be forced to improve their situation by themselves. Access to the workhouses was determined by a range of set criteria that were intended to ensure that only those that were considered most destitute, desperate, and of immediate risk of death were granted access.

Summary Points

- Starvation and famines are of great antiquity in human history.
- Bioarchaeology – the study of archaeological human remains – provides unique insights into how famine affected human societies in the past.
- In recent years, skeletal remains of victims of the Great Irish Famine have been discovered in mass burial grounds associated with workhouse institutions across Ireland.
- The skeletal evidence of scurvy is a direct reflection of the impact the potato blight – which was the principal cause of the Irish Famine – had on the physical health on those who died.
- Skeletal manifestations of scurvy are only apparent during the convalescent or healing stages when Vitamin C has been reintroduced to the diet.
- The so-called "osteological paradox" will result in low rates of infectious disease in human skeletons, as death by infectious disease during a famine is relatively rapid and skeletal manifestations of infectious disease generally only occur in chronic cases.

The Barker Hypothesis

12

Matthew Edwards

Contents

Abstract

The Barker hypothesis proposed that adverse nutrition in early life, including prenatally as measured by birth weight, increased susceptibility to the metabolic syndrome which includes obesity, diabetes, insulin insensitivity, hypertension, and hyperlipidemia and complications that include coronary heart disease and stroke. Periods of rapid postnatal growth associated with high-energy intake seem to be risk factors, along with a high-energy western diet. Theories proposing the mechanism of this association include the thrifty gene, bet-hedging, fetal predictive adaptive response, and drifty phenotype hypotheses. The cause of metabolic syndrome is likely to be multifactorial, with many nuclear DNA and cellular RNA sequences acting in concert with environmental influences.

Epidemiological data in humans and experimental data indicate that transgenerational epigenetic inheritance is a possible mechanism where a history of starvation or deprivation during early life is seen in a grandparent and transgenerational effects are seen in their grandchildren. It remains to be seen whether this is mediated by heritable RNA sequences, or by acquired, possibly mosaic mutations in DNA coding for example for regulatory RNAs. Recent research has raised the possibility that the nature and quantity of gastrointestinal microorganisms (microbiota) can be modified by diet and conversely can modify an animal's metabolic program. As the microbiota is inherited largely from the mother, modification of her nutrition, health before and during pregnancy, and mode of delivery could influence the child's microbiota, introducing further potential avenues to improve the prevention, reduction of complications, and treatment of malnutrition and metabolic syndrome.

Barker hypothesis · Thrifty phenotype · Genotype · Fetal programming · Intrauterine malnutrition · Epigenetic inheritance · Somatic mutation · Microbiota · Gastrointestinal microorganisms · Developmental origins of health and disease

List of Abbreviations

siRNA Small or short interfering RNA	targets messenger RNA (mRNA) of specific sequence for inactivation or degradation
miRNA MicroRNA	small noncoding RNA 22 nucleotides long which regulates gene expression by targeting mRNA
XIST X-inactive specific transcript	a gene located on the X chromosome that encodes RNA, which inactivates the same X chromosome

The Barker hypothesis proposed that obesity, hypertension, hyperlipidemia, and type 2 diabetes, combinations of which have been called the metabolic syndrome (Hales and Barker 1992), were associated with malnutrition or some other cause of growth restriction during early development, if there was later exposure to a high-energy diet (Fig. 1). The deleterious effects of rapid "catch-up" gain in weight during early childhood were observed later. More complex multifactorial contributors to the syndrome could include the relationship between nutrition during pregnancy, maternal metabolic status, and the socioeconomic and even psychosocial status of the mother and child (Barker 2002). There was an inverse correlation between birth weight and the severity of several measures of the metabolic syndrome. Barker based his hypothesis on epidemiological research by his unit and elsewhere. Some areas of Norway had a high prevalence of poverty in the past, associated then with a relatively high child mortality rate and poor nutrition (Forsdahl 1977). Although

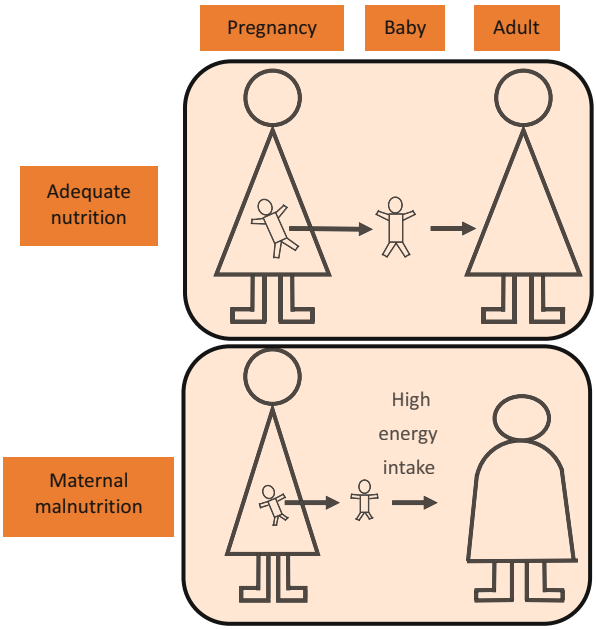

Fig. 1 Barker hypothesis. Two different scenarios for the same mother and baby, therefore irrespective of genotype in both situations. Normal maternal nutrition would result in a normal-sized baby who will be a healthy adult. Exposure of the same mother and child to famine during the pregnancy would be followed by growth restriction of the child who then develops metabolic syndrome as an adult

these areas became as prosperous as the rest of the country and their child mortality dropped to the national level by the 1970s, adults exposed to poverty in early childhood had an increased incidence of heart disease compared to those living in areas that had always been prosperous.

Based on epidemiological studies correlating birth weight with components of the metabolic syndrome that developed in adulthood, Hales and Barker proposed that fetuses survived malnutrition by irreversible adoption of a thrifty phenotype, which they called the fetal programming or thrifty phenotype hypothesis (Hales and Barker 1992) and later broadened to developmental origins of health and disease (Gillman 2005). Studies of adults who were subjected to a variety of causes of intrauterine growth retardation or restriction confirmed a relationship between reduced birth weight and adult metabolic syndrome (Varga et al. 2010). By limiting the growth or function of some organs such as the kidneys, liver, and pancreas that were inessential to immediate survival and adopting a state of insulin resistance, crucial glucose or other limited energy supplies would be diverted to the heart and brain which were crucial for survival, so the fetus survived the period of malnutrition. The irreversible reduction of hepatic, pancreatic, and renal size and/or function was assumed to be chosen by the fetus as a protective mechanism in response to malnutrition. This would improve the survival of fetuses or older children programmed this way as long as they were exposed to malnutrition (Stanner and Yudkin 2001; Victora et al. 2008). On the other hand, it would mean they would be poorly suited to any subsequent period of high-energy consumption as the permanent reduction of hepatic, renal, and pancreatic capacity

and peripheral insulin resistance would result in the metabolic syndrome. A number of refinements have been made, but most of the experimental and epidemiological evidence since has enabled its reinforcement and refinement.

The Dutch hunger winter of 1944–1945 presented a "natural" experiment comparing the adult health of people exposed to famine at different intrauterine ages to controls born elsewhere or before or after the famine. Effects of intrauterine malnutrition at different stages of gestation were found on rates of congenital abnormalities (Stein 1975), obesity (Ravelli et al. 1976), permutations of the components of the metabolic syndrome (Roseboom et al. 2006), disorders of brain growth, schizophrenia (Hulshoff Pol et al. 2000), and abnormal cognitive test results (de Rooij et al. 2010). Similar effects on incidence of schizophrenia were seen in Chinese adults exposed to famine in utero during the Great Leap Forward (Hulshoff Pol et al. 2000; St Clair et al. 2005). Other epidemiological evidence supporting the Barker hypothesis came from the appearance of metabolic syndrome in Pima, Arizona, and Nauruan Islanders after the adoption of a high-energy western diet (Dowse et al. 1991; Diamond 2003; Stoger 2008; Khambalia et al. 2011).

Thrifty Gene Hypothesis

An association between the metabolic syndrome and a high-energy western diet was observed in populations in which previous generations had been exposed to malnutrition (Neel 1962). Survival during famine would be more likely in those with DNA sequences that conferred a thrifty phenotype (Fig. 2). As the survivors with these sequences (especially women of child-bearing age) were more likely to reproduce successfully because of their favorable energy reserves, the mutations were therefore more likely to be passed on to descendants, increasing their frequency in populations prone to famine. This hypothesis was presented to explain why the metabolic syndrome more commonly affected populations exposed to a western diet relatively recently. One argument against it was that the selection of genetic thrift should have applied to every modern population as all ancestors would have been malnourished, rather than just the ancestors of groups in which metabolic syndrome is most prevalent (Speakman 2008). If everyone has thrifty genes, how can they explain the high prevalence of metabolic syndrome only in those newly exposed to a western diet? There has also been debate about when a universal ancestral exposure to famine would have occurred. Earlier assumptions about this being in the Paleolithic period have been questioned (Neel 1989). Famines and severe malnutrition were more likely after the later dependence on agriculture for nutrition than was the case for hunter-gatherer cultures (Prentice et al. 2008). There has been insufficient time since agriculture evolved for malnutrition to select favorable gene sequences. A more plausible selective effect could be the influence of malnutrition on fertility, rather than mortality, in the time elapsed since the evolution of agriculture (Prentice et al. 2008).

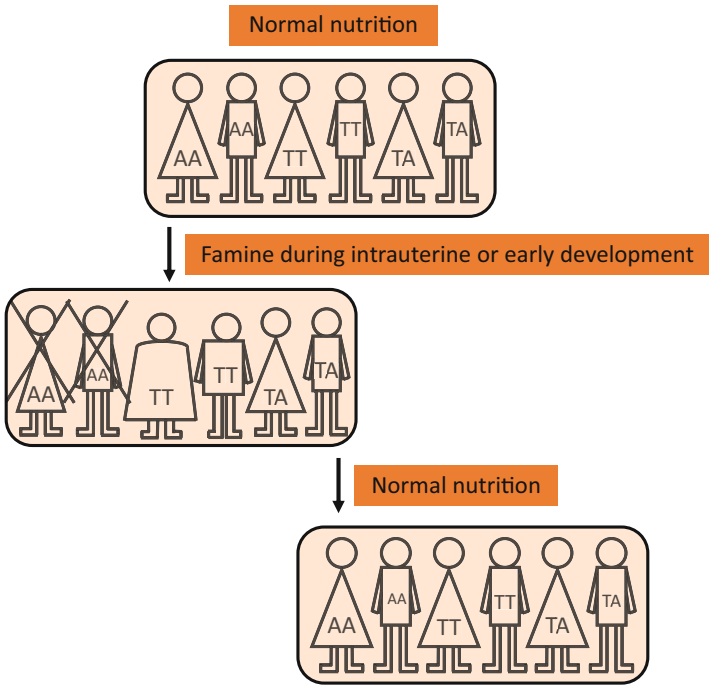

Fig. 2 Thrifty gene hypothesis: if T (Thymine) in a DNA sequence is associated with "thrift," e.g., lipogenesis during periods of adequate nutrition which increases length of survival during famine, it confers a survival advantage on carriers, compared to a sequence containing A (Adenine) at that position. During periods of plenty, it might not confer any advantage, so the frequencies of A and T return to the previous equilibrium. The increase in frequency of polymorphism A in times of adequate nutrition would take many more generations than the one shown here

Postzygotic Somatic and/or Germ Line Mutation

Postzygotic mutation occurs after conception and can affect genes that encode proteins, miRNA, or other regulatory sequences (Fig. 3). Inherited Mendelian variation in the frequency of genomic mutability might determine a higher rate of postzygotic mutation in some individuals. The potential cost of a highly mutable phenotype might be a predisposition to malignancy, autoimmunity, or degenerative disease. Postzygotic mutation could increase the frequency of embryonic cells with a mutation that is favorable to survival and mitosis under certain intrauterine conditions, which are constrained at the best of times (Edwards 2012). That cell with a competitive advantage would divide faster and colonize a tissue or the whole embryo, including much or all of its germ line. In males with continuous division and opportunity for mutation in germ cells, this process might not be limited to

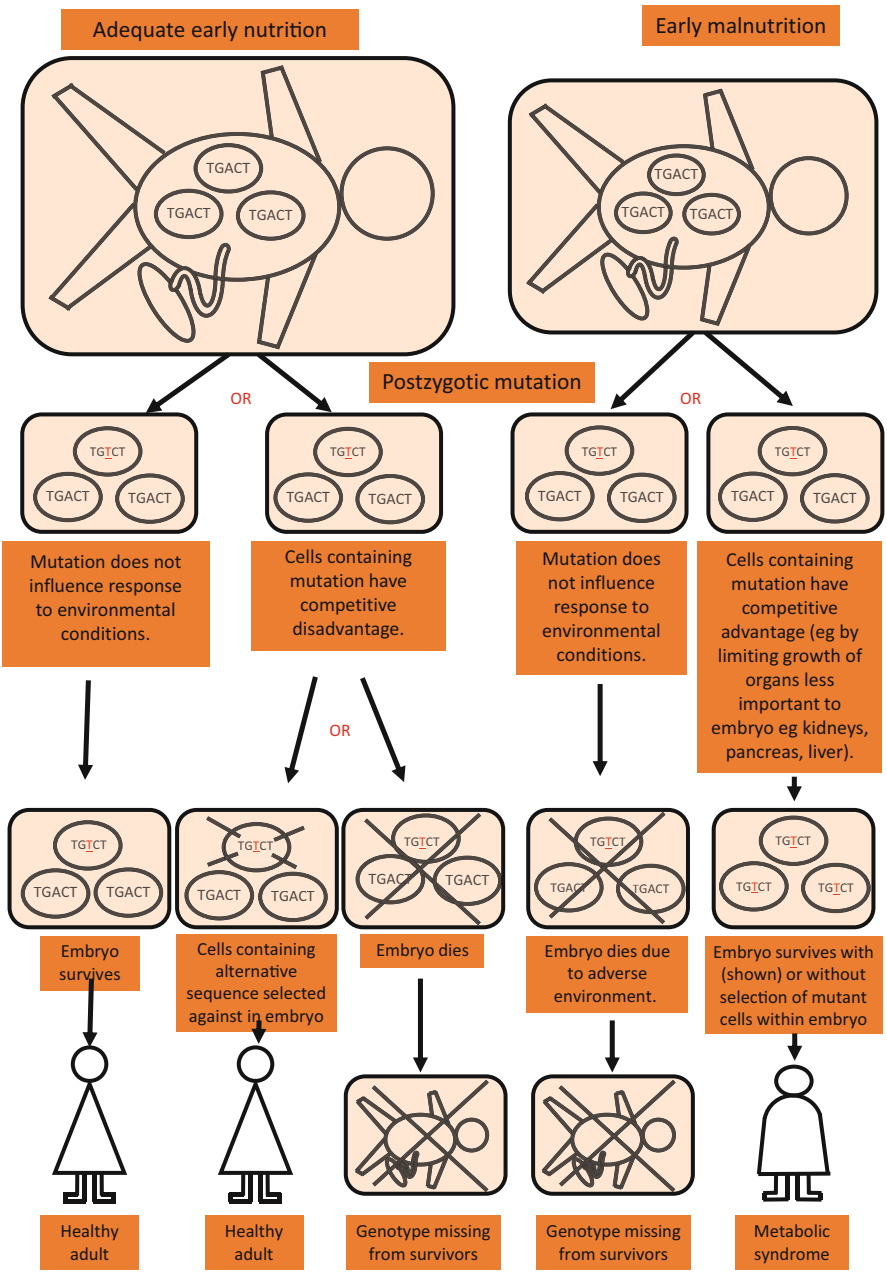

Fig. 3 Postzygotic mutation

embryonic and childhood development. If a postzygotic mutation occurs early enough in development to involve the germ line and produces a thrifty phenotype in those cells, or in tissues those cells will found, it could be a transmissible and

heritable cause of metabolic syndrome. Although Mendelian variation and Darwinian selection were thought to act very slowly over many generations, a similar process occurring within each individual human body between conception and death might explain the appearance of a cellular genetic mechanism contributing to the metabolic syndrome within a relatively short evolutionary time span. An example of this type of Darwinian process occurring in the body is the immense and random somatic mutability in the developing immune system, associated with allele silencing and cellular selection that only leaves cells whose random immune receptor gene mutations are tolerant to self-antigens. With whole genome sequencing of single cells, it will be possible to assess the contribution of this mechanism by comparing the genomic sequences of different cells from different tissues and stages of development, in patients or laboratory animals exposed to intrauterine malnutrition and those with the metabolic syndrome, parents, and controls. If specific gene sequences appear early in development and the cells or embryos containing them die and the sequences are lost in survivors exposed to malnutrition, comparing the genotypes of survivors with parents, unexposed siblings, or exposed siblings without metabolic syndrome might identify more genes of importance to the Barker hypothesis.

Drifty Gene Hypothesis

Genetic drift, the random and continuous accumulation of mutations in the absence of any selective environmental pressure, has been proposed as a mechanism for the increasing incidence of obesity (Fig. 4). A need for agility and mobility, favoring escape from predators, or successful migration in prehistoric hunting and gathering cultures would select against mutations that promote conservation of energy and predispose to obesity. The evolution of agriculture and civilization and a sedentary life would relax this selection against obesity and allow bearers of random spontaneous mutations that promote obesity to survive and pass these mutations on to their descendants (Speakman 2008).

Bet Hedging

The previous theories were based on the concept that selection favored genes for obesity during famine (genetic thrift) or that selection against genes for obesity was relaxed after agriculture developed (genetic drift). Bet hedging referred to the evolutionary advantage of flexibility in reproductive capacity and performance in different environmental conditions (Schaffer 1974). The term refers here in a genetic sense to the preservation within the population, of different DNA sequences having different, opposite, or even mutually exclusive effects. Passage of one DNA sequence to the next generation would be more likely if the prevailing environmental conditions at the time favored it (Fig. 5). If environmental conditions were changeable, as in agricultural cultures with excess food production interspersed with famines, a population could benefit from retaining both DNA sequences (Wells

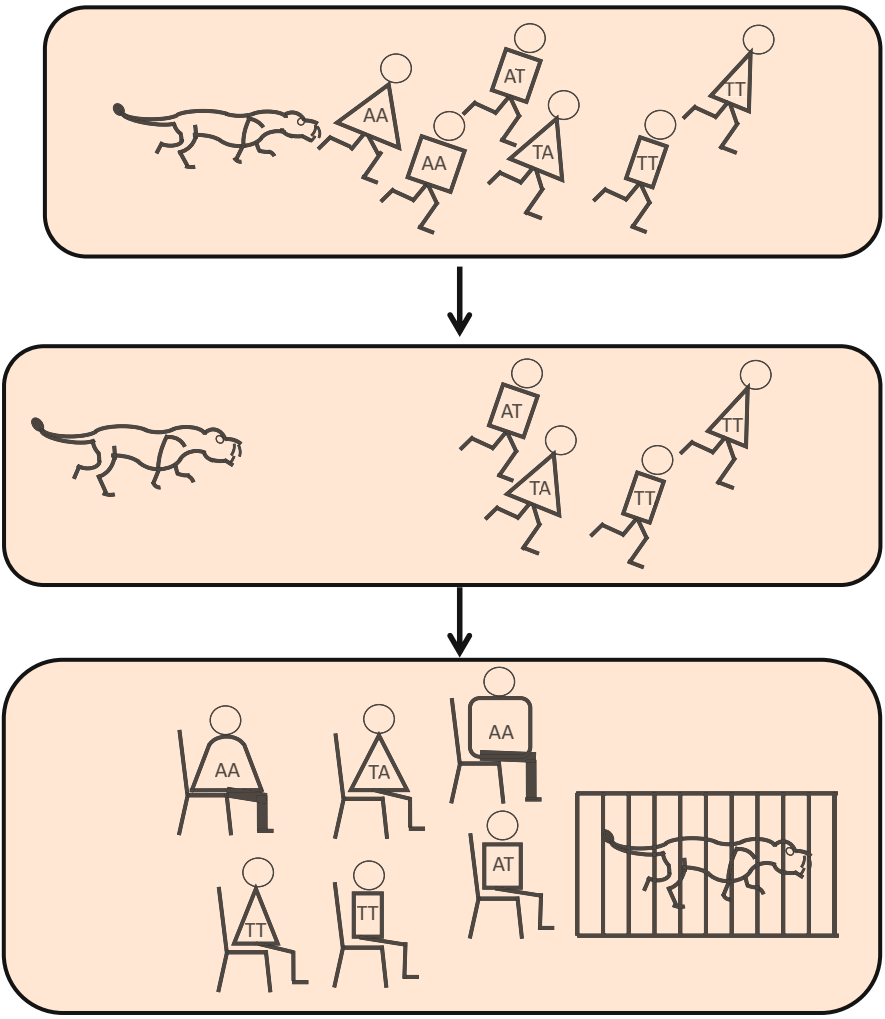

Fig. 4 Genetic drift: new A mutations appear randomly and selection against their effects on activity, consumption, and obesity alters depending on environmental conditions

2009). A thrifty genotype that promotes a positive energy balance with reduced metabolic rate and/or activity, increased consumption of food, avid assimilation of scarce nutrients, and the storage of fat during adequate nutrition might be advantageous to the population. It could ensure the passage of a repertoire of gene activities to the next generation after famines or other causes of fetal malnutrition. The population has multiple sequences at the same or other loci that have opposing effects on thrift. In addition to these, other sequences could be associated with a higher metabolic cost but come into play during periods of surplus nutrition. They could confer evolutionary advantages because as their limitation of appetite or early

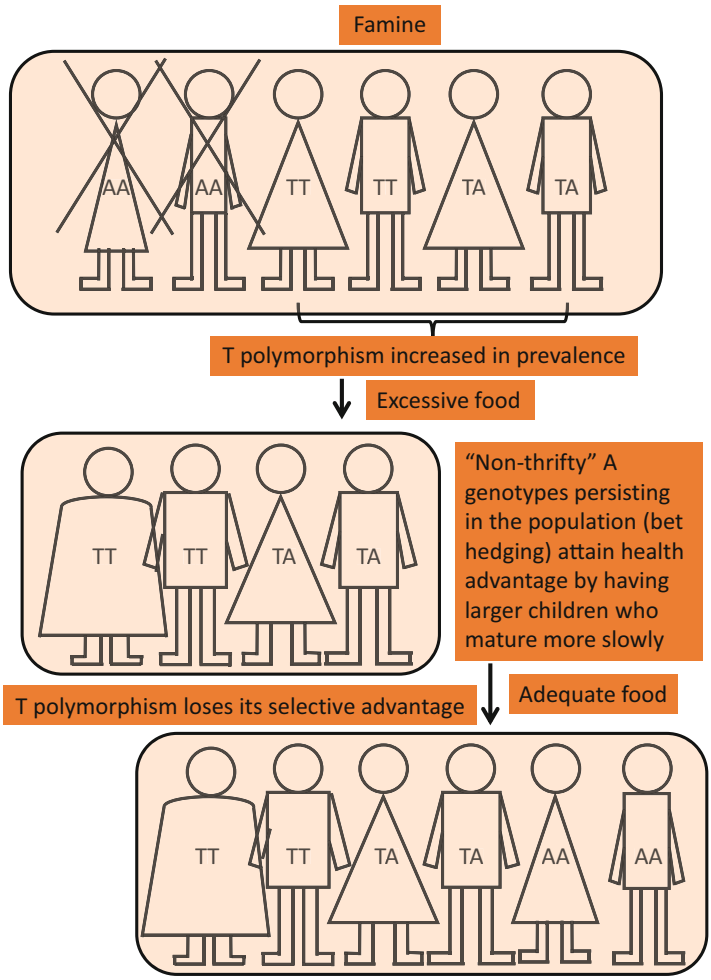

Fig. 5 Bet hedging. If T (Thymine) in a DNA sequence is associated with "thrift," e.g., lipogenesis during periods of adequate nutrition which increases length of survival during famine, it will confer a survival advantage on carriers, compared to a sequence containing A (Adenine) at that position. With adequate nutrition, it might not confer any advantage, so the frequencies of A and T return to the previous equilibrium

growth rate during periods of plenty delays maturation and reduces demands on a lactating mother, they result in slower but continued growth with delayed cessation at puberty, later age of reproduction, larger eventual lean mass and size of the adult brain, and longer life span. When environmental conditions for mothers and/or fetuses enable adequate or excessive energy supply, a denser population and increased competition for mates and territory would favor larger, stronger experienced adults whose parents and grandparents have survived to pass on genetic, social, or behavioral investments to the population. Gene sequences that influence

susceptibility to the metabolic syndrome and are inherited within populations could be sought by whole genome sequencing in adults with metabolic syndrome associated with early malnutrition and compared to parents and unaffected siblings to establish a database of sequences that could be compared in different populations.

Epigenetic Inheritance

The X chromosome contains *XIST*, an X-inactivating gene whose product diffuses along the same chromosome to initiate the inactivation of that copy of the X in each cell (Fig. 6). The inactivation of the X chromosome is an early example of epigenetic modification by methylation of DNA and histones and deacetylation of histones, associated with heterochromatic changes in the structure of the inactive chromosome. Epigenetic changes do not involve changes in the underlying DNA sequence. In female embryos one of the two X chromosomes is randomly inactivated (lyonization) and all mitotic descendants of that cell form a clone inheriting the inactivation of the same X chromosome. Females therefore consist of two clones of cells with respect to their X chromosomes: one with their paternal X chromosome inactivated and another clone has the maternal X inactivated. X inactivation occurs at the time the epiblast is formed in the gastrulating mammalian embryo, while the paternal X is nonrandomly inactivated in the extra embryonic tissues, possibly

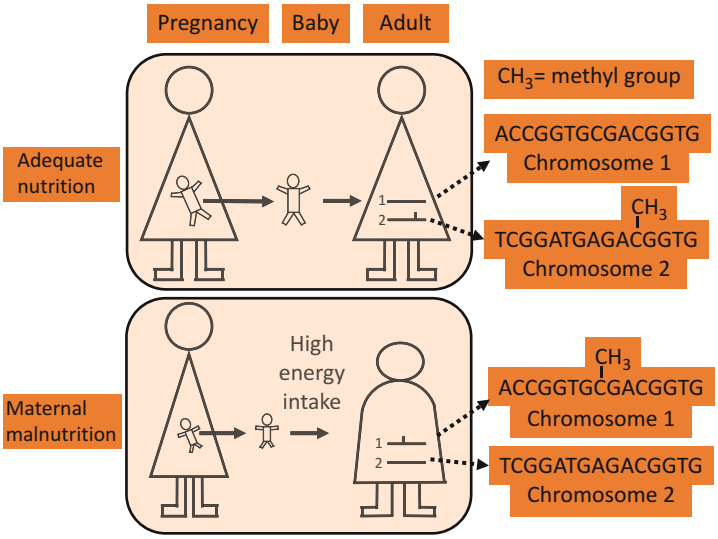

Fig. 6 Epigenetic programming of fetus is influenced by conditions during growth and development. Hypothetical genes on chromosomes 1 and 2 have different lifelong methylation patterns depending on exposures during development. Methylation pattern and other changes in histone structure affect gene expression

reflecting an evolutionary benefit in the activity just of the maternal copies of X chromosome genes at the maternal interface.

Epigenetic imprinting mechanisms inactivate some autosomal genes or chromosomal segments inherited from a parent of one sex, but not those inherited from the parent of the other sex. Sex-specific imprinting evolved independently in placental mammals and flowering plants and is thought, in the case of mammals, to enable a compromise between the competing evolutionary benefits of paternal gene sequences and maternal gene sequences. Specific paternal sequences promote fetal, placental, and childhood growth and might seem in the context of this chapter to be tailored to adverse environments. In contrast, specific maternal sequences favor smaller babies with smaller heads which present less liability for both mother and child before, during, and after the birth to equip both the mother and baby better for long-term survival and further reproduction. As the alleles segregate independently in the formation of germ cells, sex-specific imprinting needs to be reset in the embryo so that, for example, the mother's chromosome 15 imprinting pattern can be reversed from a paternal to a maternal imprint when her ovum contains the copy she inherited from her father (Lewis et al. 2015). Some genes are only imprinted in specific tissues or organs, resulting in a basic phenotype if a mutation in the gene is inherited from either parent, plus additional manifestations if the mutation is on a parental allele that is normally active in the affected tissue and the other parental allele with the normal sequence is inactivated by imprinting (Weksberg et al. 2010). Disorders of imprinting appear to be more frequent in identical twins (Fahrner and Bjornsson 2014), but studies of metabolic syndrome in twin pairs have not uniformly shown effects on some diseases associated with metabolic syndrome (Bo et al. 2000; Iliadou et al. 2004; Wannamethee et al. 2004; Petersen et al. 2011; Frost et al. 2012). Imprinting disorders appear more frequent in babies conceived by certain types of in vitro fertilization (Ventura-Junca et al. 2015), and so does monozygotic twinning. Whether the twinning process predisposes to later metabolic syndrome or both twinning and metabolic syndrome are both secondary to some other cause (Hall 1996) is unknown. Parent-specific imprinting is intimately associated with fetal and childhood growth and metabolism (Hattersley et al. 1998; Constancia et al. 2002), development, and behavior, so the epigenetic mechanisms involved could be relevant to the Barker hypothesis.

A similar process of methylation at the CpG islands of genes, associated with changes in chromatin structure, selects which genes are inactivated in different tissues during developmental differentiation, so that in each tissue only the necessary genes are active. This process does not necessarily or entirely depend on the sex of the parent contributing the allele, but is replicated at each mitosis so that all cells of the tissue usually have the same transcription signature. Genes that are not inactivated long term by epigenetic mechanisms can interact with transcription factors or other modifiers of activity to respond to short-term changes in demand on the tissue. For that to happen the transcription machinery requires access to the gene, and the epigenetic patterns of methylation and histone changes prevent this by changing the coiling and shape of the DNA. Once established, the epigenetic profile of a clone of cells is copied in all daughter cells at mitosis to direct the growth and

specific functions of an organ. The body might retain stem cells with different epigenetic patterns that enable growth and repair of tissues with more than one cell type if needed, but the epigenetic pattern of terminally differentiated cells that undergo mitosis remains stable for the life of the individual. Regional alteration of epigenetic pattern within the body with age and environmental exposure could contribute to autoimmunity (Issa 2003), neoplasia (Jones and Laird 1999), and degenerative disease (Brunet and Berger 2014). Which genes are methylated in the orderly process of differentiation appears to depend on the interplay between the temporal and spatial effects of specific genes and the levels of diffusible growth factors or morphogens.

Environmental changes are thought to influence the epigenetic status of cells by direct effects on methylation. Some drugs can directly influence methylation, and indirect mechanisms include local deficiency or excess of folic acid, which is a cofactor in methylation reactions, or alteration of the activity of enzymes involved in DNA methylation, or histone methylation or acetylation. Exposure of agouti mice to promoters of methylation such as folate or phytoestrogens (Dolinoy et al. 2006) or bisphenol A that reduces methylation (Dolinoy et al. 2007) modifies the development of metabolic syndrome in offspring. Expression of the agouti gene is determined by methylation of a transposon that acts as an ectopic promoter. Transposons comprise 45% of the human genome, and retrotransposons comprise 3%, and many varieties of noncoding RNA molecules are responsible for their regulation or inactivation, commonly by methylation. Polymorphisms in imprinted genes, including the peroxisome proliferator-activated receptors, appear to be involved in diverse processes that could explain the mechanism behind the Barker hypothesis including lipid and carbohydrate metabolism (Ahmadian et al. 2013), inflammation and immune function, atherogenesis, neuronal plasticity, memory (Roy et al. 2013), thermogenesis, healing, and myelination. Interaction between the common P12A polymorphism in the PPARγ protein and birth weight influences susceptibility to insulin resistance and hyperinsulinemia in adults (Roy et al. 2013). Genes associated with lipogenesis and appetite have a similar spectrum of actions relevant to metabolic syndrome (Ellis et al. 2014).

Retrospective epidemiological studies in the UK (Pembrey et al. 2014) and Scandinavia (Kaati et al. 2002; Pembrey et al. 2006) have revealed associations between various measures of malnutrition affecting prenatal or postnatal growth and outcome variables relevant to metabolic syndrome in grandchildren. These identified sex-specific effects on grandchildren removed at least one generation from the exposure factors and exposures as late as preadolescence. Environmental changes can alter the levels of small RNAs, or small double-stranded RNAs can be acquired from the environment. Elaborate mechanisms that regulate the transmission and subsequent replication of small interfering RNA (siRNA) for multiple generations in *C. elegans* have been reviewed (Houri-Zeevi and Rechavi 2017). These regulate not only translation but also transcription by selectively altering chromatin in the vicinity of specific genomic loci. Heritable RNA interference was only transmitted past meiosis for three to five generations, and there is a very short generation time and a limited number of cells in these animals. It is not certain if this will be found in

larger animals in which development of the germ line involves a greater number of mitotic rounds of cell division and there is a much longer time span between generations. This type of inheritance could last long enough to equip several generations of a plant or animal like *C. elegans*, with limited migratory capacity, to deal with forecast prevailing environmental conditions. This process and the epidemiological studies that appear to support its existence in humans might be relevant to the Barker hypothesis and modifications that consider the "weather forecast" model as predicted in 2001 (Bateson 2001), maternal fitness (Wells 2003), and short-term versus long-term changes in environmental conditions (Kuzawa 2008). It is now possible to study the epigenetic signature of cells by analysis of methylation at multiple gene promoter sites, to identify how transgenerational effects can be mediated, although studies on identical twins related to metabolic syndrome have been negative (Tan et al. 2014).

There is evidence for a "Darwinian" process of selection of cells that have particular epigenetic patterns. In the female rabbit embryo, there is stochastic inactivation of the X chromosome so that equal quantities of cells are formed with inactivation of neither X, inactivation of both X chromosomes, inactivation of the paternal X, and inactivation of the maternal X. The cells that have both or neither X are active and then die, leaving only those with an inactivation pattern favorable for survival and division to form a clone that populates the embryo (Okamoto et al. 2011). The pattern of organ growth seen after fetal malnutrition could just be a reflection of the differing susceptibilities of those organs to irreversible damage due to cell death followed by reduced growth rather than anything more programmed and coordinated, and the metabolic changes seen in this situation might just be "making the best of a bad job" (Bateson 2001; Jones 2005).

The epigenetic effects of environmental influences such as malnutrition, psychological stress and behavior, drugs, toxins, and xenobiotics are the subject of much recent research (Thomson et al. 2014; Jimenez-Chillaron et al. 2015). Epigenetic effects include alteration of DNA structure (e.g., histone acetylation or deacetylation) and insulator proteins, methylation of CpG dinucleotides, and the quantity and activity of regulatory molecules such as noncoding RNAs. Drugs, xenobiotics, or psychological stresses alter methylation of different genes or chromosome segments, resulting in a specific phenotype such as metabolic syndrome. Fetuses with resulting nonspecific epigenetic changes that reduce the activity of genes essential for survival to reproductive age would be lost from the population so that the survivors appear to have made a logical choice. In fact the ones that have survived might have done so because the timing is specific or the region of exposure in their case meant that some cells or organs were exposed to more severe environmental conditions or were at a more vulnerable stage of development than others, and cells with changes favorable to survival in those prevailing conditions populated the embryo, not directly because of their genomic sequences but because of their epigenetic patterns. A plausible mechanism has yet to be explained for a xenobiotic, behavioral, or other nongenetic or environmental agents to aim specifically at a particular metabolic program that perpetuates the pharmacological, psychological, physicochemical, or endocrine effects of the environmental agent in subsequent

generations. In biological systems the most parsimonious explanation for the appearance of a specific phenotype is its random appearance in a proportion, but not the whole population, followed by environmental selection for cells or organisms with favorable traits and against those with traits that do not suit the current environment. A plausible mechanism that is known to cause the random appearance of a phenotype is either somatic or germ line genomic mutation. Random nongenetic variations in epigenetic pattern might occur because the actions of agents that affect the epigenetic pattern are not uniform in time or space. Their persistence in a population would suggest they confer no competitive disadvantage under the prevailing environmental conditions.

A number of causes, plus or minus mechanisms, for epigenetic change causing thrift have been postulated. The fetus was proposed to make a predictive adaptive response, a protective "decision" to adopt an epigenetic program that resulted in a thrifty phenotype predicted by current circumstances to be beneficial when the animal was old enough to reproduce (Gluckman and Hanson 2004; Ellis et al. 2014). The thrifty phenotype did not reduce reproductive fitness so it could be transmitted to subsequent generations if it was somehow not erased in embryonic stem cells. If it escaped erasure, it might not influence fetal survival in times of adequate intake, improve survival in fetuses that had retained it and were in turn exposed to malnutrition, and only cause problems if energy consumption became plentiful.

Gastrointestinal Microorganisms (Microbiota)

Viruses incorporate parts of their genomes into host genomic DNA and RNA from viruses, although it was horizontally transmitted initially and can be replicated in mitosis and meiosis to be transmitted vertically. Bacteria and humans share nutrients and synthesize some necessary nutrients for each other. Regulatory nucleic acid sequences, known to be shared between bacteria, can also be shared between them and their human host. A significant proportion of human DNA can be cloned in fungi but not in *E. coli* (Negri and Jablonka 2016). Some of these human genomic sequences might maintain the symbiotic balance between host and enteric bacteria by coding for RNA or protein that regulates bacterial metabolism or growth. They could either promote the production of host toxins that are taken up by bacteria, or the nucleic acid sequences themselves are taken up and transcribed by bacteria. The population of gut microorganisms is established by age of 3 years, and the variety and quantity of species are influenced by the diet of the child including breast milk or other foods. Most of this population is established by colonization from the maternal enteric, vaginal, and cutaneous populations, although it possibly includes a prenatal intrauterine population (Ardissone et al. 2014; Stinson et al. 2017). Maternal malnutrition, metabolic syndrome, or other diseases predisposing to metabolic syndrome in the child might therefore be associated with particular populations of microorganisms passed on from mother to child and subsequent generations. This could contribute to the difference seen between effects of maternal malnutrition

during pregnancy and paternal malnutrition during childhood (Pembrey et al. 2006; Pembrey et al. 2014). The long generation time of humans and their slow rate of germ line evolution argue against the Darwinian selection of new mutations that could affect such large proportions of populations and appear as quickly as the metabolic syndrome. If the genetic material carried by the human is actually considered to be both the DNA in the human cells plus that of the trillions of symbiotic organisms living in or on the body, the evolution of this entity as a whole could be so rapid it could appear to have a Lamarckian mechanism (Osmanovic et al. 2016). Fascinating research involving twins discordant for obesity showed that germ-free isogenic mice receiving fecal bacteria from the obese twin developed an obese metabolic pattern that was rescued by cohousing with mice fed bacteria from the leaner twin (Ridaura et al. 2013). Children delivered by Caesarian section were more likely to develop obesity after controlling for their mothers' BMI (Mueller et al. 2017).

Conclusions

The cause of metabolic syndrome is likely to be multifactorial, with many nuclear DNA and cellular RNA sequences acting in concert with environmental influences. The Barker hypothesis has enabled new approaches to the study and management of different types of intrauterine malnutrition and metabolic syndrome. These will hopefully lead to control of this major worldwide health problem. It has not been resolved whether the Barker hypothesis affects subsequent generations, after one episode of growth retardation at one stage of development. Epidemiological data in humans and experimental data suggest that transgenerational epigenetic inheritance is possible. It remains to be seen whether this is mediated by heritable RNA sequences analogous to transposons or RNA viruses that have entered the germ line, or by acquired, possibly mosaic mutations in DNA coding for regulatory RNAs. The association of enteric microbiota with human metabolism raises the fascinating possibility of new treatment or even prevention.

Dictionary of Terms

- **Agouti** – banded lighter and darker pattern of hair pigmentation in mammals caused by pigmentary genes being turned on or off at stages of hair growth. These genes are normally only expressed in hair follicles, but a transposon can result in their expression in other tissues, leading to metabolic syndrome.
- **Chromatin** – the DNA of the chromosome is coated with RNA and proteins, especially histones, to form chromatin which coils to produce the typical structure of chromosomes that are visible through the microscope just before the cells divide. Banding of the chromosomes with a stain called Giemsa (G-banding) produces a bar-code appearance which aids in numbering and identification of deletions or duplications. The light bands were called euchromatin and dark

bands heterochromatin which largely contain active and inactive genes, respectively.

- **Clone** – all cells descended in the body that have descended, by mitotic cell division, from one ancestral cell.
- ***Caenorhabditis elegans*** – C. elegans is a tiny transparent worm which is valuable experimentally because of its short developmental period, 3-day life cycle with rapid growth to maturity resulting in a short generation time, and its fecundity, 300 offspring for each worm. Its embryonic development was studied by Sulston and colleagues so the division and migration of every embryonic precursor and eventual predictable position could be identified for every 1 of the 959 cells comprising the adult worm's body.
- **Epigenetic (adj, n epigenesis)** – the alteration of gene activity without alteration of DNA sequence; by alteration of chromosome structure, relationship between DNA and histones, histone methylation or acetylation, or DNA methylation. The nucleotides cytosine and guanine, found together on the phosphate (p) backbone of DNA, are called a CpG dinucleotide and are very frequently found in the promoter of genes, and the cytosines in this dinucleotide are methylated to inactivate the gene by preventing access of RNA polymerase to the promoter. This prevents transcription, the synthesis of messenger RNA from the DNA template.
- **Expression** – the transcription from a DNA sequence of RNA which has some metabolic or epigenetic effect in the cell.
- **Genome** – the DNA sequence of an organism. This does not include the sequence of RNA that might not be copied from genomic DNA but does include the sequence of ancestral viral RNAs that have been copied in the reverse direction into genomic DNA. Whole genome sequencing is the sequencing of all known chromosomal and mitochondrial DNA sequences, now possible for a single cell. Whole exome sequencing just included the 1% of DNA that coded for proteins, but that misses the huge majority of DNA that codes for regulatory sequences within genes (intronic sequences) and outside genes.
- **Germ line** – sperm, ova, and their precursors.
- **Imprinting** – inactivation of genes, not by altering their sequence (mutation) but by methylation of DNA and histones, deacetylation of histones, and structural changes to the supercoiled chromosome to limit access to gene promoters by RNA transcription molecules.
- **Lamarckian** – a form of inheritance proposed by Jean-Baptiste Lamarck in the 1800s to occur by transmission of acquired traits to offspring. Inheritance of epigenetic traits is an example of a Lamarckian mechanism.
- **Mendelian** – a form of inheritance proposed by Gregor Mendel in the 1800s but rediscovered in the early 1900s. It suggested that genes were in pairs and that members of gene pairs segregate independently. Mendelian inheritance is the inheritance of alleles now known to be sequences in genomic DNA. Mendelian variation is based on the inheritance of different alleles. Superimposed on this is genomic variation due to new mutation.
- **Methylation** – the addition of CH_3 (methyl) groups, often to cytosine where it is found paired with guanine in genomic DNA.

- **Peroxisome** – a tiny cellular organelle bounded by a lipid membrane within body cells in which, among other actions, very long chain fatty acids are oxidized to release energy, components of cell membranes called plasmalogens, and enzymes, such as catalase that protects against free radicals, are synthesized.
- **Polymorphism** – a DNA sequence found in more than 1% of healthy members of a population. There might be one of more variants of the same sequence. Polymorphisms are considered not to cause disease (as do mutations), but for various reasons they might predispose to disease.
- **Postzygotic mutation** – this occurs after conception so it just affects the first cell to acquire it and all its descendants which receive copies of its DNA. If the mutation occurred before the differentiation of the germ line, it could affect both germ cells and somatic cells, but if it occurred after separation of the germ line, it would only affect the germ line or only somatic cells but not both. As only some of the embryo cells have the mutation, the embryo has *mosaicism*, more than one population of cells, each with a different genome sequence.
- **RNA interference** – RNAs introduced from the environment, or synthesized from endogenous DNA or RNA sequences, bind to complementary nucleic acid sequences of other RNA or DNA molecules and in association with proteins such as dicer or argonaute inactivate or destroy the other nucleic acids (such as viruses, transposons, or messenger RNAs) or are transferred to the nucleus, possibly also in the germ line.
- **Somatic mutation** – mutation just affecting somatic cells which are body cells other than the germ line. These mutations occur after conception and just affect a proportion of body cells: the first cell to acquire the mutation and its descendants which receive copies of its DNA.
- **Transcription** – the copying of a genomic DNA template in the synthesis of RNA.
- **Translation** – the copying of a messenger RNA sequence to synthesize a protein
- **Transposon** – a DNA sequence that was introduced into the ancestral genome of an organism. They can shift from one chromosomal location to another, resulting in new activation or inactivation of genes, or new gene functions, but most commonly when this happens it is deleterious causing disease. They are tolerated in the genome because most are inactivated by various mechanisms including RNA by a process called RNA interference, and because their changes in location (transposition) have contributed to genetic variation, and thus evolution. Retrotransposons were originally part of an RNA viral genome, incorporated into the host's DNA by a process called reverse transcription, where a viral enzyme called reverse transcriptase synthesises a DNA copy of the viral RNA.

Summary Points

- The *Barker hypothesis* linked early childhood malnutrition to adult-onset diseases comprising the metabolic syndrome. Synonyms include the *thrifty phenotype* hypothesis, *developmental origins of health and disease*, or the *fetal programming* hypothesis.

- Mechanisms postulated to explain this association included:
  - Refinements of the earlier thrifty gene hypothesis which claimed that early malnutrition selected for genes for obesity. It was discarded because metabolic syndrome appeared or disappeared too quickly from populations to be caused by genetic selection based on mortality.
    - The bet-hedging hypothesis suggests that genes for obesity or genes favoring leanness can both be retained in the population by selection under different environments at different times.
    - Genes predisposing to the metabolic syndrome might appear by new mutation somatically or by selection of inherited polymorphisms. Their contribution could be assessed by comparing the whole gene sequences of survivors of malnutrition in early life who now have metabolic syndrome and controls including parents and unexposed siblings.
  - The drifty gene hypothesis means release from selection of genes for obesity associated with civilization, agriculture, and freedom from predation.
  - Maternal well-being and fetal programmed adaptive response hypotheses are modifications of the Barker hypothesis. The former involves fetal programming based on the mother's past and present health and nutritional status, while the latter involves fetal programming that integrates information from the past and postulated future environmental conditions.
- Epigenetic gene inactivation programs have been implicated in fetal programming and metabolic syndrome:
  - These could be transmitted to subsequent generations, and there is molecular evidence for this in laboratory models of metabolic syndrome.
  - There is epidemiological evidence for inheritance of effects associated with malnutrition in early life in humans for at least one generation.
  - RNA interference is a postulated mechanism for transgenerational passage of epigenetic information.
- Gut microbiota is passed from mother to child. There is evidence that diet and other factors modify the population of gastrointestinal microorganisms, and in turn these can modify the metabolic program of the human host.

Contents

Abstract

The socioeconomic growth of some countries is impacted by immigration. For example, Canada has sheltered numerous refugees and promptly responded to the global refugee crisis. Food insecurity, dietary acculturation, inadequate access to healthcare, and poor nutrition are major contributing factors to newcomer health. For refugees, compared to immigrants, barriers to health include pre- and post-migration factors such as language, trauma, social stratification, and lack of access to healthcare. Newcomer children can be negatively affected by these inequities. Refugee children, specifically, are at higher risk of poor nutritional health. Studies on refugee children showed they were vulnerable to excess weight, chronic conditions, mental health issues, poor education, and poverty. Newcomer

health decreases over time, which can increase the burden on the Canadian healthcare system. Limited information is available regarding the relationship between food security and social determinants of heath and how this affects unique subgroups of newcomers. Research is required to identify culturally appropriate and cost-effective ways to promote traditional food, and to assess nutritional quality and safety in Canada. Although Canada is used as an example, there is wide applicability to other countries where refugees have similar experiences and data regarding children is lacking.

Introduction

International migration occurred at a faster rate than the world's population growth (United Nations 2016). As of 2015, there were approximately 244 million migrants worldwide (United Nations High Commissioner for Refugees [UNHCR] 2017). There were 65.3 million people forcibly displaced from homes around the world, among them, nearly 21.3 million were refugees, which is more than the number of people displaced after World War II (UNHCR 2017). More than ten million of these refugees were children and youth (UNHCR 2017). Ten million people worldwide have been denied a nationality and lack access to basic necessities including employment, food, education, and healthcare (UNHCR 2017). Immigrant is often used for immigrants and refugees. However, these two populations differ due to cause of migration, different countries of origin, cultures, pre- and postmigration factors, and socioeconomic status, all of which affect quality of life and integration into a new society (Nisbet 2011). Immigrants choose to migrate for a better future while refugees are forcefully displaced from their homeland.

Canada is thought of as the land of immigrants since the majority of its population is new immigrants or descendants of previous immigrants (Fig. 1) (Government of Canada 2011). People migrate to Canada for multiple reasons including job opportunities, health, and ultimately a desire for a better life. Canada's first Governor

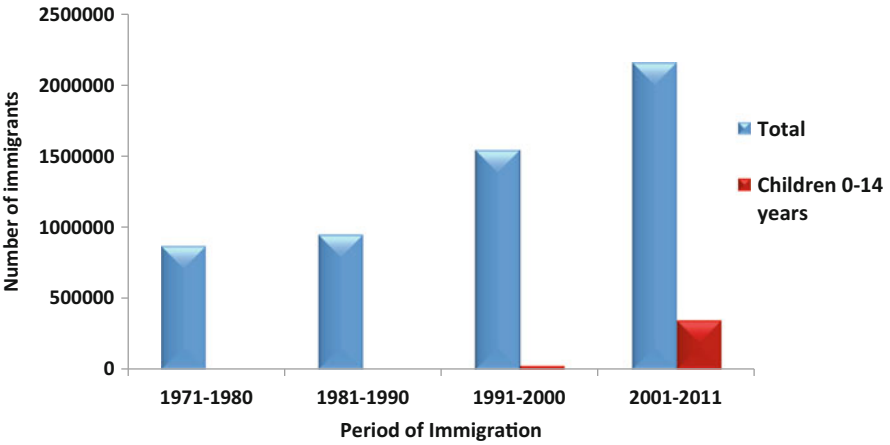

Fig. 1 The number of immigrants and immigrant children to Canada according to period of immigration. This figure indicates a rise in the total number of people who have immigrated to Canada as well as the number of children who have immigrated to Canada from 1971 to 2011. (*Data retrieved from Statistics Canada (2017))

General, John Buchan, stated that immigrants "should retain their individuality and each make its contribution to the national character" (Government of Canada 2011). This philosophy has been maintained throughout the years in Canada's Multiculturalism Policy (Government of Canada 2011). Immigration has had a major impact on the population and socioeconomic growth of Canada. Statistics Canada (2011) states the level of education is higher among immigrants than Canadian-born. Politicians at all levels of government believe immigration is necessary for economic growth and stability (Statistics Canada 2011). The racial diversity of Canada's immigrants may be responsible for the superior social cohesion compared to other developed nations (Statistics Canada 2011).

According to the 2011 census, 6.8 million people living in Canada are foreign born, which accounts for 21% of the total population. People migrate to Canada as individuals or families and are grouped into four categories: economic, families, refugees, and others (Pottie et al. 2015). Based on available data, as of 2011, there were more than one million newcomers in Canada who immigrated between 2006 and 2011, out of which 19% were children aged 14 years and under (Fig. 1) (Statistics Canada 2016). Another 15% were youth between the ages of 15 and 24 years (Statistics Canada 2016).

Refugees entering Canada come with hopes, experiences, and skills, which contribute to a wealthy and affluent society. Canada, in the past, has responded on various occasions to the global refugee crisis and sheltered numerous refugees. From November 2015 to January 2017, approximately 40,081 Syrian refugees arrived in Canada (Government of Canada 2017a). In 2016 (January–September) alone, there were 16,369 in-person refugee claims (Government of Canada 2017b).

Health of Newcomers to Canada

Newcomer health is influenced by culture including knowledge, skills, practices, beliefs, and experiences associated with traditional, complementary, or alternative medicines (World Health Organization [WHO] 2000). Social determinants of health include income, education, employment, social structures, culture, gender, and child development. They play an important role in the health status of newcomers, particularly regarding food security, which is discussed later in this chapter.

Immigrants with a higher socioeconomic status possess more knowledge about health and follow the Western medicine system (Rothstein and Rajapaksha 2003). Highly educated and wealthy immigrants are more likely to maintain a healthy body weight, adhere to preventive health advice, and exercise more frequently (Rothstein and Rajapaksha 2003). Those who are not satisfied with Western healthcare, whether due to high costs, long wait times, or perceived discrimination, have a tendency to use traditional or complementary medicine more than those who are satisfied (Ku 2007). Exposure to factors such as past harmful exposure from war, lack of nutritious food, violence, trauma, poor sanitation, socioeconomic status, English- or French-language proficiency, limited access to preventive services, and specific disease vectors exposure, put refugees at higher risk of ill health and poor nutrition when compared to immigrants (Ng et al. 2011). English language proficiency was greater in immigrant children compared to refugees (Hoover et al. 2016). Refugee newcomer children to Canada were significantly more likely to come from families where neither parent had a secondary level education and where their main source of income was social assistance compared to immigrants (Nisbet 2011). Newcomer immigrant and refugee families with children found themselves in the lowest income category at 49% and 62%, respectively (Nisbet 2011).

The Healthy Immigrant Effect

Previous literature suggests the health status of immigrants upon arrival is high, eventually deteriorating over a period of 5 years postmigration before matching that of native-born Canadians (Newbold 2009). This healthy immigrant effect is associated with three hypotheses, selective immigration, better access to healthcare services over time, and acculturation (Antecol and Bedard 2006; Gushulak 2007). In order to understand the healthy immigrant effect, these hypotheses need to be investigated further.

Selective Immigration

Self-selection is a term that describes individuals who are economically affluent and healthy in their home countries and more likely to migrate due to better opportunities. Immigrants must pass a screening process, including a medical examination, which removes those with severe medical conditions who pose a danger to public health or safety and strain the healthcare system more than the average Canadian, which was $5,292USD per capita in 2014 (Antecol and Bedard 2006; WHO 2014). However, refugees are "protected by law from exclusion on the basis of noninfectious

burden of illness" (Government of Canada 2017c). Immigrants from Asia, Africa, and South America were not as likely to indicate excellent/very good health compared to immigrants from Europe, the United States, Australia, and Mexico combined (Ali et al. 2004). The definition of health changes for immigrants and refugees over time due to acculturation, as they compare themselves to the general population, which affects their perceived health (Newbold 2005).

Although self-selection exists, it is likely only one contributing factor to the healthy immigrant effect and may not be applicable to all immigrants. This theory does not consider the weakening health of refugees after migration. Investigation of other hypotheses is necessary.

Healthcare

Large scale migration inevitably impacts migrants' health as well as the healthcare system of the host country. Compared to native-born Canadians, immigrants and refugees healthcare needs can vary drastically, and they seek access to medical care less, although, they do not necessarily have better health even though their self-perceived health is higher upon entry (Gushulak 2007). Although self-assessed health of immigrants to Canada decreased, their utilization of hospitals did not increase from 1994/1995 to 2000/2001 (Newbold 2009). Barriers to healthcare affecting immigrants can include poor socioeconomic status, loss of social networks, use of traditional medicine, familial and cultural responsibilities, hesitation providing personal information, perceived discrimination, weak language skills, and poor working environments related to "deskilling" (Newbold 2009; Canadian Paediatric Society 2013). The Canadian healthcare system can be difficult to understand as it is not consistent throughout the country. Some provinces have a waiting period of 3 months, which may contribute to lower usage of the healthcare system upon entry (Government of Canada 2016a). For protected persons like refugees, a temporary health card and programs are available (Government of Canada 2016b).

The decline of newcomer health after migration is not limited to poor healthcare access. Healthcare services utilization by immigrants increases with length of stay. This could possibly increase identifying, diagnosing, reporting, and treating health-related issues (Newbold 2009). Certain groups of refugees are given immediate access to healthcare services upon arrival in Canada; hence the hypothesis of self-selection and poor access to healthcare does not apply to them. Therefore, the healthy immigrant effect could be associated with several other factors.

Dietary Acculturation

Adaptation of an individual of a particular ethnicity to a new culture is known as acculturation. Acculturation in itself is a combination of various stages. Typically, the last stage is "assimilation," which occurs when someone from a different ethnicity completely adopts the norms of their new culture, leaving their own behind (Kittler and Sucher 2012). Those who migrate at an older age are less likely to adopt the new culture when compared to those who migrate at a younger age (Kaushal 2009). It is important to note that acculturation is complex and nonlinear, occurring along a spectrum (Berry et al. 2006). A balance should be maintained between the traditional culture and the new culture.

Obesity is a serious condition that can increase the risk of chronic conditions including, certain cancers, coronary heart diseases, hypertension, elevated blood cholesterol, and type 2 diabetes. These conditions could be attributed to poor dietary choices. The possibility of becoming obese increases during the process of acculturation (Kittler and Sucher 2012). When an individual or group of immigrants adopts the eating patterns of the host country, dietary acculturation occurs (Satia-Abouta et al. 2002). Dietary acculturation is important among immigrants to developed countries as diets are high in fat and sugar, which negatively affects their health as their length of stay increases in the host country (Satia-Abouta et al. 2002). Poor accessibility to traditional food items, lack of nutrition education, and convenience of Western food results in increased consumption of prepackaged items or fast food and can be attributed to dietary acculturation (Kittler and Sucher 2012). Dietary acculturation has been associated with increased chronic conditions among adults; hence health could be negatively affected among those children who experience dietry acculturation.

Food Security

One of the most common approaches to evaluate income-related household food security is using a questionnaire developed by the United States Department of Agriculture (2016) and adapted by Statistics Canada (Tarasuk et al. 2014). The United States classifies responses to these questions into four categories whereby households, adults, or children with high or marginal food security are considered food secure and those with low or very low food security are food insecure. Canada uses the same questionnaire and classifies households as food secure, marginally, moderately, and severely food insecure. Food security is directly related to income. Nonvisible minority Canadians are more likely to receive a higher wage job when compared to that of visible minority immigrants (Simich and Jackson 2010). Higher income, greater food security, and better opportunities are typically associated with higher education levels. However, for immigrants, higher education levels do not result in better job opportunities due to deskilling. This explains why immigrants have lower levels of food security when compared to native Canadians. Recent immigrants, even those with postsecondary education, were more likely to be underemployed, low-income, and need housing compared to the Canadian-born (Simich and Jackson 2010).

Since 2004, Statistics Canada has collected information on the food security status of Canadians by means of the Canadian Community Health Survey. Almost 13% of Canadian households (four million individuals) experienced some form of food insecurity, which included 16% (1.15 million) of children (Tarasuk et al. 2014). Food insecurity was more prevalent in households with low income, children, and single-mothers, and where the respondent was Black or Aboriginal (Tarasuk et al. 2014). Recent immigrant households had a higher prevalence of food insecurity (20%) compared to nonrecent immigrants (11.8%) and Canadian-born (12.4%) (Tarasuk et al. 2014). A pilot study, Healthy Immigrant Children (HIC), examined newcomer immigrant and refugee children in Saskatchewan, Canada, and found the

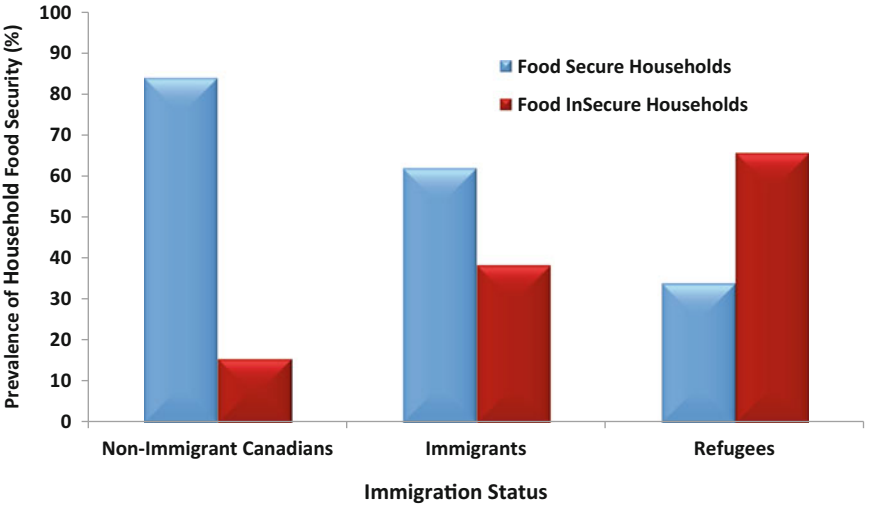

Fig. 2 Prevalence of household food security among households with children. This figure compares national data (Tarasuk et al. 2014) to local data from Saskatchewan in immigrant and refugee children in the Healthy Immigrant Children study (Nisbet 2011) (*Data retrieved from Tarasuk et al. (2014) and Nisbet (2011))

prevalence of household food security was 62% and 34%, respectively (Fig. 2) (Nisbet 2011). Child food security status was 51% compared to household food security at 46% (Nisbet 2011). Although a higher prevalence of household food insecurity was observed in refugee newcomer families, child food security was not significantly different between immigrant and refugee families (Nisbet 2011). As the duration of stay in Canada increased, the risk of food insecurity in children decreased (Nisbet 2011). The study also noted that children living in households with more than two children were more likely to be food insecure (Nisbet 2011).

Food insecure individuals can binge eat, consume high-calorie food, and, therefore, develop overweight/obesity (Che and Chen 2001). Children living in households where high school is the highest level of education are at greater risk of being overweight/obese in comparison with those living in households with a post-secondary degree (Shields 2005). Studies also showed that 21% of people in food insecure households had at least three chronic conditions and 15% of these people were obese (Che and Chen 2001).

Nutritional Health of Newcomers

The health status of individuals is strongly affected by the food they consume. Culture strongly influences people's food choices. Healthy food choices can be limited by the ability to purchase expensive food items (Kittler and Sucher 2012). Data gathered by Statistics Canada (2014) using body mass index (BMI) showed nearly 20% (5.3

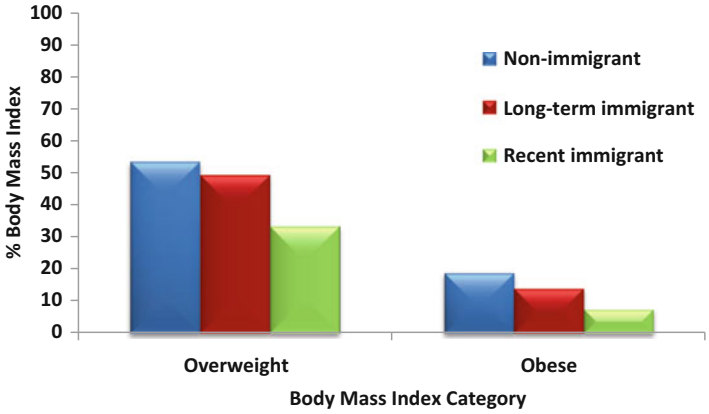

Fig. 3 Classification of overweight and obese according to immigration status. Overweight and obesity is shown for adult non-immigrants, long-term immigrants, and recent immigrants. This figure supports the healthy immigrant effect, as overweight and obesity increases with length of stay in Canada (*Long-term immigrants were in Canada 11 years and longer and recent were in Canada less than 11 years. Data retrieved from Tremblay et al. (2005))

million) of Canadian adults were obese (self-reported height and weight). Estimates suggest that Canadians consume about 13% of their caloric intake from added sugar. High sugar consumption is frequently associated with adverse health outcomes including cancer, dental caries, diabetes, heart disease, high blood cholesterol, overweight/obesity, and stroke. Figure 3 portrays overweight and obesity according to immigration status. Culture influences newcomer food choices, possibly due to lack of access to traditional food items. Newcomers also witness differences in schedules, such as working long hours, which results in minimal time to prepare food in a traditional manner. Immigrant children tend to prefer Western food, while parents particularly prefer traditional food items (Gray et al. 2005). Income, country of origin, city of relocation and comprehension of its primary language all affect the likelihood of food habits changing postmigration (Gray et al. 2005).

Health of Newcomer Children

Detailed information on health and nutritional status of newcomer children is not available in Canadian literature. A large number of youth (37%) acculturate by being involved in activities of both traditions (Berry et al. 2006). The Canadian Institute of Child Health reported that immigrant children and youth were less likely to consume alcohol, smoked less, and had lower suicidal behavior when compared to native-born Canadian children (Pottie et al. 2015). A huge proportion of immigrant youth reported being in good stable physical and mental health (Kukaswadia et al. 2014). Also, 88% of immigrant youth aged 12–14 years reported having a strong sense of belonging to their community compared to 82% of native-born Canadian youth

(Pottie et al. 2015). Canada's vision is dependent on the well-being of children and youth who are the future of the country, and the diversity of immigrant and refugee children plays a vital role.

Refugees, particularly children, are prone to infection, which is only heightened by unsanitary living conditions and malnutrition (Food and Agriculture Organization 1995). Unfortunately, many immigrant and refugee children face serious issues with poverty, education, dietary needs, and emotional changes while coping with North American culture (Tienda and Haskins 2011). Immigrant children and youth are subjected to a wide range of mental health issues. Causes for mental health issues were a combination of several complex factors including language barriers, loss of friends or family members, living in poor neighborhoods, and cultural discordance or dissonance (Canadian Paediatric Society 2016). Cultural discordance occurs when a child perceives divergence between two cultures. This discordance is greater for children who migrate at a younger age and can have a negative impact on various aspects of their lives including relationships with peers, mental health, and tension with family (Rohmann et al. 2006).

Prevalence of nutritional anemia, growth abnormalities, malnutrition, dental caries, enteric parasites, and psychiatric disorders among the children of recent immigrants is high (Pottie et al. 2015). The term "malnutrition" comprises both under- and overnutrition and develops due to poor nutrient absorption within the body and inadequate or excess intake of protein, energy, and micronutrients (WHO 2001). Malnutrition causes deficiencies, which can affect children's physical development/growth, increase their risk of diseases, and decrease their concentration levels/performance at school (International Development Committee 2008; WHO 2001). The likelihood of being malnourished increases among families who have lower household incomes and poor health education (e.g., newcomer refugees) (WHO 2001). A study conducted in Toronto, Ontario, showed 7% of immigrant children were below the third percentile for height-for-age and 12% for weight-for-age (Salehi et al. 2015). The same study also showed the prevalence of anemia and iron deficiency among immigrant children was 23% and 53%, respectively (Salehi et al. 2015). Health issues in children postmigration can arise because of poor dietary choices leading to overweight/obesity, and eventually chronic diseases (Shields 2005).

Nutritional Health of Newcomer Children

Diversity in diet is important to ensure adequate intake of all nutrients for optimal growth and development. Children have specific requirements as they go through this particular stage of life. Over the last three decades, the prevalence of overweight/obesity has increased among children in Canada. The possibility of being an obese adult increases if obesity is acquired during childhood. Research on immigrant and refugee children in Canada is lacking in the literature.

The predisposition to numerous negative health outcomes associated with obesity makes childhood obesity a serious public health concern. From 2005 to 2014, 29% of boys and 17% of girls were classified as overweight/obese (Statistics Canada

Table 1 Indices of disease in newcomer Canadian children. Considering the paucity of data, information was included from a pilot study in Saskatchewan to show a small picture of the health status of newcomer children

Characteristics	Immigrants n = 33 (45.8%)	Refugees n = 39 (54.2%)	All participants n = 72 (100%)
Blood cholesterol in mmol/L (Mean ± SD)	4.6 ± 0.7[a]	5.3 ± 0.9	5.0 ± 0.9
Borderline high ≥4.4 mmol/L High ≥5.2 mmol/L	10 (34.5%) 7 (24.1%)	10 (26.3%) 20 (52.6%)	20 (29.9%) 27 (40.3%)
Total serum vitamin D in nmol/L (Mean ± SD)	45.7 ± 13.9[a]	37.8 ± 15.5	41.2 ± 15.2
Deficient and insufficient < 50 nmol/L Sufficient >50 nmol/L	19 (63.3%) 11 (36.7%)	31 (79.5%) 8 (20.5%)	50 (72.5%) 19 (27.5%)
Total body bone mineral content (TBBMC) in grams (Mean ± SD)	984.9 ± 245.0	947.8 ± 208.8	964.6 ± 224.9
Low TBBMC	13 (41.9%)	14 (35.9%)	27 (38.6%)

Data retrieved from Nisbet (2011)
[a]Significant difference between immigrants and refugees

2014). In 2011–2012, immigrant youth were less likely to be overweight (15%) when compared to their Canadian counterparts (19%) (Pottie et al. 2015). The chance of being overweight/obese was higher among refugees compared to immigrants (Nisbet 2011). Hypertensive levels were reported in 26% of overweight/obese newcomer children (Nisbet 2011). Table 1 displays indices of disease in newcomer children to Canada.

In 2004, 71% of Canadian children 4–8 years and 62% of girls and 68% of boys 9–13 years were lacking the daily recommended servings of fruit and vegetables (Garriguet 2007). This value jumps to 80% for newcomer children 7–11 years (Nisbet 2011). Reduced intake of fruit and vegetables depletes nutrients from the body; this decreases immune system function and increases the chance of developing chronic conditions (Kirkpatrick and Tarasuk 2008). Also, 37% of children 4–9 years and 61% of boys and 83% of girls 10–16 years were not getting the daily recommended milk and alternatives servings (Garriguet 2007). When examining newcomer children 7–11 years of age, 76% did not meet recommendations for milk and alternatives (Nisbet 2011). Over 25% of children aged 4–8 years and 89% of newcomers aged 7–11 years were not consuming enough whole grains (Garriguet 2007; Nisbet 2011). Another 14–18% of girls aged 9–18 years were not getting the recommended amount of meat and alternatives (Garriguet 2007).

Prevalence of food insecurity negatively impacts nutrient consumption among Canadian children. Food insecure children were more likely than food secure

children to consume energy-dense food and have lower protein, milk, and vegetable and fruit intake (Kirkpatrick and Tarasuk 2008). In 2004, the average HEIC score for children aged 4–8 years was 65.4, 59.7 for boys aged 9–13 years, and 60.0 for girls in that same age range (Garriguet 2009). More than 90% of Canadian children aged 4–13 years and newcomer children aged 7–11 years had diets classified as needing improvement (Garriguet 2009; Nisbet 2011). Newcomer refugee children to Saskatchewan had a significantly lower mean score (60.4) compared to newcomer immigrant children (65.4) (Vatanparast et al. 2013). Refugees had a poor diet at 14% compared to zero immigrants (Vatanparast et al. 2013).

Nutrients of Concern

Immigrant and refugee children can be at greater risk for nutrient intake inadequacies due to previously discussed pre- and postmigration factors compared to Canadian-born children. Prevalence of intake inadequacy was <10% for all nutrients for children 1–8 years of age (Kirkpatrick and Tarasuk 2008). Among children aged 9–18 years who were food insecure, the prevalence of nutrient intake inadequacy for protein, vitamin A, and magnesium was greater compared to food secure children (Kirkpatrick and Tarasuk 2008). Newcomer children to Canada are particularly at risk for nutrient inadequacies of folate (DFE), iron, vitamin B12, zinc, calcium, and vitamin D as found in HIC study (Fig. 4) (Nisbet 2011). The prevalence of intake inadequacy of both folate (DFE) and iron was significantly greater among refugee compared to immigrant children (Nisbet 2011).

Vitamin D is important during the developmental stage of childhood. It is a major nutrient for bone mineral accrual. The majority of requirements, 80–90%, must be synthesized from the sun (Hintzpeter et al. 2008). It is available through consumption of food such as oily fish, cod liver oil, and egg yolk. A deficiency in vitamin D involves deterioration of cortical bone, which progresses to osteoporosis (Institute of Medicine 2010). Some noncalciotropic functions of vitamin D, primarily those with an immune regulatory role, are associated with cancer, multiple sclerosis, and types 1 and 2 diabetes (Whiting and Calvo 2005). Calcium deficiencies are often found among those who are also vitamin D deficient (Nellen et al. 1996). Hyperparathyroidism has been noted in individuals whose regular diets contain high amounts of unrefined cereals. These cereals have a high content of phytates, which hinder calcium absorption (Pettifor 2004).

Immigrants to developed countries, including Canada, are at greater risk for vitamin D and calcium deficiencies. Vitamin D deficiency is often found in female immigrants and refugees. Some females have minimal sun exposure due to cultural beliefs associated with full-body veils, darker skin pigmentation, which decreases the dermal synthesis of vitamin D, and higher parity (number of births) (Nellen et al. 1996). Other risk factors for vitamin D deficiency, relevant to the general population, include genetics, use of sunscreen, living in areas of high latitude (around 37° latitude in the winter months), and insufficient dietary vitamin D (Hintzpeter et al. 2008).

A vitamin D deficiency less than 25–27.5 nmol/L is considered representative of rickets (Roth 2007; Ward et al. 2007). Individuals with darker skin represented 89% of children with rickets while 24% were immigrants (Ward et al. 2007). As children

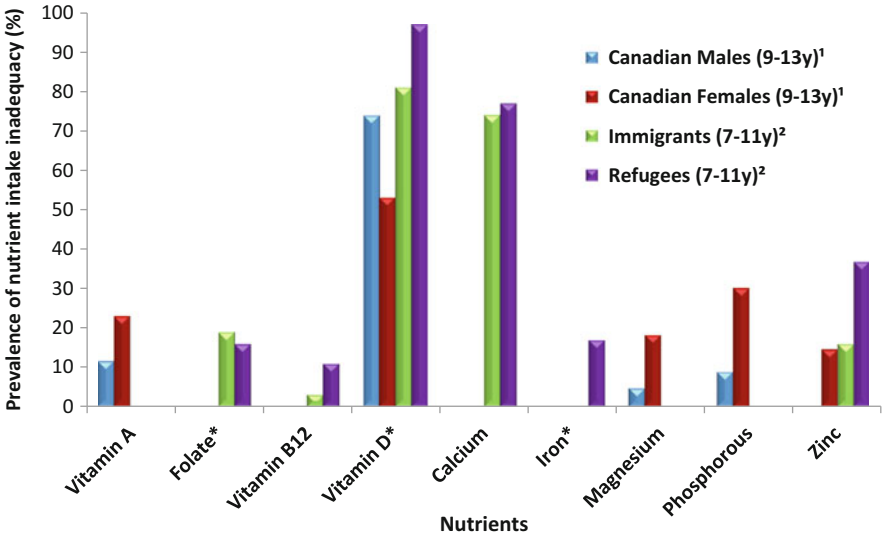

Fig. 4 Prevalence of nutrient intake inadequacy in Canadian and newcomer children. Prevalence of nutrient intake inadequacy for vitamin A, folate, vitamin B12, vitamin D, calcium, magnesium, phosphorous, and iron are compared amongst Canadian children 9-13 years of age and immigrant and refugee children to Canada, 7-11 years of age. (*Significant difference between immigrant and refugee children. [1]Canadian data obtained from Health Canada (2008). [2]Newcomer data obtained from Nisbet (2011))

age, vitamin D concentrations decrease. This may be associated with poor milk consumption, higher consumption of sugar-sweetened beverages, low sun exposure, and decreased activity levels (Roth 2007). In Canada, children who live at greater than 55 degrees latitude are more likely to be vitamin D deficient (Ward et al. 2007). A study using data from 2005 to 2010 in Calgary showed 42% of newcomer refugee children had lower than adequate vitamin D and 10% were deficient (Aucoin et al. 2013). It also showed the refugee population had lower levels of vitamin D when compared to the general Canadian population (Aucoin et al. 2013). Prevalence of intake inadequacy was significantly higher in newcomer refugee (97%) children to Saskatchewan compared to newcomer immigrant children (81%) (Vatanparast et al. 2013). Females were at greater risk of deficiency, likely due to cultural practices limiting skin exposure to the sun (Vatanparast et al. 2013). Prevalence of calcium intake inadequacy in newcomer immigrant and refugee children was 76%. This could be associated with only 24% meeting Canada's Food Guide recommendations for milk and alternatives (Vatanparast et al. 2013). Total serum 25(OH)D (nmol/L) was significantly higher in newcomer immigrant children compared to refugees (Table 1) (Nisbet 2011). Low levels of vitamin D were noted among individuals who had been living longer in Canada, particularly females (Nisbet 2011). Height and serum vitamin D status were significant determinants of TBBMC in newcomer children (Nisbet 2011).

Research Gaps and Recommendations

The health of immigrants decreases over time. However, many factors come into play and must be considered when investigating this population's health. In order to appropriately influence policy, we must turn to research to understand how and why this decline in health manifests. Research has shown that certain measures of health are poor for newcomers, particularly refugees compared to the Canadian-born. The Canadian health system could be negatively impacted. Therefore, evidence-based interventions should be carried out to mitigate the growing burden of disease. In Canada, little is known regarding the dietary transition that newcomers face post-migration. Information is particularly sparse when it comes to children and differentiating between varied experiences of immigrants and refugees.

Further investigation is required to identify culturally appropriate and cost-effective ways to promote traditional food and to assess their nutritional quality and safety in Canada. It is also imperative to identify the most important influential factors in nutrition-specific health promotion as well as priority subgroups such as culture, gender, age, and immigration status.

The relationship between food security and the social determinants of health is important to determine how they affect acculturation, immigrant dietary behaviors, and resultant health outcomes. The impact of food security on health and diet in the newcomer population is unknown as is the extent of its reach.

Literature is lacking any sort of measurement for acculturation, which would be beneficial to understand where along the acculturation spectrum immigrants find themselves and how that relates to dietary behaviors (Table 2). Further research is required when it comes to how, and to what extent, Canadian culture influences the nutrition knowledge, perceptions, beliefs, and behaviors of immigrants. The challenges of accessing and maintaining a traditional diet and how to incorporate nutrition knowledge into a traditional diet should be explored.

Nutrient deficiencies specific to immigrants and the role they play in diet-related health outcomes requires further investigation. With a wide range of cultural groups, it is important to identify the role of genetics and if these groups have unique

Table 2 Factors that increase dietary acculturation. Lending to recommendations for policy, possible measurement tools to assess acculturation were tabulated

Single item measures	Examples	Dietary acculturation
Residence	Increased length of stay	Increases
Language	Ability to speak host country's language	Increases
Generational level	Younger	Increases
Social circles/community	Work outside the home	Increases
Self-identification	Willingness to blend in with new culture	Increases
Pre-arrival exposure to the Western diet	Accelerated nutrition transition and globalization	Increases

Adapted and modified from Satia-Abouta et al. (2002)

standards in regards to health measurement tools. Further exploration is required into dietary risk factors for chronic conditions, especially among newcomer children, and how they vary across age groups, cultures, immigration status, gender, and time since migration. When it comes to providing culturally appropriate nutritional care and services, cultural competency skills among registered dietitians and the care they provide is essential.

Protocols

Anthropometry: Anthropometrics included measured height, weight, and waist circumference. BMI was assessed using the age- and sex-specific BMI calculator from the WHO (2007).

Blood Pressure: A child with a blood pressure measurement greater or equal to the 95th percentile on three occasions was deemed hypertensive (NHBPEP 2004).

Dietary Intake: The average of three 24-h dietary recalls was used to obtain usual dietary intake. Food was entered into a diet analysis program and classified in groups according to Eating Well with Canada's Food Guide (Health Canada 2007). For nutrient intake inadequacy, see the Mini-Dictionary of Terms. The Canadian Healthy Eating Index was based on recommendations for age and sex from Eating Well with Canada's Food Guide as illustrated by Garriguet (2009). Based on a total score out of one hundred, a person's diet was classified as poor (<50), needing improvement (50–80), and good (>80).

Food Security: Food security was assessed using a validated questionnaire, adapted from Health Canada (2007), whereby participants were food secure (0–1), moderately food insecure (2–5), and severely food insecure (6–10).

Serum Measures: Serum was collected on blood spot cards using a finger prick. Nonfasting total cholesterol was classified as acceptable (<4.4 mmol/L), borderline (4.4–5.1 mmol/L), and high (≥ 5.2 mmol/L) (American Heart Association 2011). Vitamin D was defined as deficient (<30 nmol/L), inadequate (30–50 nmol/L), and sufficient (>50 nmol/L) according to the IOM (2010).

TBBMC: Values were obtained using dual-energy x-ray absorptiometry and compared to estimated normal values for each child's age, sex, and ethnicity based on longitudinal studies (Baxter-Jones et al. 2009).

Dictionary of Terms

- **Deskilling** – Deskilling occurs when the host country does not acknowledge immigrants' education from their native country (Newbold 2005).
- **Food Insecurity** – The Food and Agricultural Organization (2003) states "Food insecurity exists when people do not have adequate physical, social or economic access to [sufficient, safe and nutritious food that meets their dietary needs and food preferences for an active and healthy life]."

- **Food Security** – The Food and Agricultural Organization (2003) states "Food security [is] a situation that exists when all people, at all times, have physical, social and economic access to sufficient, safe and nutritious food that meets their dietary needs and food preferences for an active and healthy life."‖
- **Health** – The World Health Organization (2004) defines health as "the state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity…and [it] is largely culturally defined."
- **Healthy Eating Index** – "The Healthy Eating Index (HEI) uses a point system on a scale of 1–100 to evaluate certain aspects of a person's diet to conclude if their diet is good (>80pts), needing improvement (50-80pts), or poor (<50pts)" (Garriguet 2009). The HEI was originally developed by the United States Department of Agriculture and adapted by Canada (HEIC) (Garriguet 2009).
- **Healthy Immigrant Effect** – Immigrants are healthier upon arrival to the host country compared to the native-born population (Newbold 2009; Kaushal 2009). The healthy immigrant effect is influenced by self-selection, access to healthcare, acculturation, and other factors (Newbold 2009; Kaushal 2009).
- **Immigrant** – "A person who has come to a different country in order to live there" (UNHCR 2017).
- **Newcomers (recent immigrant/refugees)** – People who migrated to their host country less than 5 years ago.
- **Prevalence of Inadequacy** – The prevalence of inadequacy is the percentage of a group's intake below the estimated average requirement (EAR) for a specific nutrient (Health Canada 2012). The EAR is the "average daily nutrient intake level that is estimated to meet the requirement of half the healthy individuals in a life-stage and gender group" (Health Canada 2012).
- **Refugee** – A refugee is someone who "…owing to well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group or political opinion…is unable or unwilling to return to his/her country of birth due to fear for their safety" (UNHCR 1951).

Summary Points

- In 2011, 6.8 million people living in Canada were foreign born with more than one million being newcomers. Children aged 14 years and under made up 19% of the total newcomers and youth aged 15–24 years made up 15%.
- Canada has welcomed several refugees in the past, responding to the global refugee crisis. In the last 1.5 years, 40,081 Syrian refugees arrived in Canada and in 2016 (January–September), there were 16,369 in-person refugee claims.
- The health status of immigrants upon arrival is high. However, it eventually deteriorates over time before matching that of native-born Canadians.
- Refugees are at greater risk of poor nutrition and health compared to immigrants due, in part, to premigration exposures. Refugee children, specifically, are at greater risk.

- Dietary acculturation could be due to expensive or less available traditional food items, a lack of nutrition education, and convenience in preparation of Western food, resulting in increased consumption of prepackaged energy-dense items, which contribute to elevated overweight and obesity levels.
- Newcomer households had a higher prevalence of food insecurity, less access to healthcare, and lower than recommended levels of required nutrients.
- Immigrant and refugee children face issues with poverty, education, food security, nutritional requirements, and mental health while acculturating to North American culture, which results in poor health outcomes.
- Canada lacks comprehensive information on the health and nutritional status of immigrant and refugee children. However, immigrant and refugee children were found to have higher rates of food insecurity and be at greater risk for vitamin D and calcium deficiencies.
- Continued research on food security and the identification of culturally appropriate food with consideration for availability, accessibility, quality, and affordability is important to address these issues.
- Further investigation is required to identify culturally appropriate and cost-effective ways to promote traditional food and assess their nutritional quality and safety in Canada.

Abstract

Food is generally known to be one of the basic necessities of life and is known to be crucial to the survival and well-being of individuals, family, community, and the nation at large. Food security covers a wide scope and is beyond food available to individuals, but includes access to kinds of food desired at all times and how well it is utilized. Household food insecurity is defined as the inability of household members to have access to the quantity and quality of food required at all times for their daily energy needs and maintenance of good health.

Studies have shown that the causes of hunger and household food insecurity are a mix of economic, social, poor agricultural practices, and absence of community-driven food assistance program. These factors are those that influence food production and availability of food at markets and stores referred to as supply factors and those that will affect the ability of individuals and household members to be able to purchase food for household consumption, referred to as demand factors. Household food insecurity influences nutritional status of children and is usually assessed using anthropometric methods. Anthropometry is the use of body measurements to assess and classify nutritional status of children 5 years and below. These measurements include age, sex, weight, and height (or length in children 6–23. 9 months or under 87 cm in height). When two of these variables are used together they are called an index. Mid-upper arm circumference (MUAC) is used for individuals aged 6 months and older. The common anthropometric parameters are **Height-for-age** used to assess stunting and is used to detect children who have been undernourished for not less than 6 months otherwise referred to as chronic malnutrition; **Weight-for-height** which detects children suffering from current or acute under-nutrition and is usually referred to as wasting and **Weight-for-age** used to identify underweight. The factors found to be associated with nutritional status of children less than 5 years are household food insecurity, feeding practices, family wealth status, and education of caregiver. This chapter explained the effect of household food insecurity on the nutritional status of children less than 5 years and measures designed to address both household food insecurity and identified child nutritional problems. Conclusively causes of household food insecurity and child nutritional problems were used as a guide to their solution.

Introduction

Household Food Insecurity, Hunger and Child Nutritional Status

Food is generally known to be one of the basic necessities of life and is known to be crucial to the survival and well-being of individuals, family, community, and the nation at large (Allmer 2011). Food security covers a wide scope and is beyond food available to individuals, but includes access to kinds of food desired at all times and how well it is utilized. **Household food insecurity** is the inability of household members at all times, to have access to the quantity and quality of food required for their daily energy needs and maintenance of good health. It is associated with either absolute lack of food, or food available in insufficient quantity with or without poor quality. Household food insecurity can also occur when food is available both in quantity and quality but access is denied to some significant members of the household. This may be due to inappropriate intra-household food distribution which is common in household with internal crises or disunity where those favored by the primary caregiver/household head are given more food, even in period of food sufficiency. This scenario occurs frequently in African countries where polygamy is widely practiced with poor birth control and its attendant large family members (Adebayo et al. 2012). Food and Agriculture Organization of the United Nations (FAO), 2010 define **Food security** as "when all people, at all times, have physical, social and economic access to sufficient, safe and nutritious food which meets their dietary needs and food preferences for an active and healthy life." Household food insecurity occurs in the absence all the parameter mentioned by FAO in their definition of food security.

Hunger is defined as insufficient intake of food substances or absolute lack of food, either as a result of household food insecurity, poor feeding practices, or reduced access to the consumption of adequate food substances. Household food insecurity is a precursor to most cases of hunger in the absence of self-induced denial to food consumption or an aftermath of being restricted to food consumptions by forces beyond one control even in a situation of food availability.

Children less than 5 years nutritional status is the nutritional adequacy or inadequacy of nutrition of children less than 5 years and is usually measured using anthropometric measurement which compares weight and height of the children against standards, using World Health Organization (WHO) parameters as shown below:

1. Underweight as weight for age < -2 standard deviations (SD) of the WHO Child Growth Standards median.

2. Stunting as height for age < -2 SD of the WHO Child Growth Standards median.
3. Wasting as weight for height < -2 SD of the WHO Child Growth Standards median.
4. Overweight as weight for height $> +2$ SD of the WHO Child Growth Standards median.

Household food insecurity has various scope and its impact on nutrition, especially in children less than 5 years depends on which dimension is predominant. The scope of household food insecurity is food availability, access to food, food supply stability, and food consumption pattern.

Assessment of Household Food Insecurity

There are various methods used by various researchers for the assessment of household food insecurity (Sanusi et al. 2006; Swindale and Bilinsky 2006; Coates et al. 2007; Ajao et al. 2010; Ijarotimi and Odeyemi 2011; Coleman-Jensen et al. 2013).

However, the parameters mostly used are Household Food Insecurity Access Scale (HFIAS) for measurement of food access and Household Dietary Diversity Scale (HDDS) for measurement of different food groups. However, the HFIAS which use series of questions about conditions and behaviors that characterize households which occurred in the last 12 months when they were having difficulty meeting basic food needs is preferred by this author. Each question asks whether the condition or behavior occurred at any time during the previous 12 months and specifies a lack of money and other resources to obtain food as the reason. The series includes 10 questions about food conditions of the household as a whole and of adults in the household and, if there are children present in the household, an additional 8 questions about their food conditions were added.

The food security status of each interviewed household is determined by the number of food-insecure conditions and behaviors the household reports (Wunderlich and Norwood 2007; Coates et al. 2007).

1. Food secure were households that denied all items or affirmed one or two items
2. Foods insecure without hunger were households that affirmed three to seven items
3. Food insecure with moderate hunger were households that will affirm eight or more items
4. Foods insecure with severe hunger were households that affirmed five or more foods insecure condition among children.

However, the limitation to HFIAS as a means of assessing household food insecurity is recall bias, nevertheless, it is still the most universally acceptable methods for assessing household food insecurity.

Causes of Household Food Insecurity

Causes of hunger and household food insecurity is a mix of economic, social, poor agricultural practices, and absence of community-driven food assistance program. There is a complex interplay of these factors in many households and any measure directed at reducing household food insecurity must look at these factors singly and in combination (Bhattacharya et al. 2002; Clover et al. 2003; Chaparro 2012; Coates et al. 2007; Coleman-Jensen et al. 2010, 2011; Dean et al. 2011; Diouf et al. 2010; Donna et al. 2002 and Frehiwot 2007).

During our various studies on household food insecurity and nutrition factors of children under-fives, both quantitative, observational checklist and qualitative methods were used to explore various causes of household food insecurity and malnutrition. The findings have been summarized into supply factors and demand factors. The supply factors address issues that will make food commodities available at markets, groceries stores, supermarkets, and other retail food stores, while the demand factors address those factors that will reduce the ability of individuals and household to access and purchase food commodities for consumption (New South Wale Centre (NSW) for Public Health Nutrition 2003).

These facts have been used to build an evidenced-based Conceptual Framework for Household Food Insecurity in rural and urban areas of Ondo State, Nigeria. This same scenario might operate in other settings outside Ondo State, Nigeria (Fig. 1).

This conceptual framework shows that the food security status of the household depends on factors that influence food supply as well as those factors that enhances or decreases the ability of household to demand (have access) for food as explain further below.

Supply Factors Influencing Household Food Insecurity

Household food insecurity is a function of many factors among which is the amount of food supply available for purchase by individuals, families, and households. The supply of food is influenced by macroeconomic policies of the national government, level of unemployment, transportation cost, and cost of fuel or energy.

Macroeconomic Policy of National Government

The overall management of a nation's economy by its economic team depends on its macroeconomic policies, which influence the various economic activities of that country. It influences the gross domestic products, prices of goods and services, supply of food materials, clothing, medicine, and housing. Macroeconomic policy determines the exchange rate of a country currency in relation to those of other countries, and this could either lead to devaluation or increase in the value of that

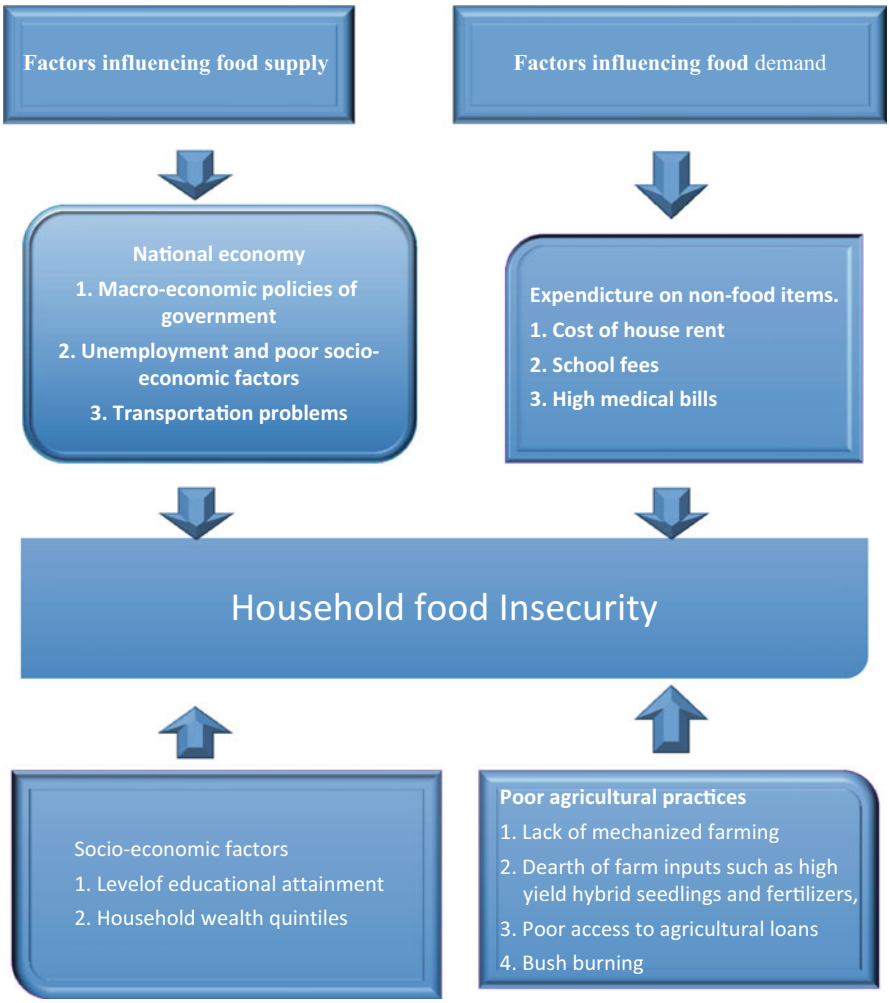

Fig. 1 The conceptual frameworks for household food insecurity (Source: Dr. Akanbiemu et al. 2012: Studies on Household Food Insecurity in Rural and Urban Commuities of Ondo State, Nigeria)

currency. Currency devaluation in countries which depends mainly on the importation of staple food, especially where food production is far below the national demand will tend to have food shortage as more money will be required to import fewer food commodities which will make demand higher than food supply and will invariably lead to increase in prices of food commodities. In a country where the currency is devalued and household income is relatively unchanged or lesser in value even in period of food price increase as is the case in Nigeria, food insecurity and hunger will become more prevalent.

Level of Unemployment and Poor Socioeconomic Factors

A country wealth and that of its citizens depends on the level of production of goods and services and this is a function of the proportion of its population engaged in economic activities, i.e., those employed by both formal and informal sectors. Employment generates income and income will lead to economic multiplier effects which could further stimulate the growth of the economy. The amount of income available to individuals and households will determine their ability to purchase the quantity and types of food required for consumption or storage. In areas of a country especially rural communities with high unemployment rate and lowest wealth quintiles, household food insecurity is as high as 90% (Akanbiemu et al. 2016b). Barriers to food security are diverse and include broadly; socioeconomic and cultural factors. Low income has been recognized by other researchers as the primary risk factor for food insecurity. Other factors acting as barriers to food security are household, community, and social and physical environments (Olson et al. 2004; Lee 2001; Sultana and Kiani 2011; Mahgoub et al. 2006; Hackett et al. 2010).

Transportation-Related Problems

The quantity of food supply to homes, groceries stores, and markets depends on critical issue affecting transportation of food products within and outside various communities. Majority of agricultural activities resulting in food production occurs in rural areas, especially the hard to reach areas. During raining seasons, many hard-to-reach rural communities are cut off from having easy access to semiurban and urban areas as roads become unmotorable. In such situations, food produced are either wasted to natural spoilage or are transported using extreme cost in such countries. This situation occurs in Nigeria where there are poor storage facilities for agricultural products especially in rural farms (subsistence farming) where over 70% of food production occurs, cost of transportation results in inability of farmers to transport their farm products to towns and urban markets, such that many of these goods are lost to spoilage. In other words, even with good food production, transportation remains a great challenge to rural farmers as many lack the means or money to move their products outside production sites and this greatly impedes food supply and increase food insecurity.

Fuel and Energy

The emerging rise in the cost of fueling small-scale farm machines and poor energy supply to local farms have of recent become a major hindrance to agricultural outputs in Nigeria. The cost of fuel has increased since January 2012, and has continue to increase thereafter, while electricity supply has continued to decreased in the mix of fuel (petrol and diesel) price increases. The implication is that majority of farmers can no longer power those critical machines used for farm grazing and

food processing. This has resulted in decrease production of agriculture products with the resultant low supply to homes, groceries store and markets.

This attendant poor supply of farm products will increase household food insecurity as the case in Nigeria.

Demand Factors Influencing Household Food Insecurity

Household food insecurity occurs even in situation of adequate food supply to food outlets. This occurs when households are unable to demand for these food products due to many interrelated factors. The two main demand factors militating against access and food utilization are expenditure on nonfood items and socioeconomic status of household members. These demand factors are further explained below.

Expenditure on Nonfood Items

Non-food expenditure competes with other expenses for limited family or household income and the proportion of non-food expenditure on the household income determine the amount available for food purchase. Money spent on house rent, school fees and medical bills were reported as some of the causes of household food insecurity by participants in a qualitative aspect of a study on determinants of household food insecurity in rural and urban districts of a Southwest State, Nigeria, by Dr. Akanbiemu et al. (2016b). These are:

(i) **Expenditure on house rent**: Significant proportion of household monthly or annual income is spent on rent for residential purpose. In many rural and urban dwellers in Nigeria, income is limited and in many cases mortgage facilities that will make house ownership affordable for both rural and urban dwellers are lacking. Families and households use part of their annual income to pay owners of houses built for residential profit-making purposes, making such expenditure a major hindrance for household food purchase.

(ii) **Expenditure on school fees**: Money spent on school fees has increasingly become a big drain on families and household income. In Nigeria, failure of public school system especially primaries and secondary schools have led the majority of parents or guardians to send their children to private schools which are often more expensive. This form of household expenditure competes with other needs for the scarce resources available for household such that money that would have been used for food purchase are purposefully used for their children education.

(iii) **Expenditure on medical expenses**: household expenditure on medical bills greatly impair their ability to have enough money to buy food for household consumption. Majority of the households spent more than 60% of their income on medical treatment when they or members of their household are ill. The National Health Insurance scheme in Nigeria caters only for few of the former

sector staff and even for those that benefit, the scope of treatment is greatly limited to disease that is acute in nature, while treatment of chronic diseases and cancers are yet to be widely covered. In addition, the scope of diagnostic investigation is also limited to those that are of minimal cost, while expensive ones are presently being excluded. In countries with low health insurance coverage, majority of those that seek medical care rely on out of pocket spending on health which could be higher than 40% of their total income (catastrophic health expenditure). Catastrophic health expenditure greatly compromises resources available for food purchase and use.

Socioeconomic Status of Household Members

Many sociocultural factors act singly or in combination to influence household ability to demand and utilize food. Poor demand for food will influence household food security status. The common factors identified in a study on Determinants of Household Food Insecurity in Rural and Urban Districts of a Southwest State, Nigeria, by Dr. Akanbiemu et al. (2016b) are a level of educational attainment and household wealth quintiles.

(I) **Level of Educational Attainment**
Households where the primary caregiver has low or no formal education are likely to be more food insecure than families with better educational attainment (Akanbiemu et al. 2016b) and are also more likely to be malnourished especially among children less than 5 years as shown in a study by Akanbiemu et al. (2016a) on the nutritional status of under-fives in rural and urban communities of Southwest, Nigeria. Education influences perception and feeding practices of household members by influencing the types and food consumption pattern. This is particularly important when household members consume poor quality food due to ignorance or preference for foods with poor nutritional values. Education may determine the type of paid income for household members and highly educated members are more likely to secure better-paid jobs that will make enough money available for food purchase for household consumption.

(II) **Household Wealth Quintiles**
The occurrence of household food insecurity is a function of wealth status of households. Study has shown that households with lower wealth quintiles were more likely to be food insecure than those with higher wealth quintiles (Akanbiemu et al. 2016b). Wealth status determined by principal component analysis of ownership of household items clearly show this important predictor of household food insecurity. In addition, study also shows that those with income higher than the national monthly minimum wage were less likely to be food insecure than those with lower income (Akanbiemu et al. 2016b). Income and wealth are important determinants of household food insecurity. This is important because the ability to purchase food items for household consumption is a function of the amount of income and other resources available to household members.

Table 1 Adjusted odds of predictors for household food insecurity

Variables for total population	Odds ratio	95% confidence interval	p-Value
Primary caregiver educational status			
No formal education	1.000		
Had formal education	0.547	0.407–0.737	<0.001
Occupation of household head			
Other occupations	1.000		
Farming	2.363	0.826–6.761	<0.001
Household wealth quintiles			
Quintile (5)	1.000		
Quintile (1)	10.340	3.632–29.438	<0.001
Variables for rural population			
Primary caregiver educational status			
No formal education	1.000		
Had formal education	0.362	0.215–0.610	<0.001
Household wealth quintiles			
Quintile (3)	1.000		
Quintile(1)	8.288	2.677–25.657	<0.001
Variables for urban population			
Primary caregiver educational status			
No formal education	1.000		
Some education	0.636	0.452–0.896	0.010
Household wealth quintiles			
Quintile (5)	1.000		
Quintile (3)	2.782	1.067–7.254	0.036

Table 1 shows the predictors of food insecurity as extracted in a study on household food insecurity and nutritional factors of under-fives in the rural and urban district of a Southwest State, Nigeria (Akanbiemu et al. 2016a).

Table 1 shows the odds for household food insecurity. In the total population, household where the primary caregivers had formal education was 0.5 times less likely to be household food insecure compared to those with no formal education (95% CI 0.4–0.7; $p < 0.001$). In addition, household with wealth quintiles (1) was 10.0 times more likely to be household food insecure compared to household with wealth quintiles (5) (95% CI 3.6–29.4; $p < 0.001$). Households where the household heads were farmers were 2.4 times more likely to be food insecure than households where the household heads belong to other occupational groups (95% CI 0.8–6.8; $p < 0.001$).

Household Food Security and Nutritional Status of Children Less Than Five Years

The survival and well-being of children depend on adequate and proper nutrition, and this is particularly important in growing children especially those less than 5 years. Nutritional status of children is usually assessed using anthropometric methods.

Anthropometry is the use of body measurements to assess and classify nutritional status of children 5 years and below (Cogill 2003). These measurements include age, sex, weight, and height (or length in children 6–23. 9 months or under 87 cm in height). When two of these variables are used together they are called an index. Mid-upper arm circumference (MUAC) is used for individuals aged 6 months and older.

In using the anthropometric method, the 2006 WHO Growth Standards is now recommended for the use of the 1978 National Center for Health Statistics growth reference (NCHS GR-WHO 2008). The WHO Child Growth Standards were developed by WHO based on a sample of children from six countries: Brazil, Ghana, India, Norway, Oman, and the United States of America. Three factors are generally considered: Height for age for assessing **stunting,** Weight for height for **wasting**, and weight for age for **under-weight**. Nutrition indices are best presented as Z-scores as opposed to a percentage of the median. Percentage of the median is no longer recommended for use in classification of individual nutrition status (WHO 2008). The indexes are used to classify children into stunting, underweight, and wasting as described by Cogill (2003).

Height-for-Age

Height-for-age index is used to detect children who have been undernourished for not less than 6 months otherwise referred to as chronic malnutrition. It is not valuable in identifying brief changes in nutritional status or malnutrition. For children below 2 years of age, the term is length-for-age; above 2 years of age, the index is referred to as height-for-age. Any deficit in length-for-age or height-for-age is referred to as stunting. Stunting is an indicator of past growth failure. It is associated with a number of long-term factors including chronic insufficient protein and energy intake, frequent infection, sustained inappropriate feeding practices, and poverty. In children over 2 years of age, the effects of these long-term factors may not be reversible. For evaluation purposes, it is preferable to use children under 2 years of age because the prevalence of stunting in children of this age is likely to be more responsive to the impact of interventions than in older children. Stunting, based on height-for-age, can be used for evaluation purposes but is not recommended for monitoring as it does not change in the short term such as 6–12 months (Cogill 2003).

Weight-for-Height

This identifies children suffering from current or acute undernutrition and is useful when exact ages are difficult to determine. The term Weight-for-length is used for children under 2 years of age and weight-for-height (in children over 2 years of age). Any deficit in this index is referred to as wasting. Wasting indicates current or acute malnutrition resulting from failure to gain weight or actual weight loss. Causes include inadequate food intake, incorrect feeding practices, disease, and infection or, more frequently, a combination of these factors. Wasting in individual children and population groups can change rapidly and shows marked seasonal patterns associated with changes in food availability or disease prevalence to which it is

very sensitive. Since it is responsive to short-term influences, wasting is not used for evaluation but is useful for screening or targeting purposes in emergency settings. Weight-for-height is not advised for evaluation of change in nonemergency situations since it is highly susceptible to seasonality (Cogill 2003).

Weight-for-Age

This index is used to identify underweight. Any deficit in this measurement reflects both past (chronic) and/or present (acute) undernutrition but may not distinguish them. It is a composite measure of stunting and wasting and is recommended as the indicator to assess changes in the magnitude of malnutrition over time (Cogill 2003).

Mid-Upper Arm Circumference (MUAC)

This is a good predictor of immediate risk of death. It is used for rapid screening of acute malnutrition from the 6–59-month age range. MUAC overestimates rates of malnutrition in the 6–12-month age group. MUAC can be used for screening in emergency situations but is not typically used for evaluation purposes (Cogill 2003).

Factors Associated with Under-Fives Nutritional Status

These parameters for assessing nutritional status as described by Cogill (2003) and are important for the overall assessment of nutritional status of children as well as for evaluating nutrition intervention programs.

Many factors have been identified as important determinants of child nutritional status (Morrow et al. 2008; Nakabo-Ssewaryana 2003; Nyaruhucha et al. 2006 and Mondal et al. 2009). Study by Akanbiemu et al. (2016a) shows that the occurrence of stunting in children less than 5 years was significantly associated with household food insecurity, primary caregiver body mass index, household wealth quintiles, and educational status of household head. The study shows that children in food insecure households were found to be significantly more stunted than those in food secure household. The binary logistic regression of factors associated with stunting of children less than five year show that household food insecurity was an important predictor of stunting both in the total population, rural and urban areas. In the total population, children of food secure households were 0.2 less likely to be stunted compared to those who are in food insecure household, while in the rural and urban areas, children in households that were food insecure were 3 and 8 times more likely to be stunted compared to children in household that were food secure respectively. This finding agrees with that of Helen Keller International, Nepal, 2010, which showed that stunting and underweight, was significantly associated with household food security status; in order words, the more food insecure the household, the higher the prevalence of stunting and underweight.

Wealth quintiles as measured by Principal Component Analysis were significantly associated with stunting. This association was significant for both the total and

urban population where regression analysis for covariates factors showed that households with lower wealth quintiles were 12 times and 18 times more likely to be stunted than those children in higher wealth quintiles respectively.

Household head educational status was found to be significantly associated with stunting in the urban population with children in households where household heads had some level of formal education being 0.731 times less likely to be stunted compared to those children where the household had no formal education.

In terms of **under-weight**, Akanbiemu et al. (2016a) show that household food insecurity and household wealth index were the only predictors.

Wasting is a measure of acute hunger or food shortage and is one of the most hazardous nutritional problems among the three of stunting, underweight, and wasting. Wasting is also amenable to food intervention problem. Its prevalence is more in regions with socioeconomic disruption, such as civil wars, religious conflict, armed insurrection, and natural disasters. Wasting is currently a major problem in North-Eastern Nigeria, the hub of terrorist insurgency which has claimed over a million lives and created the largest humanitarian and severe acute malnutrition crises in Nigeria history. Hunger among internally displaced persons at risk of wasting is estimated to be as high as 49,0000 (UNICEF 2016).

It is important to note that a child can manifest with one or a combination of stunting, underweight, and wasting. This point is very germane because a child who is chronically malnourished can develop both stunting and underweight, while a child who is stunted can also manifest with wasting at the same time. It is therefore imperative to bear this in mind when planning nutritional intervention programs. Measures design to tackle any form of malnutrition in under-fives should be holistic and should on the long run be able to eradicate any form of under-fives malnutrition.

Table 2 shows the odds for stunting. In the total population, children of food secure households were 0.2 less likely to be stunted compared to those who are in food insecure household (95% CI 0.1–0.4; $p < 0.001$). Also, children in households with wealth index quintiles (1) were 11.7 times more likely to be stunted compared to those in household with wealth index quintiles (5), (95% CI 5.6–24.7; $p < 0.001$).

In rural population, only household food insecurity was significantly associated with stunting using binary logistic regression analysis. In other words, children in households that were food insecure were 2.6 times more likely to be stunted compared to those children in food secure household (95% CI 1.1–6.2; $P = 0.028$)).

In urban population, children in household where the household head has some level of formal education were 0.731 times less likely to be stunted compared to those children where the household had no formal education (CI 0.5–1.0; $p = 0.048$). In addition, children in food insecure households were 7.297 times more likely to be stunted compared to children in household where households that were food secure (95% CI 3.5–15.0; $p < 0.001$). Also, children in households with wealth index quintiles (3) were 18.9 times more likely be stunted than those in household with wealth index quintiles (5), (95% CI 8.0–44.5; $p < 0.001$).

Table 3 shows the odds for underweight. In the total population, children in households that were food secure were 0.3 times less likely to be underweight compared to those children in households that were food insecure (95% CI 0.1–0.6; $p = 0.00$). Also, children in households with wealth quintiles (1) were

Table 2 Adjusted odds of predictors for stunting

Variables for total population	Odds ratio	95% Confidence interval	p-Value
Household food security status			
Household food insecure	1.000		
Household food secure	0.201	0.115–0.351	<0.001
Household wealth index			
Quintile (5)	1.000		
Quintile (1)	11.705	5.554–24.669	<0.001
Variables for rural population			
Household food security status			
Household food secure	1.000		
Household food insecure	2.625	1.112–6.196	0.028
Variables for urban population			
Household head educational status			
No formal education	1.000		
At least primary education	0.731	0.535–0.998	0.048
Household food security status			
Household food secure	1.000		
Household food insecure	7.297	3.539–15.046	<0.001
Household wealth index			
Quintile (5)	1.000		
Quintile(3)	18.888	8.015–44.513	<0.001

27.8 times more likely to be underweight compared to those children in households with wealth quintiles (5) (95% CI 8.3–92.6; $p < 0.001$).

In the rural population, children in households that were food insecure were 3.3 times more likely to be underweight compared to those children in households that were food secure (95% CI 1.2–8.9; $p = 0.020$). Also, children in household with wealth quintiles (3) were 0.614 times less likely to be underweight compared to those children in households with wealth quintiles (1), (95% CI 0.4–0.8; $p < 0.001$).

In urban area, children in households that were food insecure were 2.7 times more likely to be underweight compared to those children in households that were food secure (95% CI 1.1–6.6; $p = 0.03$). Also, children in household with wealth quintiles (3) were 0.4 times less likely to be underweight than those children in household with wealth quintiles (5) (95% CI 0.3–0.7; $p < 0.001$).

The findings as shown above indicate that the most common determinants of stunting and underweight are household food insecurity and wealth status of the households.

Correcting Household Food Insecurity and Child Malnutrition

The predictors of child malnutrition are attainment of some level of education by household heads, food insecure households, and wealth status of household members. Education and household food insecurity will be addressed further here.

Table 3 Adjusted odds of predictors for underweight

Variables for total population	Odds ratio	95% Confidence interval	p-Value

Educational Attainment

There is a compelling need for individuals, household members, community, and government at all levels to work together to promote educational development for all if we must improve nutritional conditions of under-fives. Education has a multiplier effect on all facet of human life; education will help improve on safe-feeding practices such as exclusive breastfeeding in the first 6 months of life, and avoidance of harmful feeding practices such as depriving children of eating protein-rich diet by preventing them from eating fish, egg, and meat considered only good for adults. Perception is a function of knowledge and attitude, and it affects feeding practices. Individuals with education are better placed to discard culturally based poor feeding perception and practices that negatively affect child nutritional status. In addition, a good education will enhance the chances of a better-paid income and improve the household wealth.

Food Insecurity

Food insecurity is the most recurrent predictor of all forms of malnutrition in children less than 5 years and measures directed at improving household food insecurity will greatly improve the status of under-fives nutrition. The study has shown that education of primary caregivers, household head occupational status, and

household wealth status are the common predictors of household food insecurity (Akanbiemu et al. 2016b). Therefore, for a holistic approach to solving child malnutrition, these factors must be taken into consideration when planning nutritional intervention programmes.

As explained earlier, education cuts across all activities of life and there is a strong interrelationship between education of individuals, families, and household income as well as household wealth quintile.

Occupation of household members, especially house head, influences household food insecurity. Farmers and other low-income earners must be empowered by government through improving job conditions, enhancing farming income through better pricing of agricultural products, and eliminating middle-men phenomena. It is also imperative to provide farmers the skills and resources to be involved in agricultural products processing, which is a better way of improving farming income.

Food assistance programme(FAP), a concept not common in Nigeria, was seen by many participants in a qualitative study on improving household food insecurity as a veritable means of improving food security status of individuals and households. Many participants in the qualitative study expressed readiness and eagerness to participate in any community-driven food assistant program. However, it is important that technical support from experts on FAP from both local and international organizations, e.g., Civil Society Organizations, the World Food Program of UN, etc., assist such community-driven FAP in building the skills and the initial trust if it must succeed and produce the desired outcome.

Therefore, addressing hunger, starvation, food insecurity, and child malnutrition will be better achieved if all the interrelated factors are addressed in an all-inclusive manner.

Policies and Protocols

This chapter has shown that household food insecurity is the most recurrent predictor of all forms of malnutrition in under-fives children, as well as the major cause of food deprivation and hunger. Household food insecurity is strongly associated with economic, social, poor agricultural practices, and absence of community-driven food assistance program. Household food insecurity is usually measured by various methods of which HFIAS is the most validated and mostly used by various researcher including the author of this chapter. It uses a series of questions about conditions and behaviors that characterize households which occurred in the last 12 months when they were having difficulty meeting basic food needs. Each question asks whether the condition or behavior occurred at any time during the previous 12 months and specifies lack of money and other resources to obtain food as the reason. The series includes 10 questions about food conditions of the household as a whole and of adults in the household, and if there are children present in the household, an additional 8 questions about their food conditions were added. The food security status of each interviewed household is determined by the number of

food-insecure conditions and behaviors the household reports (Wunderlich and Norwood 2007; Coates et al. 2007). Food secure were households that denied all items or affirmed one or two items; foods insecure without hunger were households that affirmed three to seven items; food insecure with moderate hunger were households that will affirm eight or more items; foods insecure with severe hunger were households that affirmed five or more foods insecure condition among children. Therefore, HFIAS is strongly recommended for the measurement of household food insecurity by researchers and government at all levels when assessing and planning intervention programs in situations of food insecurity crises.

Nutritional status of children less than 5 years is globally assessed using the anthropometric method. The child's weights are measured in kilograms to one decimal and the child's length in centimeters to one decimal. Weight measurements are better obtained using UNICEF-SECA mother-infant scales with a digital screen (this author preference). Height measurements are carried out using a measuring scale produced by Pfizer Nutrition, though other standardized height measurement scale will suffice. Children younger than 24 months are measured lying down on the board, while children aged 24–59 months are measured standing. The height and weight measurements are converted into Z-score using WHO Anthroplus software and are used to estimate the nutritional status of children less than 5 years (WHO 2007): **Height-for-age** is used to identify stunting; **Weight-for-height to** identify **wasting** and **Weight-for-age** to identify underweight. These three indices are expressed in standard deviation units from the median of the WHO Multicentre Growth Reference Standard. Any Z-score below minus two standard deviations (−2 SD) from the median (0 SD) are considered stunted, wasted, and underweight respectively and below minus three standard deviations (−3 SD) as severely stunted, severely wasted, and severely underweight respectively.

The predictors of stunting and underweight among the under-fives are the attainment of some level of education by household head, food insecure households, and wealth status of household members. It is imperative that nutritional assessment of children less than 5 years should be carried out following the above protocols, and all nutritional interventions by local, regional, and national health/agricultural authorities should consider addressing the predictors identified above and any other as may be identified by other credible researchers.

Dictionary of Terms

- **Food security** – When all people, at all times, have physical, social, and economic access to sufficient, safe, and nutritious food which meets their dietary needs and food preferences for an active and healthy life.
- **Household food insecurity** – Is the inability of household members at all times, to have access to the quantity and quality of food required for their daily energy needs and maintenance of good health. It is associated with either absolute lack of food, or food available in insufficient quantity with or without poor quality.

- **Household Food Insecurity Access Scale (HFIAS)** – Is a widely validated tool for Measurement of Household Food insecurity recognized by the Food and Agriculture Organization (FAO) of the United Nations and the United States Agency for Agriculture Development (USDA).
- **Overweight** – Weight for height plus 2 standard deviations (SDs) of the WHO Child Growth Standards median for the same age and sex.
- **Stunting** – Height for age minus 2 standard deviations (SDs) of the WHO Child Growth Standards median for the same age and sex.
- **Under-fives** – Children male or female aged 0–59 months of life.
- **Underweight** – Weight for age minus 2 standard deviations (SD)s of the WHO Child Growth Standards median for the same age and sex.
- **Wasting** – Weight for height minus 2 standard deviations (SDs) of the WHO Child Growth Standards median for the same age and sex.

Summary Points

- This chapter tried to give a simple definition of household food insecurity, hunger, and under-fives malnutrition.
- It also describes the conceptual framework of household food insecurity, which was used to explain the supply and demand factors responsible for household food insecurity.
- The supply factors are those issues that affect food production and availability in the markets, groceries shops, supermarkets, and retail shops.
- The demand factors address those factors that will influence household and individuals to be able to access or purchase food items for household use. It went further to explain in details each of the factors using evidence-based information.
- The concept of child nutritional status was also described and the methods for assessing nutritional status using anthropometric methods was provided.
- The factors associated with various forms of malnutrition were discussed.
- Methods designed to address hunger, starvation, food insecurity, and under-fives malnutrition were provided.
- The approach adopted by this author was based strictly on his understanding, knowledge, and findings from research on household food insecurity and nutritional status of children less than 5 years in a Southwest state of Nigeria and is by no means exhaustive, but meant to add to body of knowledge on the topics, provide insight on possible methods of food insecurity and hunger intervention programs, as well as to stimulate more research on food insecurity, hunger, and under-fives malnutrition.

Abstract

This book chapter examines the relationship between food insecurity, education, and federally supported school lunch programs, with a focus on elementary education in the United States of America. Previous studies indicated that there is a strong inverse relationship between food insecurity and educational outcome: malnutrition and poor diet generate physical and psychological problems that impair the student's ability to learn. In this chapter, qualification for school lunch programs is considered an indicator of food insecurity, primarily because school lunch participation is based on family income which has been found to be the main factor associated with food insecurity. The National School Lunch Program,

the largest school lunch program in the USA, is the focus of the chapter. Specifically, Georgia's public schools, a state in the Southern USA with a strong presence of food insecurity, are used as a representative case study. Descriptive simple statistics indicate that the negative relationship between food insecurity and academic success does not just reduce educational performance on standardized assessments, but it appears to be one of the causes that reinforce inequality and segregation, thus undermining the development of effective social mobility.

SAT	Scholastic attitude test required for the college admission in the USA

Introduction

A strong inverse relationship between food insecurity and educational achievement outcomes has been found in previous studies (Jyoti et al. 2005; Frongillo et al. 2006). The reasons behind this are numerous. First, poor nutrition contributes to developmental problems, possibly fostering attention deficit and hyperactivity disorders. This directly reduces the student's capacity to learn, lowering educational performance. Food insecurity is also empirically associated with higher drop-out rates and fewer years of schooling. Students have difficulty studying and retaining information in the presence of malnutrition and a poor-quality diet. This makes learning more challenging, increasing school drop-out rates, and reducing the number of years of completed education (Alaimo et al. 2001).

This chapter also examines how qualification for school lunch programs, such as the National School Lunch Program (NSLP) in the United States of America (USA), can be considered an indicator of food insecurity. This proxy is possible because participation in NSLP is based on the income. In general, when a family's income does not exceed a given threshold, the student is eligible for free or reduced price school meals. This is typical of the National School Lunch Program (NSLP), the largest school meal program in the USA (USDA, 2014). Similarly, in the United Kingdom (UK) a child is eligible for free school meals if at least one parent receives income support or income-based jobseeker's allowance (UK Government 2017).

A representative case study is used in this book chapter to illustrate and define the inverse relationship between food insecurity and academic achievement.

Specifically, the NSLP and Georgia's public schools, a state school system in the Southern USA with a strong presence of food insecurity, are presented. Georgia schools with a high percentage of students that qualified for the NSLP tend to have a low proportion of students that pass the mathematics exam. The opposite is also seen: Georgia schools with a low percentage of students that qualified for the NSLP tend to have a high proportion of students that pass the mathematics exam. Moreover, the inverse relationship between food insecurity and educational outcomes shows a strong spatial pattern. Regions characterized by prevalent poverty, such as the inner part of the Atlanta Metropolitan Area, are also characterized by limited school performance. This problem is common to several metropolitan areas in the USA where the inner cities are often characterized by poor socio-economic conditions (Chetty et al. 2014). Food insecurity appears related to not just poor nutrition and lower academic performance, but it can involve a higher engagement of parents, lower level of criminality in the community and, consequently, higher chances to complete schools and find a better job (Reardon 2011). Thus, the negative relationship between food insecurity and academic success is not limited to reduce the educational performance, but it appears to reinforce inequality and segregation, thus undermining the development of a more effective social mobility.

Relationship Between Student's Performance and Family Income

Student academic performance can be affected by numerous socio-economic factors which include school quality, the family's economic status, and the student's personal characteristics (Hoxby 2000). Previous studies have indicated that the family's economic background plays an important role in determining a student's performance. For instance, Dahl and Lochner (2012) analyzed a sample of 9796 US children and their families from 1998 to 2000. They found that a $1000 increase in family income raised combined math and reading test scores by 6% in the short run. Moreover, test gains were larger for children from disadvantaged families. Similarly, Henderson and Berla (1994) reviewed 66 research studies on the factors shaping student academic performance and found that low-income was one of the crucial drivers for educational success.

Among the indicators of household socio-economic status, eligibility for free school meals plays a fundamental role. The first such reason is that eligibility is usually based on income of the family, providing a gauge of its living standards (Food Research and Action Center 2013; USDA 2014). In the USA, the National School Lunch Program (NSLP) is a federally assisted program that targets students whose family's income does not exceed threshold values based on the poverty line (USDA 2014). Specifically, children from families with incomes below 130% of the poverty level are eligible for free meals. Children from families with incomes between 130% and 185% of the poverty level are eligible for reduced-price meals. In 2017, the year of this volume's publishing, the poverty line for a household of three persons was equal to $20,420 (Federal Register 2017). Thus, children of families with an income below $26,546 were eligible for free school lunch, while

families with income below $37,777 were eligible for reduced price lunches. Similarly, in the UK a child is eligible for free school meals if at least one parent receives income support or income-based jobseeker's allowance (UK Government 2017). In the UK, the job seeker's allowance is a form of unemployment benefit paid by the Government to people who are unemployed and are actively seeking work (UK Government 2017).

Another reason for this proxy is that low-income families are negatively and significantly associated with food insecurity, which directly impacts student academic achievement. Several studies have indicated that children who are hungry are less likely to be ready to learn, translating into reduced academic performance. For instance, Jyoti et al. (2005) have shown that by the third grade, children who had been food insecure in kindergarten incurred a 13% lower achievement scored in their reading and math tests compared to their food-secure peers. Similarly, Hirsch (2007) summarized findings on the impact of poverty and educational disadvantage in the UK. He concluded that "low income is a strong predictor of low educational performance . . . and [that] children in poverty have on average lower educational achievement and are more likely to continue to under-achieve" (Hirsch 2007, 1). This is especially true among children from disadvantaged backgrounds that qualify for free school lunches in the UK and Scotland. He concluded that disadvantaged socio-economic circumstances in a child's early years may result in lower adult qualifications on the job market and adult educational opportunities, possibly perpetuating poverty across generations.

In general, the negative relationship between food insecurity and future academic performance in early childhood is three-fold in its effect. First, food insecurity can cause permanent, physical damage to children's developing brains without a proper diet. Nutritional deficiency includes severe acute malnutrition, chronic under-nutrition, iron deficiency, and iodine deficiency. Such deficiencies impair physical and cognitive development (Prado and Dewey 2014). Moreover, the rapidly developing brains of children are more vulnerable to the effects of insufficient nutrients such as protein, energy, certain fats, iron, zinc, copper, iodine, selenium, vitamin A, choline, and folate (Georgieff 2007).

Second, food insecurity can also cause long-lasting cognitive problems, including attention deficit and hyperactivity disorders. Melchior et al. (2012) examined a longitudinal studying using data collected from 2120 children born in the Québec region, Canada, in 1997–1998. Children's mental health symptoms were assessed longitudinally using validated measures of behavior at ages 4.5, 5, 6, and 8 years. Family food insecurity was determined when children were 1.5 and 4.5 years old. Results indicated that family food insecurity predicts many symptoms of children's developmental difficulties, particularly hyperactivity and inattention. Moreover, the authors suggest that addressing food insecurity and associated problems in families could help reduce the burden of developmental problems, having the potential to reduce inequalities in student physical and social development.

In addition to physical and cognitive developmental impairment, food insecurity may also reduce a student's academic performance during the food-insecure time. This has the potential to have lasting and negative repercussions on future

educational success. Beside, Bratti and Staffolani (2013) found that the measurement of students' previous educational outcomes is the most important indicators of students' future achievement. Specific studies such as Reynolds et al. (2001) studied the long-term effects of early childhood educational programs for 1580 African-American students from low-income families over 25 years in Chicago, Illinois, USA. They found that participation in early childhood educational programs increases future academic achievement scores and raises the school completion rate (Reynolds et al. 2001). Similarly, a study in the US state of Minnesota (2007) indicated that higher educational performance depends on the student's previous years' test scores.

Chinyoka (2014) examined the impact of poor nutrition on the academic performance of seventh grade students in two primary schools in Chivi, Zimbabwe. Findings revealed that malnutrition affected physical growth, cognitive development, overall health and wellbeing, and academic performance. Hungry children were less likely to attend school on a regular basis and, if they did, were less able to concentrate and learn as well as being less likely or able to participate in sporting activities at school. Food insecurity and malnutrition can have direct effects on children's performance and academic achievements in school, impacting their future employment and career opportunities. Thus, persistent food insecurity may contribute to intergenerational transmission of poverty at the local level and weak economic growth at the national level.

If malnutrition, often indicated by food insecurity, impairs proper physical development, accompanied by physiological and behavioral problems, negative and long-term effects on student academic performance are possible. One study, Alderman et al. (2006), examined the impact of malnutrition in the preschooling period on subsequent human capital formation in rural Zimbabwe. They analyzed 680 children in rural Zimbabwe in two periods: 1983–1984 and a re-survey of the same sample in 2000. Their results indicated that better-quality nutrition during preschool years fostered improved physical development of students (i.e., their height) and was associated with a larger number of completed school grades.

The trend remains the same in other geographic locations. For instance, Glewwe et al. (2001) studied a sample of 1239 Philippine children in the 1983–1987 period and in the 1994–1995 period. Their research indicated children with better nutrition perform significantly better in school due to entering school earlier and greater learning productivity per year. Themane et al. (2003) studied a sample of 1033 South African children and they found that better anthropometric measures, such as body mass index, height for age, and weight for age, were positively associated with higher test scores in mathematics and English.

This negative empirical relationship between nutrition and student performance is not a characteristic exclusive to developing countries. For instance, Florence et al. (2008) indicated that a low-quality diet depresses future achievement scores of fifth grade Canadian students. Similarly, Alaimo et al. (2001), Ames et al. (2016), and Angioloni and Ames (2015) found comparable results for the American students.

Addressing these problems in the USA, federal, state, and local level educational policies are in place to reduce the achievement gap (Roza 2010). Achievement gaps

occur when there is a significant difference in achievement across groups, such as gender, ethnicity, and income. Card and Payne (2002) studied school finance reforms across richer and poorer districts and the consequences of spending equalization for the relative test performance of students from different family backgrounds. They found that the amount of state aid available to poorer districts led to increases in the spending of these districts, narrowing the spending gap between richer and poorer districts. Moreover, using SAT scores, they found evidence that equalization of spending leads to a narrowing of test scores across family background groups. Thus, if family economic status has a negative effect on the student's performance, it may be necessary to invest a larger amount of public funds to properly deliver educational programs (Roza 2010).

The increasing pressure on public school finances makes the necessity of effective policy recommendations more urgent. An Organization for the Economic Co-operation and Development (OECD 2013) study found that the aftermath of the 2008 financial crisis has meant a significant number of countries have cut public spending on education. Despite GDP rising in most OECD countries between 2009 and 2010, public expenditure on educational institutions fell in one-third of them. In the USA, Lechman and Mai (2014) reported that States are providing less per-pupil funding for kindergarten through twelfth grade than they did 7 years ago. Similarly, in Georgia, the focus of this chapter's case study, the per-pupil spending decreased by 7% moving from $8775 in the school year 2010–2011 to $8169 in the school year 2013–2014 (Georgia Department of Education 2015).

Finally, the negative effects of poverty on student development can undermine social mobility, reducing long-term economic growth. Chetty et al. (2014) used administrative records on the incomes of more than 40 million children and their parents to describe three features of intergenerational mobility in the United States. They found that high mobility areas are associated with lower residential segregation, more income equality, better primary schools, greater social capital, and greater family stability. From a more general perspective, Clark (2016) examined and compared the family status in such diverse cases as modern Sweden and Qing Dynasty China. He demonstrated that family status is determined by ancestry and that almost all societies exhibit similar limited social mobility rates. Thus, the risk of food insecurity and accompanying lower educational achievement can generate negative repercussions over the future generations.

The National School Lunch Program (NSLP) in the USA and in Georgia Public Schools

This section considers the National School Lunch Program (NSLP) as an example of childhood nutritional programs in schools. Another example in the USA is School Breakfast Program. International examples include in South Africa, the National School Nutrition Programme and in Ireland, the School Meals Programme. The NSLP is a US government-assisted program that operates in over 100,000 public schools, residential child care institutions, and some nonprofit schools in the USA.

The goal of NSLP is to provide nutritionally balanced, low-cost, or free lunches to children each school day. Children from families with incomes at, or below, 130% of the poverty level are eligible for free meals. Those children from families with incomes between 130% and 185% of the poverty level are eligible for reduced-price meals, for which students can be charged no more than $0.40 USD.

In the 2011 academic year, the NSLP subsidized the cost of free or reduced-price lunches for over one million students in Georgia's schools (Food Research and Action Center 2013). Students in Georgia are particularly vulnerable, as the state is currently ranked seventh highest in the USA for food hardship rates. While 46% of the households with children in Georgia qualify for free lunches, an additional 21% of households qualify for reduced price lunches (Food Research and Action Center 2012). Schools where 40% or more of the students get free or reduced price lunches also qualify for Title I federal funds to pay for special programs to close students' achievement gap. Thus, the importance of the relationship between food insecurity and academic achievement has been long recognized by policy makers and analysts (Georgia Department of Education 2015).

The percentage of fourth grade student who qualified for the National School Lunch Program has been increasing over time. This is especially alarming considering US family incomes have been expected to recover from the economic downturn of the Great Recession (2008–2016). Overall, Fig. 1 shows that in the

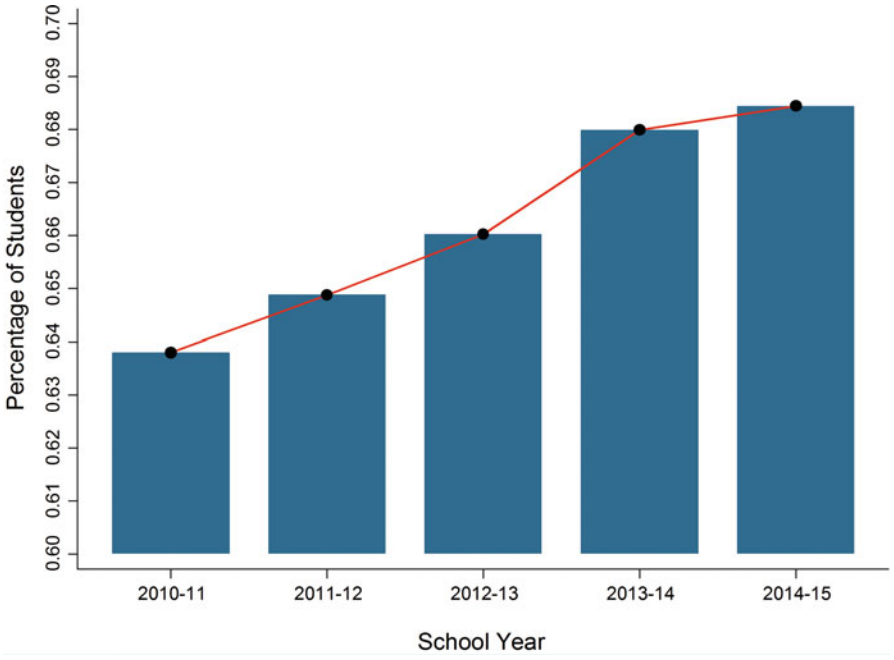

Fig. 1 Percentage of Fourth Grade Students Qualified for NSLP in Georgia's Public Schools. NSLP: National School Lunch Program. Source: National Center for Education Statistics (2016)

2011–2015 period, two-thirds of the fourth grade students qualified for free or reduced price meals in the Georgia public schools (National Center for Education Statistics 2016). Moreover, Fig. 1 shows a clear increasing trend over time of the percentage of students that took part in the NSLP. This indicates that food insecurity is not just strongly present in the Georgia public schools, but it is also gradually increasing overtime.

Achievements in Scoring Patterns

Educational achievement data were taken from the Georgia Department of Education (2016). Georgia has 159 counties, with 1283 elementary schools. The data are representative of student achievement at the school level, and they can be employed to analyze the relationship between food insecurity, as exhibited by participation in the NSLP, and achievement test scores.

With regard to the educational performance, the Pearson correlation coefficients between the percentage of students who qualified for the NSLP and those passing the fourth grade math test range from −0.64 to −0.69 in the 2011–2014 period. This is in agreement with previous studies on the inverse relationship between achievement score and food insecurity (Alaimo et al., 2001; Ames et al., 2016). Figure 2 graphically illustrates this relationship. The predicted values in Fig. 2 were estimated from a fractional probit model, as in Papke and Wooldridge (1996), to allow for the fact that the achievement score is bounded between zero and one. Figure 2 clearly indicates that an increase of the percentage of students qualified for the NSLP is associated with a lower proportion of students that reach predetermined standards on the fourth grade math test. In general, similar relationships are observed for different school exams (Angioloni and Ames 2015), grades (Ames et al. 2016), US states (Dahl and Lochner 2012; Jyoti et al. 2005), and countries (Hirsch 2007; Florence et al. 2008). This suggests that the negative relationship between food insecurity as represented by participation in the National School Lunch Program and educational performance generalizes to other locales.

The negative relationship between food insecurity and achievement score is not just limited to mathematics, but it involves every the school subject. Table 1 shows the summary statistics of the achievement scores in mathematics, reading, English Language-Arts, Science, and Social Studies for the fourth grade students in the Georgia's public schools. Moreover, Table 2 shows the correlation between these achievement scores and the percentage of fourth grade students qualified for the NSLP. As shown from Table 2, the correlation is negative and quite large in magnitude. In particular, the achievement score in Science and Social Studies showed the highest negative correlation with the percentage of students qualified for the NSLP.

With respect to the spatial distribution, Figs. 3 and 4 plot the quartile distribution of the percentage of students eligible for the NSLP and that passed the fourth grade math exam, respectively. These figures were drawn through the Voronoi tessellation, a geometric technique employed to divide space in disjointed contiguous cells, one for every observation (Turner 2014). The cells represent the closest points to a given observation. Thus, if the observations are schools as in this case, the Voronoi cell

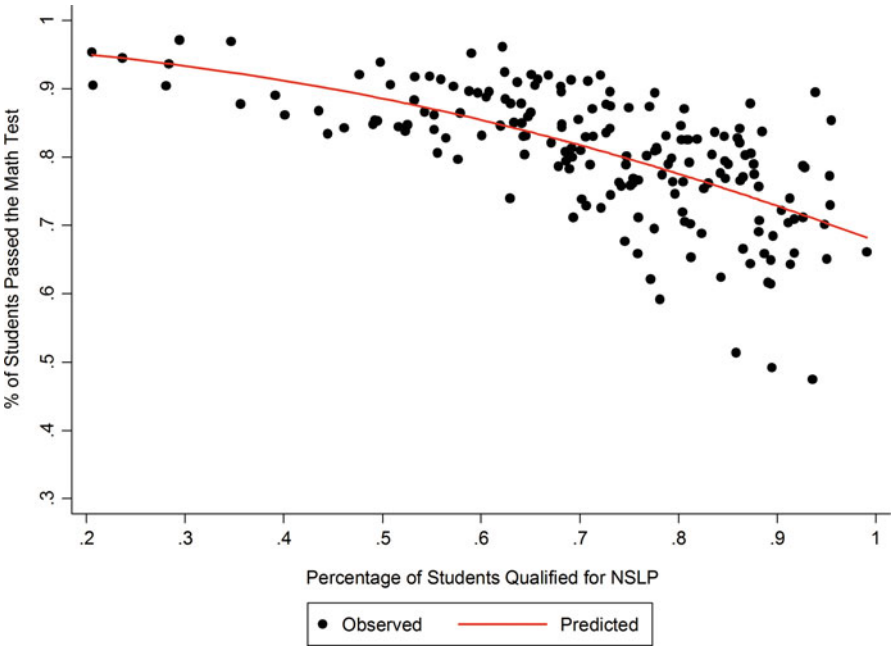

Fig. 2 Mathematics Achievement Score vs. Percentage of Students Qualified for NSLP. Math achievement score: share of fourth grade students who met or exceed the standard of the Criterion Reference Competence Test (CRCT) in mathematics (Georgia Department of Education, 2016). NSLP: National School Lunch Program (National Center for Education Statistics 2016). All the values are averaged at the school district level (180 observations)
The predicted values were estimated from a fractional probit model of the math achievement score vs. the percentage of students qualified for NSLP and a constant (Papke and Wooldridge, 1996).

Table 1 Achievement Scores and Qualification for NSLP in Georgia's Public Schools. Summary Statistic

	Average	Standard deviation	Minimum	Maximum

NSLP: National School Lunch Program (National Center for Education Statistics 2016).
The achievement score of a school subject (mathematics, reading, English Language-Arts, Science, and Social Studies) corresponds to percentage of fourth grade students who met or exceed the standard of the Criterion Reference Competence Test (CRCT) in that school subject (Georgia Department of Education, 2016).
The Pearson correlation coefficient is defined as the ratio between covariance of two variables and the product of their standard deviations.

students qualified for the NSLP from yellow (first quartile) to dark red (fourth quartile). Similarly, Fig. 4 shows the spatial distribution of the math achievement score.

Figures 3 and 4 confirm that the negative relationship between achievement score and food insecurity is also present at the geographical level. This is particularly clear from the analysis of the Atlanta Metropolitan Area (AMA, U.S.A. Office of Management and Budget 2013). The Atlanta Metropolitan Area is the most populous metropolitan area in Georgia. The AMA is located in the Northern part of the state, and it is easily recognizable from the high density of schools and small cells. According to Fig. 3, the inner part of this region is characterized by schools with a high percentage of students qualified for the NSLP (dark red cells), while the outer part of this region, and in particular to the Northern part of the AMA, is characterized by schools with limited presence of students who qualified for the NSLP (yellow cells).

Figure 4 shows the spatial distribution of the math achievement score and it indicates a similar, but *reversed* pattern. The outer part of the AMA is characterized by high performing schools (i.e., schools with a high proportion of students that succeeded in the math test), as they are identified by the dark red cells representing the fourth quartile. In contrast, the inner part of the AMA is characterized by schools that belong to the first quartile of the distribution of the achievement score as indicated by the yellow cells.

Additionally, the spatial pattern is not limited to the Atlanta Metropolitan Area. For instance, a similar pattern is observable along the Black Belt, a region of the southern USA that crosses Georgia in the middle along the North-East, South-West

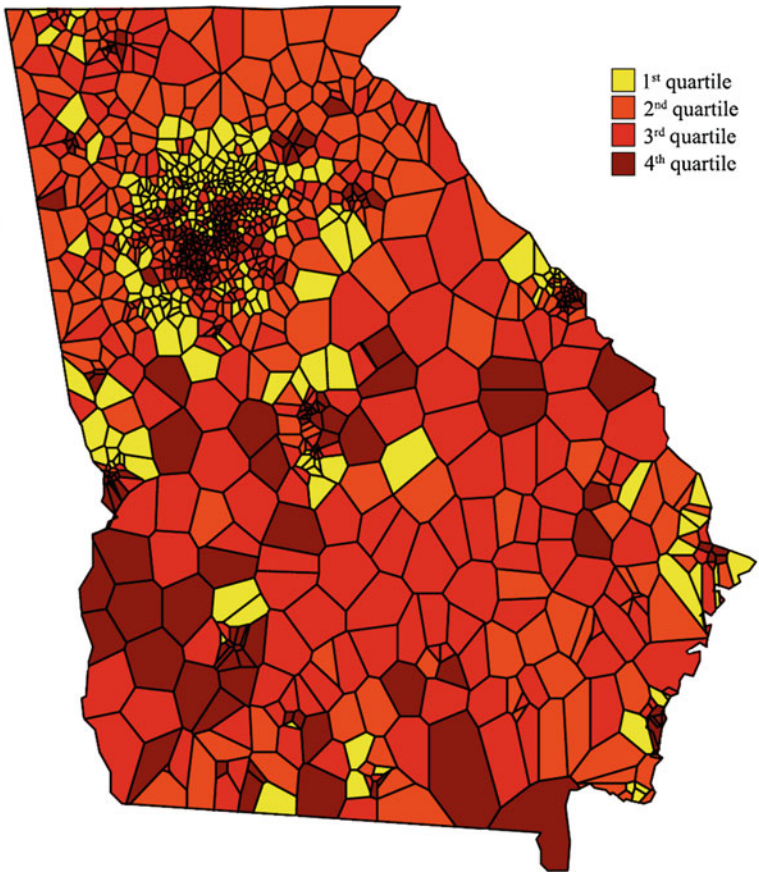

Fig. 3 Percentage of Students Qualified for NSLP in Georgia Public Schools. NSLP: National School Lunch Program (National Center for Education Statistics 2016). The figure shows the Voronoi tessellation of the public elementary schools in Georgia. Each cell corresponds to a school and was coded according to quartile of the math achievement score (Turner, 2014).The school coordinates were collected from the National Center for Education Statistics (2016)

diagonal. In Georgia, this region is mostly rural with some small towns and it is characterized by a substantial presence of African-American population (for a review of the socio-economic characteristics of the Black Belt, see Webster and Bowman, 2008). Along this region, Fig. 3 indicates that there is strong presence of food insecurity with many cells colored red (fourth quartile of the poverty rate). In contrast, Fig. 4 shows that the spatial pattern of the math achievement score is basically the opposite with areas mostly tending to be yellow in color.

Overall, Figs. 3 and 4 confirm previous studies (e.g., Angioloni and Ames 2015) and they indicate that the negative relationship between achievement score and food insecurity is present in Georgia public schools (Ames et al. 2016; Angioloni and Ames 2015). Regions characterized by high food insecurity are, on average,

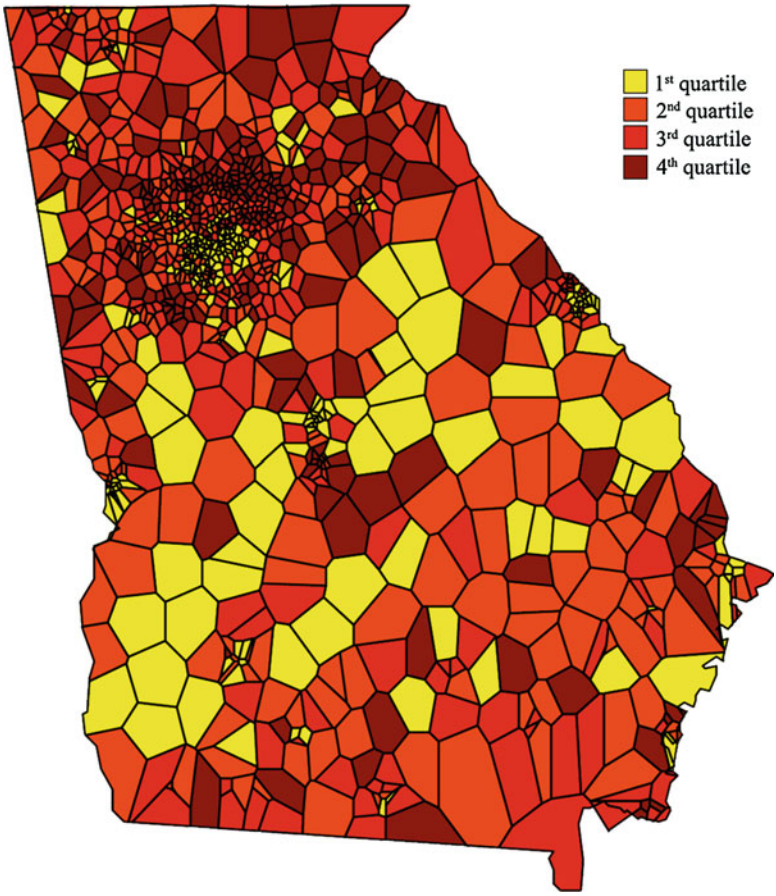

Fig. 4 Math Achievement Score in Georgia Public Schools. associated with a low educational performance. Moreover, the descriptive illustrations provided in this chapter indicate that there is a clear spatial pattern with schools characterized by low poverty rates and high academic achievement and schools characterized by high poverty and limited educational achievement. This problem seems particularly worrisome from a policy prospective.

In the USA, the achievement gap between students from more affluent families and students from less affluent families increased in recent years. Reardon (2011) shows that the achievement gap between children from high- and low-income families is roughly 30 to 40 percent larger among children born in 2001 than among those born 25 years earlier. The differences in the achievement gap are also

associated with the socio-economic difference of the neighborhood. Students from high-income families are usually from wealthy neighborhoods with better jobs, infrastructure, and schools (Lareau and Goyette 2010). Thus, differences in the level of food insecurity is not just related to a better nutritional level, but it can involve a higher engagement of parents, lower level of criminality in the community and, consequently, higher chances to complete schools and find a better job (The Saguaro Seminar 2016). Thus, the inverse relationship between food insecurity and academic success is not just limited to reduce the educational performance, but it appears to be one of the causes that reinforce inequality and segregation and thus undermine the development of a more effective social mobility (Clark 2016; Chetty et al. 2014).

Policies and Protocols

This chapter has summarized previous research and studies regarding the relationship between food insecurity and educational outcome, with a particular case study focusing on the state of Georgia in the USA. In general, these studies found that academic performance is inversely related to food insecurity. Moreover, this relationship is differentiated over time. In the short term, food insecurity reduces the student's capacity to learn and it can generate cognitive and behavioral problems (Jyoti et al. 2005). In the long term, the effect of food insecurity is more articulated and potentially, stronger. In general, this may be due to the long-term effects of poverty and food insecurity being a summation of short-term effects (Hamilton 1994). Thus, the repercussions of food insecurity on the achievement score are amplified over time (Reynolds et al. 2001; Barnett 1998). In particular, the negative effects of food insecurity range from health problems as an improper development of the child's brain, lower height and weight, and reduced body mass (Themane et al. 2003). Other socio-economic consequences are that reduced educational performance over time generates higher drop-out rates from school, lower graduation rates, and substantial difficulties in finding more skilled and higher paying jobs (Reardon 2011).

The National School Lunch Program is a clear response to food insecurity in the USA and it was used to illustrate the relationship between poverty rates and achievement scores of fourth grade students in the Georgia's public schools. The descriptive analysis indicated that the negative relationship between food insecurity and limited educational performance is present also for the fourth grade students. In particular, schools in the inner part of the Atlanta Metropolitan Area are characterized by substantial poverty and limited academic success. A similar relationship is observed in rural areas, historically characterized by a substantial presence of low-income racial minority families, namely African-American.

From a policy perspective, these results indicate that food insecurity can generate negative effects on long-term academic achievement. Policies that increase the accessibility to free or reduced price meals can be optimal in schools where the students are from very low-income families (Reynolds et al. 2001). Where food

insecurity is extreme, these initiatives can be combined with tutoring and mentoring programs designed to mitigate the achievement gap where it is present, particularly in scientific subjects (Duncan et al. 2007).

These results have very broad long-term implications for local, regional, and national competitiveness. States and local administrations compete vigorously for new industries and tout the quality of the local workforce among the incentives for companies to locate or relocate to a specific locality (Georgia Department of Economic Development 2017). If an increase in the poverty rate has a negative effect on the achievement scores, then efforts to attract high tech industries to a particular county, municipality, or state will be aided or hampered by the skills of the local workforce. Since food insecurity impacts the level of educational achievement over a student's academic career, it reduces the attractiveness of the local workforce and increases the cost of training labor for new jobs in high tech industries. This clearly impacts a region's overall competitiveness in the global economy.

Future research should extend the approach highlighted in this study to analyze the relationship between food insecurity and student's performance with student-level observations and for a longer period of time, ideally from the first grade to the eighth grade. This would allow for studying the persistence effect of food insecurity over time and space on the student's academic performance.

Dictionary of Terms

- **Achievement score** – Percentage of students, per school, that pass the school test.
- **Poverty rate** – Percentage of students, per school, that are eligible for free or reduced price meals under the National School Lunch Program.
- **Food insecurity** – Limited or uncertain availability or inability to acquire nutritionally adequate, safe, and acceptable foods due to financial constraints.
- **Correlation** – The change of a variable is associated to a change of another variable.
- **Voronoi tessellation** – Given a set of points over a plane, the Voronoi tessellation divides the plane in disjointed polygons such that they are the closest ones to the given points.
- **Probit** – Statistical model that explains the behavior of a binary variable.
- **Fractional probit** – Statistical model that explains the behavior of a fractional variable.

Summary Points

- The eligibility for free or reduced price school meals is based on the family's income.
- The family's income is strongly inversely related to food insecurity.
- The eligibility for free or reduced price school meals can be employed as a proxy for food insecurity.

- Hungry children are less likely to be ready to learn and exhibit a lower academic performance.
- A higher educational performance depends on the student's previous test scores.
- Thus, an increase in food insecurity in the current school year has negative repercussions on the student's future academic performances.
- Where food insecurity is extreme, policies that increase the accessibility to free or reduced price meals may be optimal for improving the academic achievement.
- Where food insecurity is extreme, tutoring and mentoring programs can be designed to mitigate the achievement gap where it is more present.
- Specifically, 22% of Georgia's residents indicated that at times in the past 12 months, they have been without adequate resources to secure sufficient food for the family (Food Research and Action Center 2013). Furthermore, the state of Georgia has a particularly troubling number of students at risk for decreased academic performance due to food insecurity.

Contents

Abstract

Food waste has been of growing concern in the society over the past 10 years, and especially the focus on food waste prevention. This is the case both in Norway and the Scandinavian countries, as well as in Europe and globally. Up to now most efforts have been allocated to developing good statistics for food waste over the whole food chain, get a good definition of food waste, develop strategies and implement measures for food waste prevention at each stage in the food chain as well as between actors along the chain, and finally to develop governmental policies and regulations of food wasting and treatment of food waste. Activities to cope with increasing food waste globally have been initiated both by UNEP, FAO, OECD, and EU. EU DG Sante has established an Expert Platform for food waste prevention in 2016, with experts and representation from all 28 EU countries as well as private organizations, NGOs, etc. Main focus in 2017 will

Introduction

In Norway, the work with food waste prevention started more systematically with the ForMat project in 2010, as a collaboration between the retail sector, the wholesale sector, and the food industry (see Hanssen and Schakenda 2011), in close contact with the government (Ministry of Food and Agriculture and Ministry of Climate and Environment). All the work from 2010–2016 in the ForMat project was based in voluntary efforts from key actors in the food sector, supported by annual funding from the Government (several ministries). The project was formally closed in 2016, after having reported all the main results from 6 years work with gathering food waste statistics, carrying out network projects between actors in the food chain and implemented a number of voluntary actions and measures to promote food waste prevention (Stensgård and Hanssen 2016; Matvett 2016). During the ForMat project, a company was established by the main actors in the food chain to operate all common activities on behalf of the organizations in the food chain (Matvett Ltd). The project was then followed by an interim negotiated agreement between seven food business organizations (from primary production to hospitality sector) and five ministries. The main aim of the interim agreement was to prepare for a permanent negotiated agreement similar to other soft regulations covering different waste fractions in Norway, focusing on how to define food waste, how to measure and develop statistics for food waste, and how to develop strategies to and implement measures to prevent food waste. This agreement will probably be signed by all parties in 2017.

Similar activities have been initiated also in other Scandinavian countries. In Sweden, there has been a project organized by the Environmental Protection Agency and with representatives from the whole food chain (SaMMa project), functioning more like a network than like an organized project. Food Waste Statistics have been gathered and published for 2012 and 2014 by SMED, with financial support from the Swedish Government (Jensen et al. 2011, Naturvårdsverket 2013). Also in Denmark, there has been established a network project with the Environmental Protection Agency (Miljøstyrelsen) as the active part in initiating the network.

In Norway as well as in the rest of the Nordic region, it has been a strategy to differentiate between edible and nonedible food waste, to get a more narrow focus on those fractions of food waste that most easily can be prevented from being wasted and treated as waste. This has been a discussion in parallel with similar discussions in the rest of Europe, where the FUSIONS project proposed a definition without a clear differentiation between edible and nonedible food waste. The FUSIONS project did also define food which was used as animal feed and for bio prosperity

outside the definition of food waste. In Norway, this has not been followed up in the National definition of food waste, where both food used for feeding animals and food being used as a resource in developing new nonfood products are defined as edible food waste in the negotiated agreement. In the other Nordic countries, it has also from the beginning been differentiated between edible and nonedible food waste, but it is unclear how this will be followed up in the future after the FUSIONS definition was published, and the work in the EU Food Waste platform started in 2016.

Although all Nordic countries (except Iceland) have initiated national activities on food waste prevention and been involved in both Nordic Food Waste projects as well as EU project FUSIONS, there are some differences in the approaches that have been taken. In Norway, all food waste prevention activities were initiated by the food industry and the retail sector, and both branch organizations as well as single companies have been very active in both internal as well as common programs and activities. Governmental organizations have supported activities and also been active in promoting food waste actions by their own, but have had a more supporting than initiating and coordinating role. In Sweden and Denmark, the EPAs have been much more involved in initiating and coordinating activities, with less organized activities among companies, working more by themselves. In Denmark, Selina Juul and her organization Stop Wasting Food has taken most of the "official place" nationally, where much of the activities have been centered around her and her organization's agenda and work. There are no similar companies or organizations like Matvett Ltd. established in other Nordic countries, making the work in Norway more organized and more on the premises of the food business sector.

Edible Food Waste in Scandinavia

Food Waste Statistics in Norway 2010–2015

Through the ForMat project, edible food waste from four steps of the Norwegian food value chain was mapped from 2010 to 2015: the food industry, wholesale, retail, and households.

Food waste from primary production, the hospitality sector, parts of the food industry (fisheries, the brewery industry, and in mills and flour producers), as well as food wasted through the sewage system at the households was not mapped due to lack of data.

Edible food waste was mapped for 9 different product groups and 21 different sub-categories, where the following definition of food waste was used: "Food waste includes all edible food that could have been eaten by humans, but for some reason has been wasted or removed from the human food supply chain."

Primary data was collected from a representative sample of businesses/households within each of the four value chain steps, and scaled up to national statistics using upscaling factors based on share of total turnover (wholesale and retail), total production (industry), or number of inhabitants (household-step). For the wholesale and retail step, key figures of cost per kg edible food waste (NOK/kg) was used,

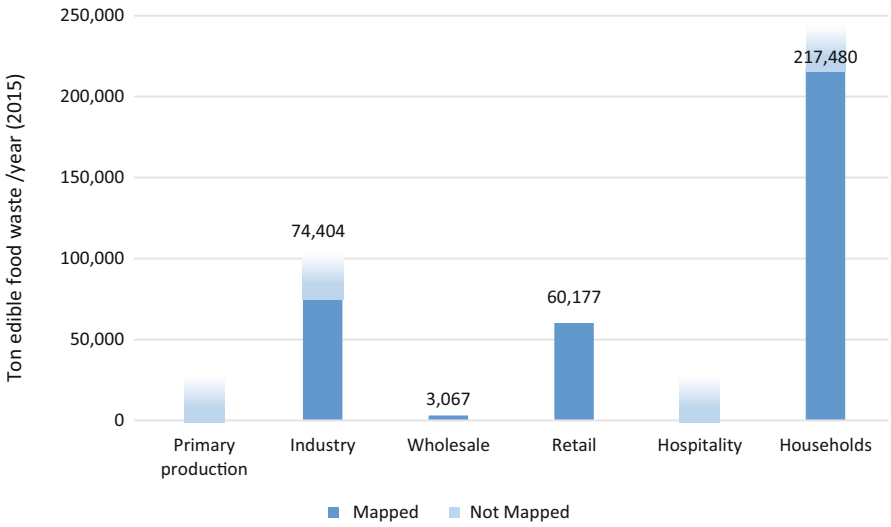

Fig. 1 Ton edible food waste in Norway and data gaps (2015)

as primary data was economic (for detailed information concerning data and methodology, see the final ForMat report, Stensgård and Hanssen 2016).

Figure 1 shows the up-scaled results of ton edible food waste per value chain step (2015) as well as markings for data gaps.

In total 355,000 tons of edible food was wasted within the four steps in 2015, equivalent to 68.75 kg/capita. The household-step was the main contributor (61%), followed by the industry (21%), retail (17%), and wholesale (1%).

The industry-, wholesale-, and retail-step provided data annually from 2009 to 2010. For the household-step, data was only retrieved in 2011 and 2015 through detailed waste-composition analysis. To fill in the missing years for the household-step (2010, 2012, 2013 and 2014) the 2011 and 2015 data was extrapolated using the trend-line function in Excel.

Figure 2 shows kg edible food waste per capita from 2010 to 2015 for each of the value-chain steps and total.

For the analyzed time period (2010–2015), edible food waste was reduced by ca. 10 kg per capita, or 12%. Food waste had decreased for three out of four steps (all except wholesale), and the reduction was most significant at the households.

At the household step, edible food waste was reduced by 4.2 kg per capita, or 11%, from 2011 to 2015 (the analyzed years). The two waste-composition analysis also showed that the development varied between the different product groups.

Figure 3 shows the development and composition of edible food waste at the household-step per product group and year.

Edible food waste at the household step was reduced from 46.3 kg/capita to 42.1 kg/capita. Bread was the product group with the most significant decline, reduced by 3.75 kg/capita or 40%, followed by "other" edible food wastes, which

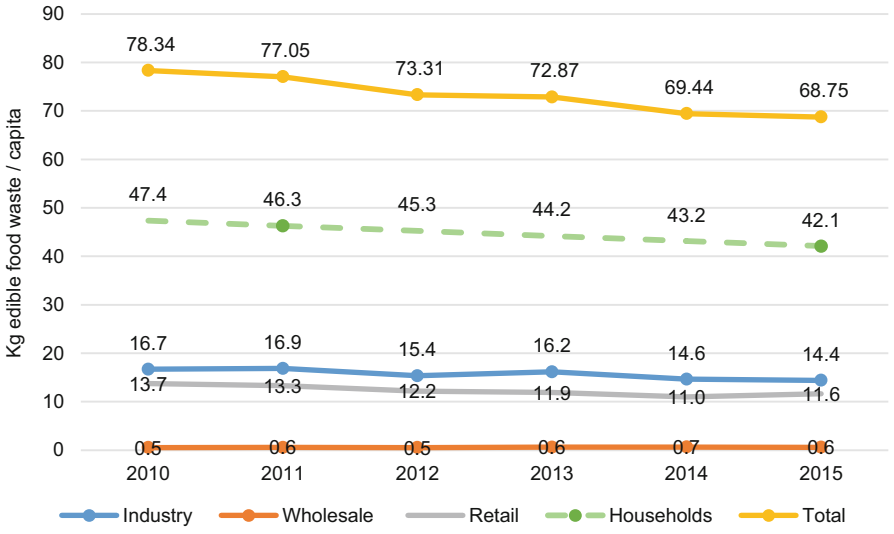

Fig. 2 Kg edible food waste in Norway per capita from 2010 to 2015, for each value-chain step and total

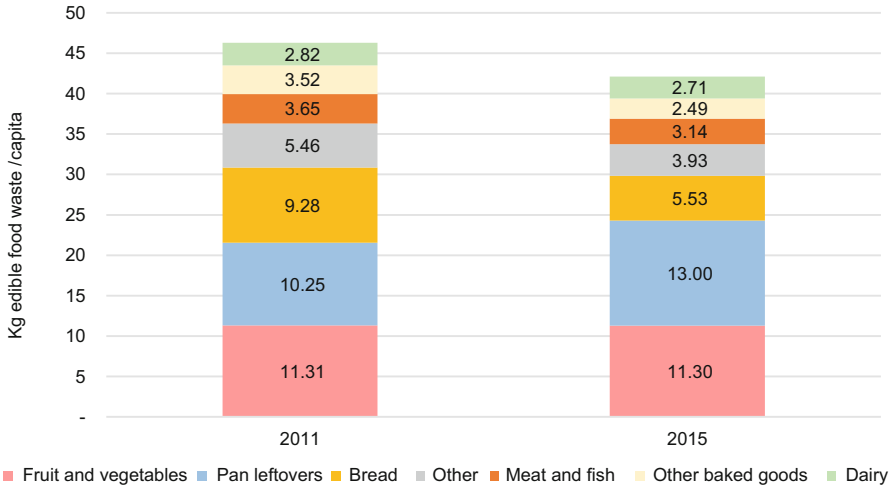

Fig. 3 Kg edible food waste per capita at the household-step, per product group and year (2011 and 2015)

were reduced by 1.53 kg/capita or 28%. Pan leftovers was the only product group that increased during the period, adding 2.75 kg/per capita.

The project also estimated costs and environmental impact (limited to greenhouse gas emissions (GHG)) related to food waste, based on the national food waste statistics. The costs were calculated by using key figures of cost per kg edible food

waste (NOK/kg) per product group as well as upscaling factors based on share of total turnover (wholesale and retail), total production (industry), or number of inhabitants (household-step). All costs were calculated in 2015 value, to ensure comparability between the years.

Environmental and Economic Effects of Food Waste at Home

The environmental impact was calculated by multiplying the amount of food waste in ton (for each product group and value chain step) by a corresponding emission factor. The emission factors were calculated through life cycle analysis methodology (LCA) in accordance to ISO 14040/44 and the European Commission JRC (2010, 2011). These factors included all GHG emissions related to production, transport, an packaging of food. Emissions related to storage at the retailers, transportation home, cooking, and waste handling was not included. All GHG emissions were converted into CO2 equivalents.

Figure 4 shows the costs and Fig. 5 shows the environmental impact related to edible food waste in Norway for each value chain step and year, as well as total (Fig. 5).

From 2010 to 2015 economic costs related to edible food waste was increased by NOK 0.3 billion, or 1.5%, and GHG emissions decreased by 25,000 tons CO2-eq., or 3%. Yet edible food waste was reduced by 7% (25,500 tons), meaning that the development of economic and environmental impact related to food waste did not align with the development of ton food wasted. The deviation between ton food wasted and economic and environmental costs is a result of offsets between different

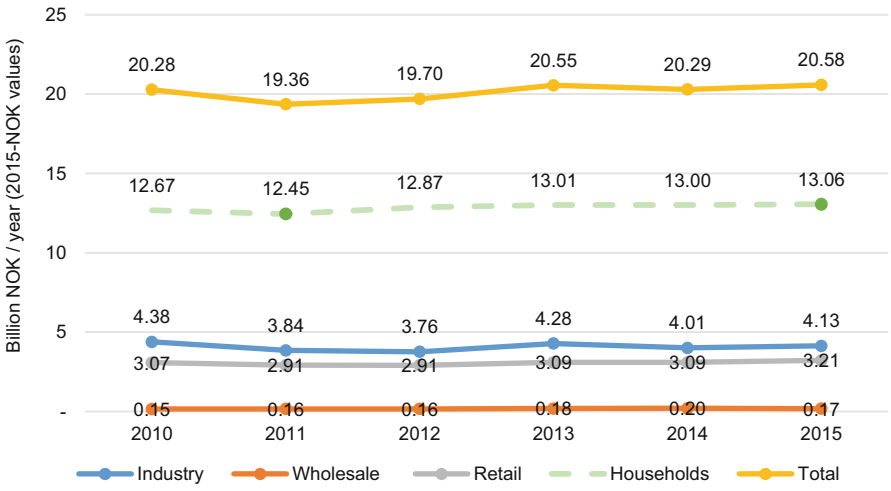

Fig. 4 Economic costs (Billion NOK) related to edible food waste in Norway per year, value chain step and total

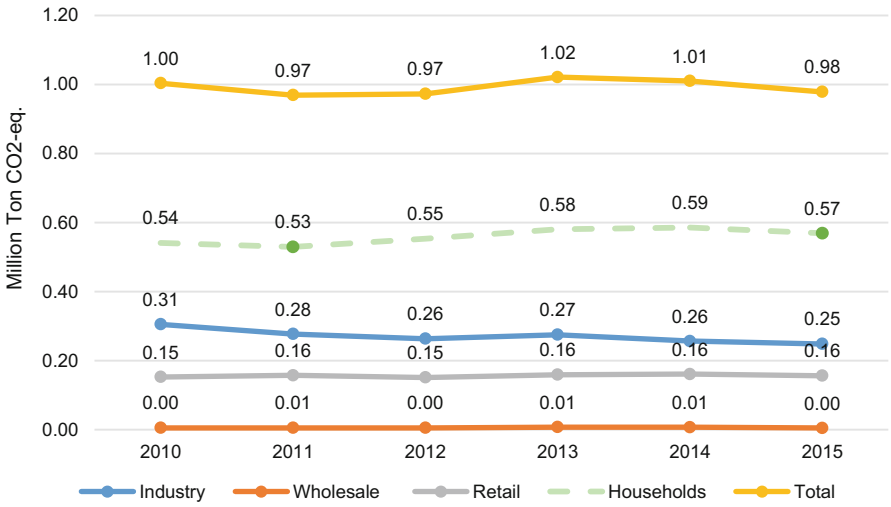

Fig. 5 Environmental impact (million ton CO2-eq.) related to edible food waste in Norway per year, value chain step and total

product groups within the food waste. Through the period 2010 to 2015, the composition of edible food waste was altered from relatively cheap and climate friendly products to relatively expensive and climate intensive products.

The household step was the main contributor to economic and environmental cots, as well as increased costs and environmental burdens per kg edible food waste. As shown in Fig. 3, the composition of edible food waste at the household step is quite rough, and the only product group that increased during the period was pan leftovers, a relatively vague product group. In the analysis, it is assumed that the cost and carbon footprint of pan leftover is relatively high compared to bread and fruits and vegetables. This is decisive for the result of GHG and costs.

Consumer Surveys Explaining Why Food Is Wasted

In the ForMat project, a number of 1000 consumers were asked about their food wasting of different food products in a given week before the study was done every year between 2010 and 2015. The main results are shown in Fig. 1, indicating percentage of consumers that said they wasted the given food product and percentage points change between 2010 and 2015. Leftovers from pots was the most frequently wasted product (26%), followed by biscuits (20%), eggs, fresh fruits (both 19%), fresh vegetables, and frozen ready-made food (both 16%). Milk/cream (14%), fresh bakery products (13%), and fresh meat (12%) did also rank high in food wasting. An interesting observation was that all food types other than fresh fruits showed reduction in frequency between 2015 and 2010 (Fig. 1), with the largest reduction by eggs (5.9%-points), leftovers of dinner meals (5.4%-points), and fresh

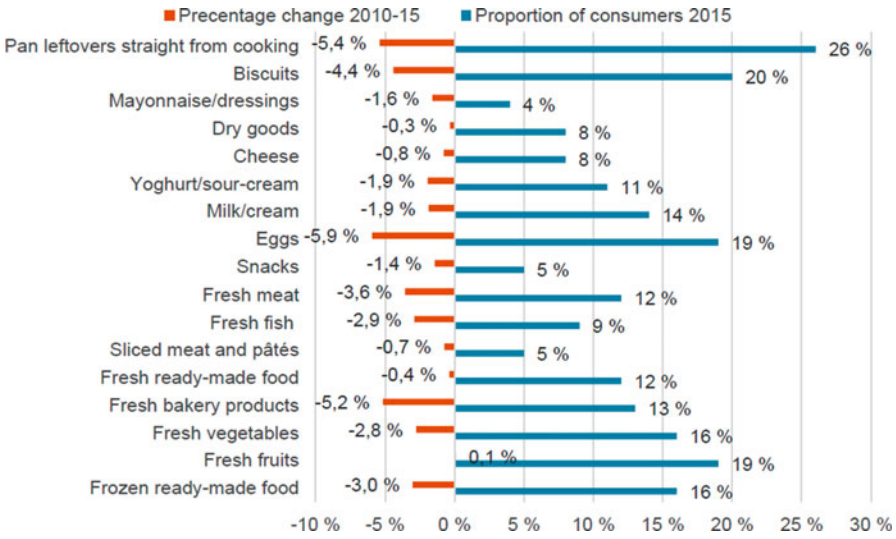

Fig. 6 Changes in share of consumers saying they are wasting different types of food waste in Norway 2010–2015 (Based in Stensgård and Hanssen 2016)

bakery products (5.2%-points). It is thus quite good agreement between the consumer study by self-reporting and the results from the waste composition analyses shown earlier in the chapter, if focusing on the type of food being wasted and the overall trends (Fig. 6).

Through the ForMat project, another cohort of consumers was asked each year from 2010 to 2015 about their behavior and attitudes with regard to important factors that could influence on food wasting from households, with main focus on shopping behavior, food preparation and eating, storing and transport of food, packaging and date labeling of food, as well as food wasting (Figs. 2 and 3). With regard to food planning, about 85% claimed to know how much they needed to buy food, whereas 64% said they normally used shopping list. Only 26% and 24%, respectively, said they either bought too much of each product or more food than they needed. All trends between 2010 and 2015 were positive with regard to food wasting behavior, as the two last factors were reduced in frequency whereas the two first increased slightly over time (Fig. 2). For eating behavior, 48% said they normally took smaller portions to prevent food waste, being more or less stable over the 5-year period. On the other hand, about 33% said they made too much food and throw away the leftovers, and 31% said they made too much food for dinner. Both frequencies were reduced over the years from 2010 to 2015 (Fig. 7).

Consumers have high thoughts about their abilities and behavior to store food properly at home (87%) and at the right temperature in cars from retail shop and markets to home (48%). Only 14% say food often are stored unproperly at home, and 9% that food is often damaged under transport to home from retail shops (Fig. 3). Forty-nine percent of the respondents said they normally store food in new and special packaging solutions at home.

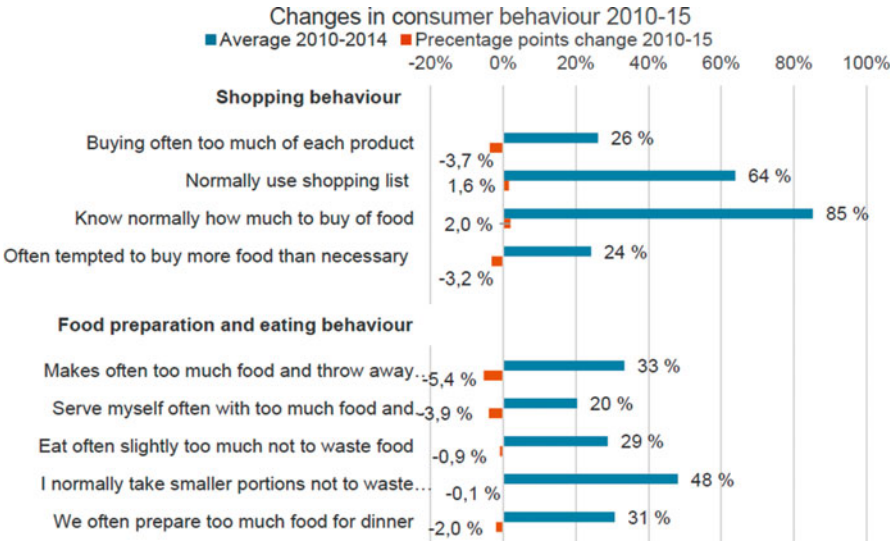

Fig. 7 Changes in behavior and attitudes regarding shopping and food preparation and eating among Norwegian consumers 2010–2015 (Based in Stensgård and Hanssen 2016)

An unexpected share of consumers said they knew well the differences between "best before day" and "used by day" (78%), increasing even slightly over time from 2010 to 2015. About 30% of consumers said they always wasted food that had passed date, and with a significant reduction (8.6%-points) over time from 2010–2015 (Fig. 3). About each third respondent said that there was too much food in each packaging unit (32%), whereas only 24% said they had to waste food due to bad packaging. This figure was also reduced with close to 5%-points over the project period from 2010 to 2015. There has been a high focus on date labeling as a reason to food waste in Norway through the ForMat project and from many different actors, which might explain the significant reduction in respondents saying they are wasting food only due to passed date labeling (Fig. 8).

Similarities and Differences Between Scandinavian Countries in Food Waste Generation and Composition

Statistics of edible food waste from households in four Nordic countries are shown in Fig. 1 and indicate that amount and to some extent composition of edible food waste differ significantly between the four countries. Denmark and Norway are both generating more than 40 kg edible food waste per capita (46.6 kg in Denmark and 42.1 kg in Norway), whereas Finland and Sweden both are generating 50% less edible food waste (Sweden 22.0 kg and Finland 23.3 kg). Also composition of edible food waste differ slightly between the countries, with fruits and vegetables as the most important food type being wasted in Sweden (37%) and Finland (32%), whereas leftovers from

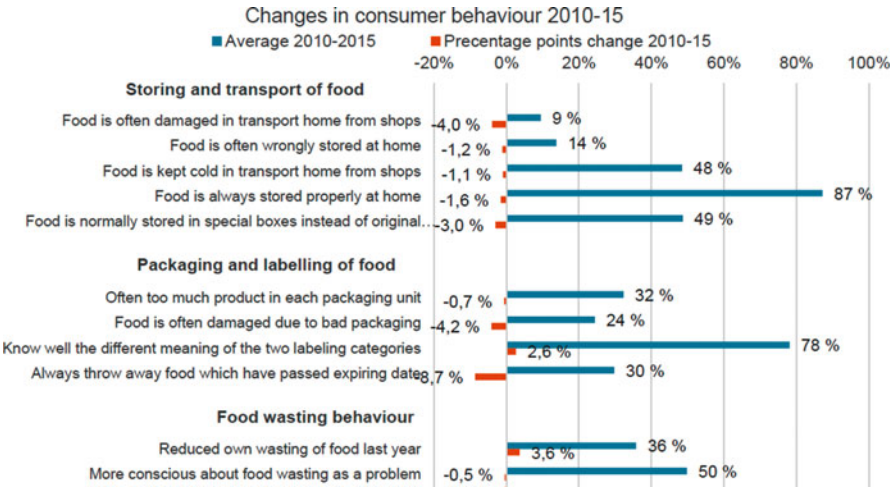

Fig. 8 Changes in behavior and attitudes regarding storing and transport of food, packaging and labeling, and food wasting among Norwegian consumers 2010–2015 (Based in Stensgård and Hanssen 2016)

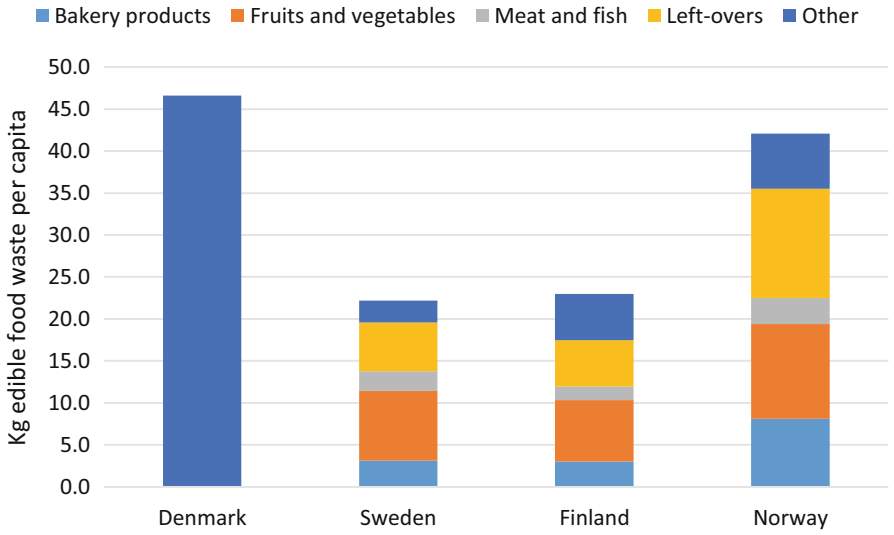

Fig. 9 Total mass of edible food waste from studies of household in Nordic countries

meals is the most important category in Norway (31%). Bread and bakery products are relatively more important in Norway (19%) than the other countries, whereas meat and fish have a higher share in Sweden (11%) than in other countries. Data are taken from Miljøstyrelsen (2014; Denmark), Katajajuuri et al. (2014; Finland), Naturvårdsverket (2016; Sweden), and Stensgård and Hanssen (2016; Norway) (Fig. 9).

As shown by Hanssen et al. (2016) total amount of food waste per capita differs less than the edible food waste per capita (Table 7). Both Finland and Sweden have lower shares of edible food waste than Norway, which coincides to some extent with the differences in data on edible food waste. The question of where to define the border between edible and nonedible food waste should thus be further discussed in follow-up studies between countries.

Differences in amounts of food waste might also be due to variations in food consumption and eating habits between countries. Norwegian consumers eat more bread-based meals than Swedish and Finnish consumers; the latter tend to consume warm lunch both in job canteens and schools. This might explain the high percentage of fresh bakery products in Norway (Fig. 9). Norwegian consumers have also different preferences for fresh bread than Swedish and Finnish consumers, with more focus on "crunchy" products which will naturally soften quickly and hence be more vulnerable to wastage. Credible statistics on food preferences in Nordic and European countries are, however not available, making such explanations more speculative than empirically based.

Policies and Protocols

Policies and Regulations of Food Waste Prevention

Treatment of food waste is strictly regulated in all 28 countries in EU, both from agriculture, food business operators, as well as from households and municipalities. Regulation of wasting of food as such is, however, so far very seldom regulated, and only from food business operators as in France, where the retail sector and wholesale sector is not permitted to waste food.

Norway

Norway has a long tradition in using soft regulations within the waste area, where negotiated agreements alone or in combination with a general regulation by law have been the most used type of policy. This is the case for packaging waste, as well as WEEE, batteries, cars, etc. Producer Responsibilities Schemes have been established by the business sectors themselves, where payment of a certain fee per unit of material used is paid by the industry. This packaging fee is paid to operate collection and recycling schemes, as well as waste prevention actions, information and motivation measures as well as development of more sophisticated and effective solutions. At the end, it is the consumers who pay the cost of the packaging waste recycling and prevention measures.

It has thus been natural to use the same approach to prevent and regulate treatment of food waste in Norway. An interim negotiated agreement between five Ministries and seven food business organizations was signed in May 2015, and will most probably be followed up by a permanent agreement which can be signed up before summer 2017. This permanent agreement will regulate food waste over the whole food chain, where the ambitions and long-term goals are defined in the common

agreement, but where the food sector will identify the best strategies and measures to prevent food waste. A common definition has been agreed upon, as well as a system for how to measure edible food waste or surplus food along the whole chain (Hanssen 2016). In parallel, the Norwegian Parliament has decided that the Government shall evaluate the need for a Law against food waste, based on the French Food Waste regulations. This can eventually be an incentive to make the negotiated agreement effective by the food sector, as regulations by Law probably will be less flexible than a negotiated agreement. The food sector in Norway has been the initiator behind food waste prevention from day one, where both the retail and wholesale sectors as well as the food industry and the hospitality sector have taken initiatives to measuring edible food waste and surplus food, as well as implementing specific measures to prevent food from being wasted. Most of the food waste is generated in households, where it is very difficult to regulate and follow up regulations of food wasting, making it questionable if a Law will be necessary in Norway if the negotiated agreement is implemented by all actors along the food chain. This is a question which will be important to answer in the next couple of years based in experiences also in other countries.

Finland

In Finland, more than a hundred (out of 200) MPs signed a bill 29/2016 of the Food Act (23/2006) proposing that edible food that is not possible to sell ordinarily, should be offered for redistribution or other ways of human food. The initiative aims to reduce amount of food waste and the effects of food waste.

In Finnish LA 29/2016, on Parliament's website is https://www.eduskunta.fi/FI/vaski/KasittelytiedotValtiopaivaasia/Sivut/LA_29+2016.aspx

Ministry of Agriculture and Forestry has commissioned a study (completed January 2017) estimating the costs related to implementation of the bill, including monitoring of food waste statistics, as well as effect of the bill to the amount of food waste and amount of food being donated.

The cost of the bill caused to the operators was estimated to be significant. Also Evira (food safety authority) evaluated the obligation to distribute (on premises) to cause more costs. Mandatory donation of surplus food alone does not lead to increase in amount of food being redistributed and reduce waste. The main problem is not lack of willingness of the actors to make food donations, it is lack of resources with the redistributing actors. Food distribution directly from the stores (shops, bakeries, food catering) is problematic, and is not supported.

Food should be eaten by humans, and not put in the trash. Opportunities to reduce food waste through legislation are sought through Prime Minister's office project "How to develop legislation to reduce food waste?" The final project report including policy brief will be completed before 31 December 2017.

Sweden

In Sweden, the Government initiated an action for food waste prevention in 2013, which was finalized with a report in March 2016. This has been followed by a new action initiated by the present Government in February 2017, where environmental

and food authorities shall identify long term measures to reduce food waste from the whole food chain in close collaboration with stakeholders and actors. The action plan shall contribute to an understanding of how Sweden shall reach the global goal of 50% reduction in food waste by consumers and retail before 2030. This is part of the program to develop policies for sustainable consumption and a circular economy. The short term action plan shall be reported in February 2018, but is not clear if this implies regulations by law or more soft regulations.

Protocols

Edible food waste is measured in a number of different ways, and there are several reports from the EU project FUSIONS that give comprehensive overview of both alternative methodologies as well as manuals with more specific descriptions of "how to measure" (Møller et al. 2013, 2014, Tostivint et al. 2016). An international protocol for measuring food waste and loss has also been developed in collaboration between United Nations Environmental Program (UNEP) and World Resources Institute (WRI), which to a large extent is based in the work from FUSIONS.

As our work with the ForMat project in Norway started well before the FUSIONS project back in 2010, we had to develop our own approach and methodologies for dealing with food waste statistics, and the methodologies are well described in the final report from the project (Stensgård and Hanssen 2016). The more detailed work with food waste from households through waste composition analyses have been described in detail by Hanssen et al. (2016).

Our work is only focused on what is defined as edible food waste, and differ in that respect from the broader definition of food waste from FUSIONS project in two directions:

- We have excluded all types of inedible food parts from peels, bones, stones, etc.
- We have included food that ends up as animal feed or to industrial nonfood products.

Our definition includes all types of food that ends up in the solid waste fractions from the food industry, wholesalers, the retail sector, the service sector, and households, including food to animal feed and new bioproducts.

Through the ForMat project, routines have been developed for voluntary reporting of edible food waste from the food industry, from wholesale companies, as well as the three big retail companies in Norway. Statistics are gathered for 21 food types within 9 main groups. The methodology is well described by Stensgård and Hanssen (2016) and by Hanssen et al. (2016) for the households. We have data covering more than 25% of the economic value of food manufacturing industry in Norway, more than 40% of the wholesale sector and 90 retail shops being representative for the whole retail sector in Norway. The food industry measures edible food waste in tones and gives data per tones of production, while the retail sector and wholesalers register food waste in economic value by scanning all

products that are wasted instead of being sold. Amount of edible food waste is then estimated based in economic value of a sample of 185 food products. All data are sent to Ostfold Research and treated confidentially and presented as aggregated figures and scaled up to national statistics based in weighted measures from economic value. Data from edible food waste from households are based in annual data on organic waste registered by all Norwegian municipalities and used to estimate amount of food waste in total and per capita based in coarse waste composition analyses from about 50 municipalities in Norway. In addition, detailed waste composition analyses were carried out in 200 households in two urban and rural municipalities in 2011 and 2015, to get specific data for the 9 main groups of food (Hanssen et al. 2016). National guidelines for how to carry out waste composition analyses to register organic waste and more detailed data on food types have been developed and published by Avfall Norge (2015).

Based in literature data from LCA studies of food production, Ostfold Research has developed indicators for GHG emissions from a number of different food products, both from Norwegian production as well as foreign production. Those data have been used to generate national statistics for GHG emissions related to food that has been produced and ended as food waste, including waste treatment processes. Economic value of the 185 sample products have been used to generate average economic value per kg of food of the 21 main food types. Further on, this has been used to estimate and upscale to gross economic value of food being wasted in Norway.

Principles for Developing a Safe and Sustainable Valorization of Food Waste for Animal Feed: Second Generation Feedstuff

Contents

Abstract

Developed countries are producing and consuming more food than needed, which generates a significant amount of food waste. Within this framework, three main strategies have been proposed to control this food wastage: reduction, reuse, and recycle. In the hierarchy of valorization options for any food waste, the reuse for human food or ingredient has to be prioritized, however, due to technical requirements; this option could not be always implemented. The use of food wastes as a second generation feedstuff is an interesting option to many food sectors since it could reduce land use competition, the dependence on the current feed raw

materials, the cost of animal feed, as well as the environmental impact associated to its production. However, the feasibility of this option depends on several legal, technical, and economical requirements as well as environmental and social sustainability conditions. In addition, this valorization alternative demands some treatments in order to stabilize and preserve effectively.

Technological cooperation, knowledge, and involvement of different actors in the demonstration of new valorization schemes, from generators to processors and end-users, are of crucial importance due to the important and frequent constraints which affect the technical and economic feasibility of their reutilization: logistic costs, processing costs, availability of raw materials, and heterogeneity of the quality and composition of the wastes. Moreover, food safety experts and regulatory bodies have to be also involved and may contribute to promote the safe and responsible use of food waste for feed.

Introduction

One third of all food produced in the world – approximately 1.3 billion tonnes – is lost or wasted every year (Gustavsson et al. 2011) while, according to FAO estimations (2015), even as more than 800 million people are still undernourished. Major global organizations and governments agree that the food waste and losses produced along

the food supply chain is one of the biggest issues now facing humanity. Moreover, it is one of the Sustainable Development Goals published by the UNEP, "Target 12.3: By 2030, halve per capita global food waste at the retail and consumer levels and reduce food losses along production and supply chains, including post-harvest losses."

However, the precise definition of food waste or losses has generated some controversy between the stakeholders. For the European Commission (2010), food waste (FW) is all food lost or discarded in the process of manufacturing, distribution, retail, food service activities, up to the consumer level. FAO (2014) gives another perspective in their definition and considers FW a part of food loss distinguished by the causes of its generation. Thus, while "food loss refers to all food produced for human consumption but not eaten by humans," FW refers to this part that being safe and nutritious for human consumption is discarded or used for nonfood purposes and can be generated in all steps of the value chain, including primary production. Thus, FW is generated mainly due to inefficiencies in the food chain and inadequate consumption patterns.

Additionally, in 2014, Garrone et al. define the concept of surplus food, which consists of edible food products that for various reasons are not purchased or consumed by customers or people for whom they were produced, processed, distributed, served, or purchased. Instead, FW is the part of surplus food that is not recovered for human or animal consumption, for producing goods or energy. However, from the social perspective most surplus food could be considered as waste.

For the purpose of the present chapter, the most recent definition provided by FUSIONS platform (Stenmarck et al. 2016) is considered, where FW is the fraction of "food and inedible parts of food removed from the food supply chain." In this definition, feed (food going to animals) is not considered as waste. Food that is redistributed is not accounted for as FW as it does not quit the food chain.

Beyond ethical aspects that obviously underlie food wastage, it should be considered as a big failure in the efficiency of food value chain. While food demand will increase at global level but mainly in developing countries in the next years driven by population and income growth, high income countries still produce and consume more food than they need. In this context, all measures taken to increase the efficiency in the use of the resources, like avoiding food losses, is of critical significance.

According to Gustavsson et al. (2011), the causes of food losses and waste are different in low and in high income countries. While in developing countries the biggest losses, more than 40%, occur in the primary production due mainly to deficiencies in the production systems, in developed countries more than 40% of losses occur at retail and consumer level, due to inadequate planning or bad purchasing habits as well as to "high appearance" quality standards.

All actions taken against food wastage can be classified into three strategies: reduction or prevention, which means minimizing the generation of FW (as redistribution in food banks), reuse or reentering the food chain (as for animal feed), and recycle, giving FW a second life in other applications as materials or in composting or energy production.

According to the main causes of FW generation above mentioned, main actions to be taken shall be focused in first instance to prevention. Thus, in relation with

household waste generation, actions shall be focused on educational measures, increasing the awareness of the consumer or promoting social initiatives, while in relation with waste generation in the processing and distribution, on a better planning and communication between steps in the food value chain, adequate marketing or labeling strategies, redefining quality specifications and product innovation.

Regarding the reuse of food waste, following the hierarchy of waste or by-product management established by the Waste Framework Directive of the EU parliament (2008) (Fig. 1), the reuse for human food or ingredient has to be prioritized, but the use as raw material for feed is an option that interests many food sectors. One reason is the growing demand for animal products in the high income countries that will cause that livestock production will have to substantially increase proportionally to the global demand on food which is expected to increase by 60% in 2050 (FAO 2016a). As a consequence, a significant increase in the need of feed raw materials is expected.

Thus, a lot of foodstuffs which were manufactured for human consumption but have been discarded due to reasons that do not affect their safety reenter the food chain as feed raw materials. These are defined as "former foodstuffs" in the EU Catalogue of Feed Materials (Regulation (EC) No 68/2013). The European Former Foodstuff Processors Association claims that five million tonnes of former foodstuffs are nowadays used as animal feed and this can increase to seven million tonnes until 2025 (EFFPA 2016).

But there are unavoidable parts of FW that represent an important percentage of the total FW. Namely, by-products are those unavoidable fractions generated through the different food production steps that are not part of the final product. They can be recovered and recycled for different applications being upgraded as raw materials for other products, such as food, feed, or as a source of chemicals, then not considered as

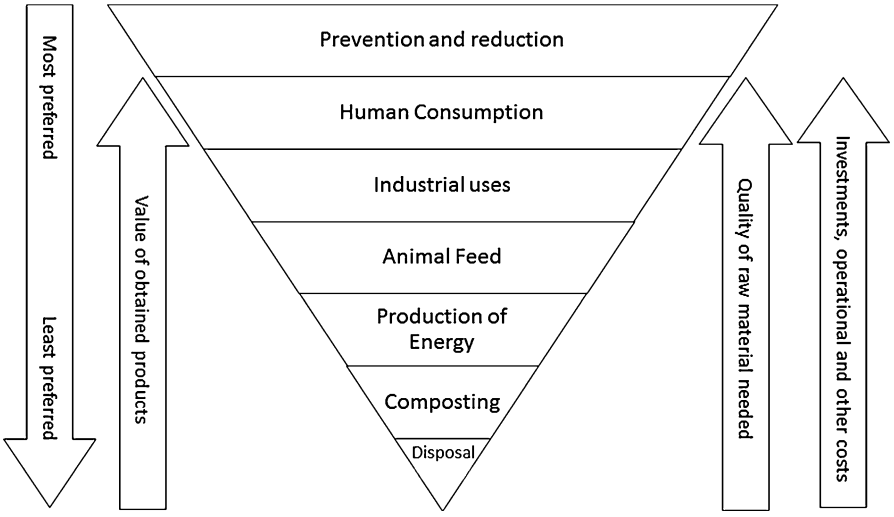

Fig. 1 Hierarchy of food waste valorization adapted from EU waste framework directive and USA-EPA

waste. However, nowadays, those by-products are sometimes managed as waste and disposed into landfills, due to economical, technical, logistic, and/or regulatory constraints.

The reduction of food loses and the recovery of food by-products into the food chain can have also an indirect impact on food security. As the livestock sector is the world's largest user of agricultural land through grazing and the use of feed crops, the use of former foodstuffs and by-products in animal feed could allow the release of land and other agricultural resources for feeding up people. The impact on the lowest income countries would be very high as agriculture accounts for more than 30% of their economic activity (FAO et al. 2012). Moreover, in these regions the expected subsequent increase in the prices of raw materials for animal feed could even exceed the price of the same crop when used for human consumption (CAST 2013).

Food loss and waste have also a high environmental impact. Organic wastes associated with food can take up space in landfills and contribute to greenhouse gas emissions during decomposition (Hanson et al. 2016). Moreover, food production consumes water, land, energy, and resources that are finally wasted when food is lost. As an example, according to a study of Kummu et al. (2012), global losses in the food supply chain account for a quarter of the crops wasted, 24% of total freshwater resources used in food crop production, 23% of total global cropland area, and 23% of total global fertilizer. In addition, livestock production uses a considerable amount of resources to produce feeds and makes a significant contribution to global carbon emissions (FAO 2016a).

Climate change can have also a negative impact on agriculture. It is estimated that depending on socioeconomic and climate change assumptions, by 2050, relative to a world with no climate change, global average crop yields will decline by 5–7%, while the area harvested will increase by around 4% (Wiebe et al. 2015). The high dependence on agriculture makes developing countries even more susceptible to the effects of climate change.

As a conclusion, all measures targeted to increase the efficiency and reduce the food waste will contribute definitively to reduce the environmental impact, increase food security alleviate poverty and favor the economic growth (FAO et al. 2015).

Food processing unavoidable waste should not be considered as waste but as a raw material that may reenter the food chain and has to be treated as such. Most food industry by-products are unstable and highly perishable, which means that they have to be stabilized and preserved adequately before being processed to obtain feed ingredients and feed products. Besides, there are still several constraints that affect the technical and the economic feasibility of their valorization such as the availability of raw materials (geographical and seasonal), the logistic costs, the processing costs, and the heterogeneity of the quality and composition of the by-products. Technological cooperation, knowledge, and involvement of different actors in the demonstration of new valorization schemes, from generators to processors and end-users are of crucial importance. Also food safety authorities and regulatory bodies have to be involved and may contribute to promote the safe and responsible use of FW for feed.

In addition, every recovery and recycling proposed option should not imply an increase in the environmental impacts in comparison with the actual treatment or

disposal option. For this purpose and in accordance to EU recommendation (COM (2005)666), life cycle analysis (LCA) appears as a useful methodology to demonstrate the environmental benefits of the alternative option.

In the present chapter, main important aspects related to the valorization of food industry by-products of different sectors for feed purposes are presented. Different approaches, technological and methodological solutions are described.

Principles for a Safe and Sustainable Valorization

Due to its characteristics and nature food by-products needs to be pretreated, often dehydrated, stabilized, and preserved to obtain safe and nutritious feed ingredients and feed products. As any raw material, feed products from FW are subjected to legal, technical, and economical requirements, as well as environmental and social sustainability conditions.

Following, the principles for a safe and sustainable valorization and the different uses of food industry by-products produced by different sectors for feed purposes are presented.

Legal, Hygienic, and Sanitary Requirements

One of the main aspects to assure the feasibility of any valorization option is to accomplish all the legal aspects that limit the hygienic and sanitary requirement for the proposed solution. Moreover, there is also some legislation that promotes the use of FW.

Regarding the EU legislation, FW is considered a biodegradable waste, or bio-waste, and has a specific regulation. On the one hand, the Landfill Directive (1999/31/EC) obliges member states to reduce the amount of biodegradable waste they landfill but without prescribing a particular treatment option. The European Commission adopted an ambitious Circular Economy Package in which the recycling strategy is the precondition using these wastes as a secondary raw material (Fig. 2).

Fig. 2 Circular economy scheme

Also the Sustainable Development Goals (UN 2015) include a target to halve per capita FW and reduce food losses along the food production and supply chains.

The Council adopted Regulation 183/2005 EC the European Parliament and of the Council laying down requirements for feed hygiene which ensures that feed safety is considered at all stages that may have an impact on feed and food safety, including primary production and operators. Main elements of the regulation are:

- The compulsory registration of all feed business operators
- To implement the application of good hygiene practices
- To introduce the Hazard Analysis Critical Control Point (HACCP) system
- To introduce compulsory requirements for feed production at farm level

Also EU legislation on undesirable substances in animal feed (Council Directive 2002/32/EC) has to be taken into account to ensure that these secondary raw materials do not represent any danger to human health, animal health, or the environment or do not adversely affect livestock production.

Regarding limiting values of contaminants for animal feed, the legislative framework differs worldwide. Currently, most comprehensive regulations are those of Europe and North America. Hence, while in the European Union, the legislation on animal feed is already harmonized, in many developing countries, particularly in Africa, around 50 countries do not still perform the statutory control of contaminants or it is still at best rudimentary (D'Mello and Macdonald 1998). However, in order to fulfill quality and safety standards for imported animal feeds, since 1999 non-EU feed manufacturers are required to have representatives based in the EU who can confirm declarations.

On the other hand, also Regulation (EC) No 1069/2009 of the European Parliament and of the Council and Commission Regulation (EU) No 142/2011 constitute the community legal framework applicable to animal by-products not intended for human consumption and products derived from them, that stablishes which by-product can be used for further purposes and the traceability, transport, and processing solutions. In brief, only category 3 materials can be destined to animal feed and are subjected to several restrictions for their use as feed for farmed animals, fur animals, pets, or aquaculture.

Technical Parameters

The feasibility of any valorization option is also conditioned by technical factors which could limit the use of food by-products as raw material for animal feed. Those factors can be found at two different levels. Hence, whereas the first level is linked to food by-products and their generation points, the second level is related to the animal feed production plant.

Regarding to the technical factors associated to food by-products, nutritional parameters determine the value of the by-products for animal feed. Preferred values are low contents of humidity and ashes and high contents of protein, fiber, or lipids. In addition, vitamins, minerals, or polyphenols are considered for animal feed. Finally, the digestibility of these parameters will determine the capacity of assimilation by the animal.

However, as well as nutritional parameter, there are also other undesirable substances known as anti-nutritional factors. These substances when present in animal feed or water reduce the availability of one or more nutrients and can negatively affect the health of animals.

Despite the nutritional quality, another strategic factor which makes by-products use feasible is their availability related to the generation rates. Only, producers with high generation rates are expected to be feasible from the logistic point of view and also in terms of the high environmental impact they cause.

With regard to the technical factors linked to the production plant, many factors can be taken into account in land studies. They should be in accordance with the required objectives, the information available, and planner's experience.

The geographic dispersion of the FW generation, as well as the ground-use area where the plant can be built or geo-natural factors, will determine the location of the processing plant and the logistics routes for centralizing all FW in the treatment plant.

Moreover, the technology used for FW processing is other technical aspect related to production plant that it is necessary to take into account because it will determine the energetic requirements, the processing capacity or the investment and the process costs.

In conclusion, a multicriteria design analysis which takes into account all technical factors, combined with geographic information systems (GIS), is advisable to ensure the feasibility of reusing FW for animal feed (GISWASTE Project 2016).

Economic and Market Factors

The profitability of reusing unavoidable FW as a raw material for animal feed depends on several economic factors.

The annual cost-to-income ratio (CIR) is one of the most important indicators of profitability and considers the main costs and incomes in a projection of 15–20 years (Perry and Green 2008).

Moreover, once quantified the CIR, it is necessary to perform a standard financial analysis to provide insight into the structure of costs and incomes and to stablish economic-profitability parameters such as:

- The net present values (NPV)
- The payback time period (PBT)
- The internal return rate (IRR)
- The capital recovery factor (CRF)

While the advantage of the NPV is its predictability and the respect of the time value money, it does not express the accurate rate of profitability. Therefore, IRR is chosen since it allows comparing very easily different proposal sizes. IRR criterion is very simple: if the project IRR is higher than the discount rate, the project is accepted, otherwise, it should be rejected. Under considered assumptions, if the IRR value is higher than discount rate the activity under study is profitable (Kwan et al. 1995).

It must be noted that the results of the financial analysis depend on unpredictable fluctuating variables. Therefore, if they are considered constant to enable the economic assessment, it is necessary to predict how the different variables may change over time and their effects over NPV through a sensitivity analysis.

Environmental and Social Aspects

Reusing FW for animal feed can be seen as environmentally and socially beneficial. However, a number of variables need to be taken into account to ensure that the new management alternative is socially faithful and environmentally responsible.

From the environmental point of view, the European Commission recommends the use of Life Cycle Thinking (LCT) when planning waste management systems (Waste Framework Directive 2008/98/EC) to reduce the environmental impacts associated with the whole life cycle of the waste management option – including the transportation, energy water and other material requirements or the emissions to the atmosphere (Fig. 3). According to several studies (Eriksson et al. 2015; Woon et al. 2016; Jin et al. 2015; Jensen et al. 2016; Franchetti 2013; Bernstad and la Cour Jansen 2012), when focusing on the environmental impact, the most relevant aspects are the following:

- Energy usage and climate change: It is necessary to take into account the energy needed to transform FW into a new feed ingredient.
- Water usage: It can also become an environmental critical point.

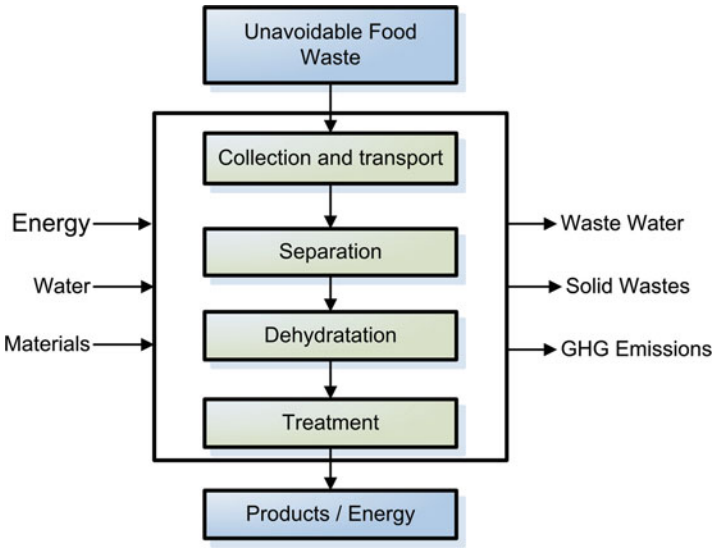

Fig. 3 Life cycle analysis scheme

- Wastewater generation: The generation of pollutant spills is also closely linked to the management of wastes and can generate a high potential for eutrophication or organic contamination of the waters where they are being discharged.
- Other aspects: Usage of toxic agents for extraction of certain compounds.

With regard to social responsibility, as discussed above, the fact of using FW as a second generation feedstuff would release the pressure exerted on the food availability in developing countries. It is estimated that about 1000 million tonnes of animal feed is produced globally every year and the 60% is produced by 10 countries, being the United States, China, and Brazil the biggest producers (FAO 2002).

Major feed ingredients have been facing market competition with human food demands of developing countries, especially for those nongrain self-sufficient countries, this is the so-called feed-food competition (CAST 2013). To cope up with this competition, feed needs to be technically treated to improve nutritional values and institutional collaborations and support is demanded in order to facilitate alternative feed utilizations.

It is also necessary to ensure that the new management model safeguards the social rights of all stakeholders in the chain. Particular attention should be paid to human rights at work such as freedom of association and collective bargaining, nonexistence of child labor, and all forms of inequality, labor conditions, or safety and health at work.

Different Uses for Food Waste

Food wastage is classified into different categories. According to FAO et al. (2015), global quantitative food losses and waste per year are roughly 30% for cereals; 40–50% for root crops, fruits, and vegetables; 20% for oil seeds, meat, and dairy plus 35% for fish. Thus, depending on the category, they could have different application for animal feed.

Following, and within this framework, different approaches, technological and methodological solutions for the main important categories of FW are described.

Vegetable and Fruit By-products

In general, vegetable and fruits by-products (Fig. 4) are characterized by their high moisture content, above 80%. The high degradation activity related to high moisture content, together with a lack of coordination between different actors in the supply chain, make that fruits and vegetables have the highest wastage rates of any food with 40–50% (FAO et al. 2015).

Only in Europe, about 200 million tonnes of fruits and vegetables are generated each year and up to 45% is wasted at different stages of the food chain (FAO 2011), in spite of having high potential to be reused as animal feed. These by-products are

Fig. 4 Vegetable by-products

an excellent source of nutrients which can contribute to supply the demand of feedstuffs for livestock, reducing the cost of feeding and giving higher profits to farmers (FAO 2013).

However, the use of these by-products as animal feed has some difficulties that can limit its feasibility. Its high degradation activity makes more difficult fulfilling hygienic and sanitary requirements, which advices subjecting them to a drying process. Furthermore, their analytical composition can vary extremely throughout the year (Westendorf 2000), which means that animal feed manufactures should have to change periodically their feed formulations depending on their composition.

Within this framework, some experiences have shown the feasibility of using vegetable wastes in animal feed. In a recent study, cauliflower and cabbage leaves or pea pods and pea vines vegetable by-products were assessed as complete feed for goat bucks (Wadhwa et al. 2006). It was concluded that they could serve as an excellent source of nutrients for ruminants and can economize the production of animals.

Moreover, the Clean Feed project (San Martin et al. 2016) showed that a vegetable flour, obtained after drying a mixture of different vegetable and fruit by-products produced by food industry and retail trade, complies with all the requirements of the animal feed market and is suitable for animal feed. In addition, Wadhwa and Bakshi (2013) assessed apple or banana by-products as livestock feed, concluding that they can act as an excellent source of nutrients.

Dairy Industry By-products

Dairy industries by-products, such as skim milk, buttermilk, and whey (Fig. 5), are valuable substances obtained during the manufacture of cream, butter, and cheese, which contain proteins, mineral salts, vitamins, and other bioactive compounds beneficial for health (Birsen Bulut and Nihat 2012).

Most of the skim and butter milk are dried and marketed as valuable ingredients for the food and feed sectors with a global production around four million tonnes/

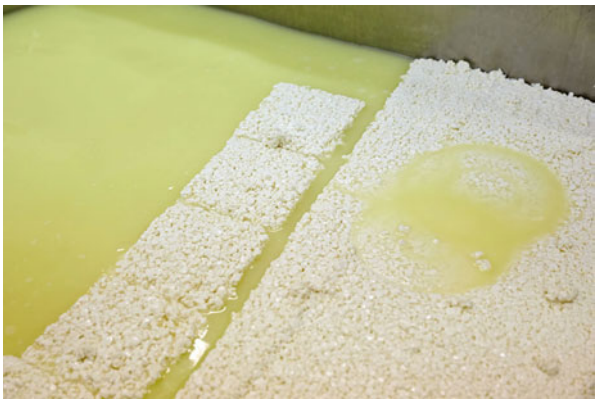

Fig. 5 Dairy by-products

year in 2013 according to OECD/FAO report (OECD and FAO 2016). Regarding to dairy whey, only about a 50% of the total generated amount (180 million tonnes/year) is used to produce whey powder (2.3 million tonnes/year) or other derived products (lactose, protein concentrates), being the rest used in a liquid form or discarded.

Dried whey and skim milk are commonly used for breeding and fattening purposes, especially as milk replacers in young pigs or calves (OECD and FAO 2016), but they are less frequently used in older animals because of possible digestive disturbances. Nevertheless, there are several recent studies indicating the benefits of the inclusion of whey in the diet of livestock.

Regarding to dried whey, results obtained in 2014 within the frame of the European Life- VALORLACT project (VALORLACT 2015) demonstrated that the addition of 6% whey in the feedstuffs produces an increase in the lying rates in hens (9%), without affecting eggs' quality, and improves the average daily rates and conversion rates in broilers (28% and 17%, respectively) as well as milk quality in sheep (increased fat and protein levels), without a reduction in production yield.

On the other hand, fresh whey feeding to animals is also a suitable and cheap alternative to avoid its disposal to the environment. It also complains the Regulation (EC) No 1069/2009 about animal by-products. However, direct supply of whey has to ensure hygienic conditions to avoid pathogenic organisms and insects proliferation. As a rule, it is desirable to provide daily fresh whey or maintain it in a refrigerated tank for a maximum period of 36 h before using. Digestive disorders such as diarrhea or bloat may also occur if the adaptation period to whey feeding is not enough (at least 1 or 2 weeks). It is estimated that ruminants can ingest from 12 to 15 liters of fresh whey per 100 kg live weight. In some cases, the intake of liquid whey can also reduce the amounts of hay or grain consumed (5–10%) (FAO 1978).

The most obvious benefit in pigs is increased feed intake, consuming on average 12% more dry matter when offered liquid rather than dry diets (Mavromichalis 2013).

According to previous cited FAO report (1978), dairy cows can drink as much as 100 liters per day, without reporting any depressive effect on milk production,

duration of lactation, or butterfat content. Experiences developed in Tunisia (Ben Salem and Fraj 2007) with lactating cows fed with 40 liters/day during 141 days showed a replacement of 2 kg of concentrate by liquid whey and an increase of 5–6% in milk fat and protein (gr/cow/day).

Fish By-products

Fish transformation industry and fish retail distribution generates a large amount of fish by-products (Fig. 6). It is estimated that 25–30% of the total fish or seafood weight ends up as a waste. These wastes, mainly considered as by-products, are typically processed to produce fish meal and oil that are used for animal feeding (FAO 2016b).

The fact that fish by-products are considered animal by-products not intended for human consumption stablishes some limitation of which by-product can be used for further purposes and the traceability, transport, and processing solutions. In brief, only category 3 materials can be destined to animal feed and are subjected to several restrictions for their use as feed for farmed animals, fur animals, pets, or aquaculture (Commission Regulation (EU) No 142/2011).

Moreover, and even though more than 85% of fish catches are used for direct human consumption, also about 10% of fish catches are used for fish meal production (FAO 2016b).

Worldwide, annual production from approximately 300 dedicated fishmeal plants has been around 5 ~ 7 million tonnes of fishmeal over the last years.

In Europe, more than 20 facilities produce approximately 500,000 metric tonnes of fishmeal and 190,000 tonnes of fish oil a year (EU Fishmeal 2016). Worldwide it is estimated that about 35% of world fishmeal production is obtained from fish residues, while in Europe this ratio is increased up to 50% (FAO 2016b). In fact, the use of fish by-products for the production of fish meal and fish oil reduces the overexploitation of the seas and the fisheries that target species for fish meal production.

Fig. 6 Fish by-products

The standard process of fish meal and fish oil obtains an average 20–25% fish meal yield and 3–5% of oil. The obtained product has an average 65–70% protein, 7–10% oil, less than 12% ashes, and less than 10% of moisture (Windsor et al. 2001).

Better quality of protein rich products can be produced through other processes such as the enzymatic hydrolyzation, increasing the amount of protein up to 80–85% and the content of ashes is considerably reduced (Chalamaiah et al. 2012).

On the other hand, these fish by-products also contain high valuable compounds such as bioactive peptides, pigments, collagen/gelatine, chitin/chitosan, chondroitin sulfate, or calcium, which can be recovered. Worldwide several industries process fish wastes to obtain such products preventing the disposal of fish waste and the use of other raw materials (Arvanitoyannis and Kassaveti 2008).

Meat Industry By-products

The majority of meat waste (Fig. 7) is produced during slaughtering and consists of the portion of a slaughtered animal that cannot be sold as meat or used in meat-products. Such waste includes bones, tendons, skin, the gastrointestinal tract content, blood, and internal organs. More than half the animal by-products are not suitable for normal consumption, due to their unusual physical and chemical characteristics. Within this framework, the vast majority of the remaining by-products after the different uses are processed to produce meat and/or bone flour in order to improve the protein levels in animal feed.

Approximately 25 million tonnes of animal by-products are rendered in North America, 15 million tonnes in the European Union, and 10 million tonnes in South

Fig. 7 Meat by-products

America and Australasia, to provide rendered products worth up to eight billion US dollars annually (FAO 2004).

Unlike other type of by-products, the recovery of meat industry by-products is bound by severe hygiene and health limitations. In the European Union, meat by-products are considered animal by-products not intended for human consumption. The Regulation (EC) No 1069/2009 stablishes the limitations for the use of these by-products regarding the traceability, transport, processing solutions, and disposal. According to this regulation, only meat by-products of category 3 can be destined to animal feed after being subjected to several restrictions for their use as feed for farmed animals, fur animals, pet-food, or aquaculture. In this category are mainly included all the meat by-products from animals with no signs of communicable disease to humans. The most dangerous disease is the Bovine spongiform encephalopathy (BSE), for which the European Union promulgated specific legislative measures to avoid that products containing BSE could end up in the meat distribution chain (Regulation 999/2001 and 853/2004). EU national authorities make official controls on these products imports from non-EU countries.

Policies and Protocols

Just one quarter of all wasted food could feed the 795 million undernourished people around the world who suffer from hunger. However, not all the food wasted could be directly used as secure human food. In this chapter, an alternative use for these wastes as animal feed is analyzed which could release enough resources to feed up to three billion people.

In this sense, farmers around the world use lots of crops that could be eaten by people. The impact on the world's developing regions may be very high as agriculture is usually their main way for subsistence. The promotion of second generation feedstuff, feedstuff produced from FWs, involves that, if farmers fed their livestock on the food that is currently wasted and on agricultural by-products, enough grain would be liberated to feed people.

Moreover, the use of FW for animal feed can reduce the competition for the use of land for some crops in circumstances when the price paid for animal feed can even exceed the price that can be paid by the human consumer in that region (CAST 2013). It could also improve social, environmental, and economic sustainability of the food chain and account as circular economy scheme, mitigating the climate change, water depletion, and other environmental impacts associated not only to the food product but also to those impacts related to the livestock production.

However, food by-products frequently need to be pretreated, stabilized, and processed adequately to obtain useful feed ingredients. Therefore, in order to ensure that the whole valorization process is economically feasible, socially just, and environmentally friendly, it is necessary to control a large amount of key parameters. Large number of technical parameters conditions the

feasibility of the proposed alternative, such as moisture, nutritional value, generation rates, or geographical dispersion. Additional variables such as market demand, prices, or energy and water requirements have to be controlled to guarantee economic and environmental sustainability of the proposed procedure. Thus, further investigation is necessary in order to explore innovative strategies for safe and sustainable production of useful second generation feedstuff.

As could be drawn from the present chapter, principal FWs from processing industries, such as fish or meat by-products, can be rather easily managed and controlled. Additionally, there are also successful approaches focused on the valorization of minor FWs, such as coffee or specific bakery processing by-products. Thus, main challenge is now focused in the valorization of highly heterogeneous FWs from distribution. These streams have also a great and valuable potential that may need further regulation for the promotion and implementation of sustainable management schemes.

Finally, it can be also concluded that innovative management systems and technologies to guarantee safety of the second generation feedstuffs could encourage EU to promote the use of FW in animal feed.

Dictionary of Terms

- **Animal by-products not intended for human consumption (ABPs)** – The whole bodies or parts of animals, products of animal origin or other products obtained from animals that are not intended for human consumption, either for health reasons or due to a decision by the operator.
- **By-products** – Those unavoidable fractions generated through the different food production steps that are not part of the final product.
- **Feed-food competition** – The market competition of major feed ingredients with human food demands of developing countries, especially for those nongrain self-sufficient countries.
- **Food waste (FW)** – Fractions of food and inedible parts of food removed from the food supply chain to be recovered or disposed, including composted, crops ploughed in/not harvested, anaerobic digestion, bioenergy production, cogeneration, incineration, disposal to sewer, landfill, or discarded to sea.
- **Second generation feedstuff** – Are the feedstuffs that are produced through the valorization of FW or any source that do not compete with human feeding.
- **Former foodstuffs** – According to the EU Catalogue of Feed Materials (Regulation (EC) No 68/2013), former foodstuffs are foodstuffs, other than catering reflux, which were manufactured for human consumption in full compliance with the EU food law but which are no longer intended for human consumption, due to practical or logistical reasons, problems of manufacturing or packaging defects or other defects, and which do not present any health risks when used as feed.

Summary Points

- Developed countries are producing and consuming more food than needed and generating a significant amount of food wasted, which is considered as a big failure in the efficiency of the food value chain.
- FW has negative consequences in the economy, the food security, and the environment, contributing as well to climate change.
- In developing countries the biggest losses occur in the primary production due mainly to deficiencies in the production systems. In developed countries most losses occur at retail and consumer level due to inadequate planning or bad purchasing habits as well as to "high appearance quality standards"
- All actions taken against food wastage can be classified into three strategies: reduction, reuse, or reentering the food chain and recycle.
- The conversion of food unavoidable waste into by-products means that this is not more considered as a waste but as a resource, a raw material that may reenter the food chain and has to be considered and treated as such.
- In the hierarchy of valorization options for any FW or by-product, the reuse for human food or ingredient has to be prioritized but the use as raw material for feed is an option that interests many food sectors.
- As any raw material for animal feed, products from FW must fulfill different principles and are subjected to legal, technical, and economical requirements as well as being environmental and socially sustainable.
- The reuse of FW in animal feed can reduce the competition for the use of land for some crops for animal feed contributing to food security.
- The reuse of food waste in animal feed implies that it has to be often pretreated, stabilized, and preserved adequately to obtain feed ingredients and feed products.
- Food wastage is classified into different categories and, depending on the category, it has different application for animal feed.
- Further research is needed to overcome some important and frequent constraints that affect the technical and the economic feasibility of their reutilization: processing costs, logistic costs, availability of raw materials, and heterogeneity of the quality and composition of the wastes.
- Technological cooperation, knowledge, and involvement of different actors in the demonstration of new valorization schemes, from generators to processors and end-users are of crucial importance.
- Innovative management systems and technologies to guarantee safety of the second generation feedstuffs could encourage UE to promote the use of FW in animal feed.

Food Waste: Metrics, Effects, and Hunger in Hawai'i

18

Matthew K. Loke

Contents

Abstract

Food waste is often ignored in mainstream America. This is not wise as food waste inflicts various adverse effects on society. It is a major source of wasted money for consumers. It also contributes to the misallocation of resources from wasted production inputs, income losses, and higher disposal costs to businesses. It further imposes damaging effects on the environment and degradation in overall environmental quality. Finally, it decreases food security and lessens the likelihood of food donations to needy households.

While quantifying food waste is challenging, it is nevertheless measureable in three alternate ways in the food supply chain – (i) edible weight, (ii) economic

value, and (iii) calorie equivalent. At the aggregate level, an estimated 237 thousand metric tons (523 million pounds) of edible food, valued at about $1 billion (1.54% of GDP), is wasted annually in Hawai‘i. This figure represents 26% of available edible food that is suitable for human consumption.

Opportunities exist to reduce food waste and to channel rescued food to feed hungry residents. Although the prevalence of household food insecurity in Hawai‘i is relatively low by national standards, the demand for “charity” food is still exceedingly high as suggested by local food advocates. As a tourism mecca, the ability to feed visitors and stationed military personnel ably but economic disadvantaged local residents to a lesser extent may lead to a false perception of inequitable treatment and unnecessarily aggravate social resentment.

Community activities to harness food waste and to feed the hungry serves as a practical strategy to preserve social cohesion, in addition to preserving the environment and supporting the economy. More tangible results are attainable with productivity and efficiency gains in the process to locating, rescuing, and redistributing edible food. This chapter is specific to Hawai‘i. However, its content is relevant and applicable far beyond Hawai‘i’s shores.

Keywords

Food · Waste · Loss · Supply chain · Metric · Weight · Value · Calorie · Effect · Hunger · Security · Recovery · Environment · Hawai‘i

List of Abbreviations

ERS	Economic Research Service; an agency of the U.S. Department of Agriculture (USDA). It provides information and research on agriculture and economics.
FSC	Food Supply Chain; a system referencing the processes that describe how food from farms end up on our dining tables. The processes include production, processing, distribution, consumption, and disposal.
GDP	Gross Domestic Product; a key measure of the economy and is defined as the market value of all final goods and services produced in an economy during a given time period. (Usually, 1 year or every 3 months (quarterly) in the USA.)
n/a	Not available or not applicable.

Introduction

In operations management, people are fond of saying “You can’t manage what you can’t measure.” In supply chain management, it is no different, and waste in the food supply chain (FSC) cannot be addressed without knowing what to measure. At the same time, knowing what to measure is not the only requirement for reducing food waste. Jonathan Bloom, author of the inspiring book *American Wasteland: How America Throws Away Nearly Half of Its Food*, identifies clearly our conventional mindset on food waste in our culture of abundance. He has been

widely quoted as saying, "*Food waste isn't considered problematic because, for the most part, it isn't considered at all. It's easy to ignore because it's both common and customary.*" (Bloom 2011). Reflecting this sentiment, a recent study reported that 77% of Americans expressed guilt about food waste, 42% agreed that food waste is a major source of wasted money, yet 24% acknowledged they do not have enough time to worry about it (Qi and Roe 2016). This impression is reflected fully in present-day Hawai'i, a tourism dream destination offering the vacation of a lifetime – staged in the midst of stunning, natural beauty and charming cultures, with year-round, *sun-sand-surf* activities, and lounging in world-class facilities. Samuel Clemens (Mark Twain) once described the Hawaiian Islands as "the loveliest fleet of islands that lies anchored in any ocean." (Morgan et al. 2016)

Amongst such idyllic surroundings, the issues of food waste and hunger are easy to ignore in paradise Hawai'i. In reality, situated within an isolated, fragile, and ecologically sensitive environment, Hawai'i faces the same challenges relating to food waste as are experienced elsewhere, if not more. The food waste problems facing local residents are real, ranging from the misallocation of scarce resources and the coexistence of hunger and food insecurity to obvious degradation of the environment: decaying foods contribute to foul smells, larvae infestation, greenhouse gas emissions, and leaching landfills, which in turn may contaminate groundwater aquifers, streams, rivers, and coastal watersheds, and, ultimately, may influence climate change.

The Hawaii Foodbank estimates that one in five islanders is in need of public food assistance. This figure translates into 287,000 people, or 123,000 local households, which must rely on donated food to feed themselves or go hungry. Even more sobering, this statistic includes over 46,000 elders (kupuna) and an additional 48,000 at-risk youths (Hawaii Foodbank 2016a). Sliding down the age scale, Hawai'i's children (keiki) are equally challenged. A recent University of Hawai'i report estimates that 53% of public elementary-school students (ages 6–11) received free or reduced-price lunches during the regular school year (UHCOF 2015). It is commonly recognized that a lack of adequate food and nutrition may retard the physical growth, mental acuity, and overall health of these affected school children.

This chapter examines food-waste metrics in Hawai'i; assesses the economic, social, and environmental effects of this waste; reviews the coexistence of food waste and hunger; and explores potential policy responses. In light of Hawai'i's heavy dependence on imported food – estimated at 88.4% of edible food by weight (Loke and Leung 2013) – food waste literally originates at the harbor dock during unloading. Container shipment of food from the US West Coast to Hawai'i typically takes about 5 days. Some fresh produce originates from more distant places such as Mexico, Ecuador, Chile, Australia, and New Zealand via West Coast ports, thus increasing the duration of transportation in the FSC and resulting in a higher degree of food loss. Fresh fruits, fresh vegetables, and frozen seafood are most vulnerable, particularly with exposure to sunlight and unanticipated interruptions in cold-chain logistics.

Definition and Data Sources

In the absence of a universal definition for food waste and/or food loss, many different forms exist in the published literature. Some authors on the subject have used the terms "food waste," "food loss," or "food loss and waste" interchangeably without any differentiation (Timmermans et al. 2014; Dou et al. 2016). An early definition refers to food loss as any change in the availability, edibility, wholesomeness, or quality of the food that prevents it from being consumed by people (FAO 1981). An alternate definition by Parfitt et al. (2010) asserts that food waste occurs at different points in the FSC and is clearly defined at the retail and consumer stages, where agricultural production outputs are unequivocally food for human consumption.

In Hawai'i, recent work efforts have followed the definition by Gustavsson et al. (2011) that food waste represents the edible portion of food, post-harvest, that is available for human consumption but is not consumed for any reason. This approach was also adopted by the ERS (Buzby et al. 2014) and facilitates the meaningful comparison of measures between the USA as a whole and Hawai'i. The most recent study also analyzed food waste in seven different food groups, including (i) dairy (fresh milk), (ii) grain (rice), (iii) seafood protein, (iv) other protein, (v) fruits (fresh), (vi) vegetables (fresh), and (vii) others (Loke and Leung 2015).

Food Waste Metrics

Food waste in the FSC can be quantified in three alternate ways – (i) edible weight, (ii) economic value, and (iii) calorie equivalent. An estimated 237 thousand metric tons (523 million pounds) of edible food, valued at about $1 billion (1.54% of GDP), is wasted annually in Hawai'i. On a per capita basis, this is equivalent to 161.5 kg (356 pounds) or $698.36 per person per year. In the supply chain, a fairly significant proportion of this food waste is generated at the consumer level (16.5%), followed by the wholesale and retail level (8.3%), and a relatively small proportion at the postharvest (farm) level (1.1%). Overall, 26% of available edible food that is suitable for human consumption is wasted in the local supply chain. The food categories that comprised the highest quantity of waste are fresh fruits (47.5%), grain rice (41.4%), seafood (39.8%), and fresh vegetables (36%). These food measures and their comparable US metrics are shown in Fig. 1.

The assessment by measure and by food group in Hawai'i yielded definitive trends. The three fresh food groups (vegetables, fruits, and dairy milk) shared a similar distribution of food waste by weight, value, and calorie equivalent in decreasing order (see Fig. 2). These lower value-to-weight and lower calorie-to-weight ratios reflected the attributes of fresh produce. In contrast, "others" displayed food waste by weight, value, and calorie equivalent in an increasing order. The *oils and fats* and *sugar and sweeteners* components in this food group represent higher added value as well as calories. The two protein groups (seafood and other) displayed higher food-waste value over weight and calories, illustrating the more expensive nature of protein products. Finally, the lower proportion of value-to-weight and

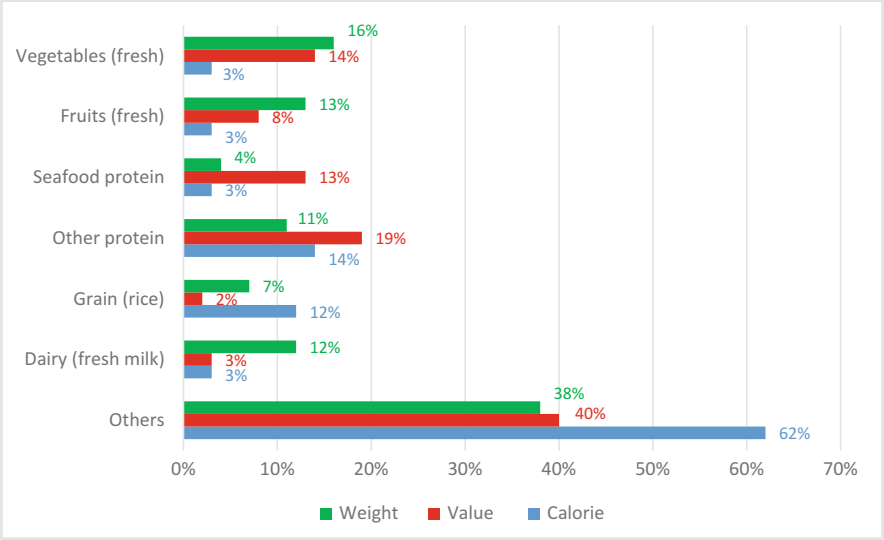

Fig. 2 Percentage of food waste by food group in Hawai'i (Source: Loke and Leung 2015)

value-to-calorie in grain rice revealed an inexpensive but high-calorie-equivalent food item, something that is highly desirable in times of emergency (natural or manmade).

Effects of Food Waste

Food waste is often viewed as an issue with multidimensional adverse effects on society and is receiving heightened attention in local media. Examples of recent coverage include Loomis (2016), Smallwood (2016), Blair (2016), and various local television networks (i.e., KITV, KGMB, KHNL). Beyond wasted money for consumers, it also contributes to the misallocation of resources, from wasted raw materials in food production to the loss of income streams and higher disposal costs paid by businesses in the FSC. It further imposes damaging effects on the environment, ranging from greenhouse gas emissions, pesticide leaching, and soil erosion to increasing disposal volumes in limited landfill areas, spillage in congested landfills, potential groundwater contamination, air pollution from fossil fuels used in waste-management equipment, and degradation in overall environmental quality.

Additionally, food waste strikes at deep social concerns about feeding the hungry. Discarded food in the supply chain decreases food security in society and reduces the likelihood of food donations to needy households. This effect weakens the social safety net and is morally wrong from an ethical standpoint. Figure 3 summarizes the positive effects of reducing food waste from a holistic viewpoint. The effects are divided into three distinct subsets – economics, environment, and social. The relative influences of these individual effects are not known, and their rankings are unlikely to be determined anytime soon.

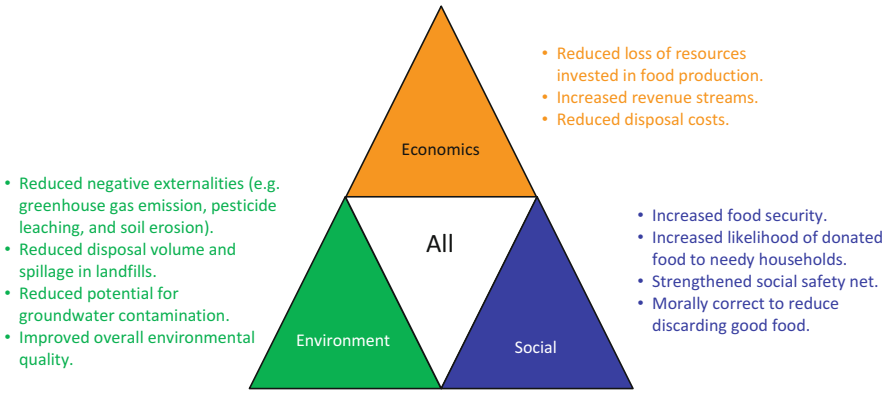

Fig. 3 Multidimensional effects of reducing food waste

Food Waste and Hunger

Feeding a growing population, particularly those in need or hungry, is an important function of society. This difficult challenge can be addressed, among other ways, by increasing the supply of food (e.g., enhancing crop yields through technology and/or productivity gains), decreasing the consumption demand of food (e.g., consuming less food per capita), or increasing efficiency in consumption (decreasing food waste). Given the current level of antagonism toward environmental degradation and biotechnology adoption in food production, and the difficulties in curbing food consumption to a sufficiency level, this leaves food-waste reduction as a practical strategy for combating hunger and food insecurity in society.

In Hawai'i, it is a common misconception to associate food availability with the concept of food self-sufficiency rather than food security. Food self-sufficiency is best described as "proportion of locally sourced production to satisfy overall food consumption." In contrast, food security is defined as "a situation that exists when all people, at all times, have physical, social and economic access to sufficient, safe and nutritious food that meets their dietary needs and food preferences for an active and healthy life" (FAO 2003). In Hawai'i, Kent (2016) articulated a definition of food security that is tailored specifically to local conditions (see Table 1).

While the "waste less to feed more" movement may address all three types of food security enumerated in Table 1, "food recovery to feed" efforts are focused narrowly at type II, so as to target the connection between food waste and hunger. Hawai'i has been fortunate to benefit from food recovery activities organized by volunteers. A University of Hawai'i at Mānoa (UHM) chapter of the Food Recovery Network (FRN) was incorporated in 2016 to fight food waste and feed people in need. A group of dietetics students led the chapter launch, in partnership with the UHM campus dining services contractor, Sodexo. They began by collecting unutilized food from campus cafeterias on a weekly basis and delivering it to the Institute of Human Services (IHS), which then distributes the food to homeless shelters in Honolulu.

Table 1 Types of food security and related characteristics in Hawai‘i

Type	Characteristic
I	Ample supplies of edible food for the general population now and into the future.
II	Attention to the special needs of low-income people, many of whom depend on federal government programs and food pantries that offer free or very low-priced food.
III	Plan for various types of public emergencies that can arise, such as shipping interruptions, crop failures, terrorism, or other force majeure events.

Source: Kent (2016)

Since then, they have increased their collection schedule to multiple times a week and distributed over half a metric ton of edible food.

Beyond campus, the nonprofit organization Aloha Harvest has been recovering quality food from participating donors (caterers, restaurants, hotels, food distributors, and others) and delivering it free of charge to other nonprofit organizations responsible for feeding the hungry in Hawai‘i. Since its inception in 1999, it has collected and distributed almost 8,165 metric tons (18 million pounds) of quality perishable and nonperishable food and beverages to feed the hungry. In 2016, it recovered over 861 metric tons (1.9 million pounds) of edible food (Aloha Harvest 2016).

This dynamic effort to reduce food waste has captured the attention of national political leaders. Hawai‘i’s Senator Brian Schatz (D) has joined his counterparts Richard Blumenthal (D-Conn.), Ron Wyden (D-Ore.), Jeff Merkley (D-Ore.), and Cory Booker (D-N.J.) in sponsoring comprehensive legislation in Congress to reduce food waste in stores and restaurants, at schools and institutions, on farms, and in American homes (Blair 2016). The legislation proposed seeks to clarify food expiration labels, increase the use of less-than-perfect-looking fruits and vegetables, and fund composting initiatives.

With an improved economy, the hunger situation in Hawai‘i appears better than before. Recent statistics published by the federal government suggest the prevalence of household food insecurity in Hawai‘i averaged 9.7% for the period 2013–2015 (see Table 2). This rate compares favorably to the 14% recorded in the immediately preceding 3-year period, 2010–2012, but it is somewhat higher than the 7.8% prevalence rate reported in 2003–2005. Between the periods 2003–2005 to 2013–2015, the rate of change in prevalence rate was 1.9%. These food-insecurity rates in Hawai‘i mirror the national trend over time, albeit at a lower rate.

Summary and Opportunities

It is important to remember that ending food waste completely is akin to chasing a rainbow, an optical phenomenon that fades upon approach and is, therefore, unattainable. Not all food waste is avoidable. Some portions of food items are not edible or are not amenable to consumer preferences. Common examples of such discarded

Table 2 Change in prevalence rate of food insecurity and very low food security, Hawai'i and USA, average, various years

Measure	Hawai'i (%)	USA (%)

portions include apple cores, bread crusts, egg yolks, meat fat, and stale bread, etc. At the wholesale and retail levels, businesses often choose to engage in surplus stocking to ensure that upswings in their customers' demand are met. Such savvy business practices build trust, loyalty, and good faith in the customer base but generate a higher level of food waste.

Additionally, along the FSC, higher food waste as one stage (say consumer) often translates into higher future sales at the preceding stage (retail) and other upstream stages (wholesale, processing, etc.). Such behavior contributes to more revenues (and profits) in the entire FSC, and consequently discourages any honest attempt at food-waste reduction. Finally, food-waste reduction is not a costless activity. Transaction, transportation, time, and other opportunity costs are often incurred by individual players in the FSC.

However, not all is lost in the fight against hunger. The household prevalence rate for very low food security in Hawai'i, averaging 3%, was markedly lower than the comparable national average of 5.4% in the period 2013–2015 (see Table 3). Likewise, the household food insecurity rate (combining rates of low and very low food security), averaging 9.7%, was also lower than the national average of 13.7%.

North Dakota was the only state with a lower prevalence rate at 8.5% but it also has a population about half of Hawai‘i’s. Nevertheless, the 9.7% food insecurity rate still represents 44,939 households in Hawai‘i (FRAC 2016). When this measure is compared to the Hawaii Foodbank’s estimate of one in five islanders (20%) in need of public food assistance, a less optimistic outlook of society’s unmet demand emerges beyond the defined food-insecurity population.

The discrepancy between the two metrics is substantial but explainable. The USDA survey-derived metric likely has a downward bias, arising from the reluctance of some residents to reveal their true food insecurity situation. Concerns over the federal survey research method have also been expressed in academic circles (Wilde 2013). Likewise, the Foodbank’s estimate may include residents who are normally able to provide for themselves but occasionally supplement with “charity” food when saddled with unanticipated personal expenses relating to healthcare, auto repairs, theft, legal fees, etc. This situation is not peculiar to normal residents living in high-cost locations.

The two metrics may also be misleading and lead to the false perception that a dream destination like Hawai‘i can competently feed its touring visitors and ably feed stationed military personnel and dependents but is lagging behind in feeding its own hungry residents. In actuality, the vast majority of visitors to Hawai‘i arrive with highly disposable budgets and members of the military establishment purchase most of their food from commissaries subsidized heavily by the US Department of Defense. Low-income residents are typically supported by various federally funded nutrition programs, administered by the state. Such programs include the Hawai‘i Food Stamp Program (SNAP), the Special Supplemental Nutrition Program for Women, Infants and Children (WIC), the School Lunch Program (NSLP), and the Senior Farmers Market Nutrition Program (SFMNP). These federal programs are complemented by a network of local charitable organizations to feed the needy. The local nonprofit organizations perform remarkable work in minimizing food waste and distributing food effectively to needy residents. For example, the Hawaii Foodbank collected about 6,214 metric tons (13.7 million pounds) of food and distributed 5,806 metric tons (12.8 million pounds) in fiscal 2016 (Hawaii Foodbank 2016b). The food-waste amount during this period is less than 6.6%, with most losses coming from rusted or leaky canned food and wilted fresh produce.

The amount of food collected is not trivial by any means. It is now known that the amount of food collected by the foodbank represents a small proportion, about 2.6% of the estimated annual food waste by weight in Hawai‘i. If all 44,939 households (or 129,874 residents); based on the 2010 Census Report of 2.89 people per average household in Hawai‘i, who are defined as food insecure are fed fully for an entire year, it would represent about 28% of the estimated food wasted in Hawai‘i. This estimate assumes food is transferable and that local residents share the same amount of food calories consumed by the average American of 2,568 kcal/capita/day (ERS 2014). Clearly, this estimate shows the potential for food recovery to feed more people exists.

Low socioeconomic status and income remain key predictors to food insecurity. The situation in Hawai‘i is exacerbated by a myriad of different factors (e.g., geographic isolation, limited land mass, desirable climate, limited housing stock, heavy regulatory framework, etc.), which have transformed the state into an elite,

high cost-of-living environment. The high cost of housing, in particular, often forces households to choose between paying for rent, food, utilities, transportation, and medicine. A recent news article from the Associated Press quoted Hawai'i as having the second-highest consumer debt in the USA, and with home mortgages accounting for 77% of the total (Bussewitz 2017). For the majority of residents, holding a higher-paying job with at least a living wage rate is all but necessary to fend off food insecurity. The phrase "living paycheck-to-paycheck" is no laughing matter in Hawai'i. Another recent report revealed that residents in Hawai'i are more likely to be living paycheck-to-paycheck as compared to residents in any other state (HNN 2016). The *GoBankingRates'* methodology is based on the percentage of a paycheck that is leftover after paying for basic necessities (housing, food, utilities, transportation, and health). California and New York ranked behind Hawai'i. Additionally, chronic under-employment is often cited as another key factor leading to food insecurity for local residents. While Hawaii's official unemployment rate was relatively low at 3% in late 2016, it is widely acknowledged that many local residents have two or three jobs. Finally, a high immigration rate of citizens from the Compact of Free Association (COFA) island nations continues to test Hawai'i's social safety net.

When additional public resources are not anticipated in the offing, community-based efforts to combat food insecurity may have to continue to rely on food-recovery programs, at least in the short-run. This simple strategy to rescue decent, edible food destined for landfills and channeling it to end hunger is a "win-win" situation for the people, environment, and economy.

Conclusions

While quantifying food waste is a daunting task, it is nevertheless measureable in three alternate ways in the FSC – (i) edible weight, (ii) economic value, and (iii) calorie equivalent. At the aggregate level, an estimated 237 thousand metric tons (523 million pounds) of edible food, valued at about $1 billion (1.54% of GDP), is wasted annually in Hawai'i. This figure represents 26% of available edible food that is suitable for human consumption.

Food waste inflicts various adverse effects on society. It is a major source of wasted money for consumers and contributes to the misallocation of resources from wasted production inputs to income losses and higher disposal costs to businesses. It further imposes damaging effects to the environment, ranging from greenhouse gas emissions, soil erosion to congested landfills, potential groundwater contamination, and degradation in overall environmental quality. Finally, it decreases food security and lessens the likelihood of food donations to needy households.

Despite the obvious challenges, there are real opportunities to reduce food waste and to channel rescued food to feed hungry residents. Although the prevalence of household food insecurity in Hawai'i is relatively low by national standards, the demand for "charity" food is still exceedingly high, as suggested by local food advocates. The ability to feed visitors and stationed military personnel ably but economically disadvantaged local residents to a lesser extent may lead to a false

perception of inequitable treatment and unnecessarily aggravate social resentment. Given Hawai‘i’s highly marketed position as a tourism dream destination, social expectations are held even higher. It is simply prudent business practice for a premier destination to competently manage its hunger issue.

With that in mind, community activities to harness food waste and to feed the hungry serve as a practical strategy to preserve social cohesion, in addition to preserving the environment and supporting the economy. More tangible results are attainable with productivity and efficiency gains in the process of locating, rescuing, and redistributing edible food. Ideally, finding a solution to Hawai‘i’s hunger problem may provide a working model for people wrestling with the same issue elsewhere in the world.

This chapter is specific to Hawai‘i. However, its content is relevant and applicable far beyond Hawai‘i’s shores. First, food waste is measurable, and knowing how and where it occurs is crucial to lessening it. Second, the adverse effects of food waste are near universal, with social, environmental, and economic impacts. Third, the coexistence of food waste and hunger is real anywhere, and opportunities to recover food to feed hunger exist. Fourth, unique strategies are applicable in specific locations to implement the “waste less to feed more” food paradigm.

Policies and Protocols

Community Policies to Strengthen Food Recovery Programs

Feeding a growing population, particularly those in need or hungry, is an important function of society. Community-based efforts to combat food insecurity can rely on food recovery programs. In moving to strengthen food recovery programs, some community policies worthy of consideration include the following:

- Provide more incentives for donation to anti-hunger entities (e.g., food banks, food redistribution outlets, and feeding centers) and recycling of produce (including composting) to wholesalers, retailers, caterers, and restaurants.
- Invest in “real-time” technologies (apps) to match food donors and recipients, manage food safety protocols, organize volunteers to collect and to deliver, rescued food between locations, and to operationalize relevant metrics.
- Increase capacity of food aggregation/distribution centers by investing in cold-chain logistics (including delivery processes), increase mechanization, and adopt conveyor belt technology to improve labor productivity of employees and volunteers.
- Dedicate resources (public and/or private) to support outreach and consumer education on reducing food waste, increasing food recovery, reuse, composting, and other tangible environmental benefits (this makes rational sense in a joint social, environment, and economic paradigm).

- Develop best practices to coordinate, motivate, and recognize the contributions of volunteers in this important community-based "food recovery to feed" effort and the broader "waste less to feed more" initiative.
- Research, prepare, and offer credible legislative proposals to raise the food tax credit limit so as to provide more relief to low-income households facing real threats of food insecurity, and therefore decelerating the growth rate of demand for "charity" food.

Essentially, various food industry associations could partner with different food recovery agencies, faith-based institutions, and media outlets to recruit, educate, and retain their members' participation in this community effort. Additionally, pro-bono work from software companies and/or academic institutions could help contribute to "real time" technologies (apps) in the food collection-delivery chain. Additional apps could support the general educational process, keep core volunteers informed and motivated, and, possibly, how to navigate the legislative process.

Dictionary of Terms

- **Cold-chain logistics** – A temperature-controlled system that provides uninterrupted transportation, storage, and distribution activities to help ensure food safety and extend shelf life of temperature-sensitive products such as fresh produce.
- **Food insecurity** – Food insecurity reports of reduced quality, variety, or desirability of diet. Little or no indication of reduced food intake (ERS 2017).
- **Food loss** – Any change in the availability, edibility, wholesomeness, or quality of the food that prevents it from being consumed by people (FAO 1981).
- **Food waste metric** – Food waste in the FSC can be quantified in three alternate ways – (i) edible weight, (ii) economic value, and (iii) calorie equivalent.
- **Food recovery** – Actions taken to harness quality food that may be discarded and channeling it to community centers that feed hungry people.
- **Food security** – A situation that exists when all people, at all times, have physical, social, and economic access to sufficient, safe, and nutritious food that meets their dietary needs and food preferences for an active and healthy life (FAO 2003).
- **Food self-sufficiency** – Food self-sufficiency is often measured by the self-sufficiency ratio and defined by FAO as the proportion of domestic production in relation to domestic food utilization, excluding stock changes.
- **Food waste (in FSC)** – Refers to food waste occurring at different points in the FSC and is clearly defined at the retail and consumer stages, where agricultural production outputs are unequivocally food for human consumption (Parfitt et al. 2010).

- **Opportunity cost** – An economics concept relating to the value of the next-best alternative foregone when a specific activity is chosen. It arises in any decision involving a tradeoff between two or more activities.
- **Real-time** – Refers to the actual time during which activities are taking place.
- **Very low food security** – Reports of multiple indications of disrupted eating patterns and reduced food intake (ERS 2017).

Summary Points

- Food waste in the food supply chain (FSC) cannot be addressed without knowing what to measure and is often ignored in our culture of abundance.
- Within an idyllic environment, the issues of food waste and hunger may not garner much attention in paradise Hawai‘i but exist with an estimated one in five islanders (20%) requiring public food assistance.
- Lacking a universal definition for food waste and/or food loss, many different forms exist in the existing literature and the terms “food waste,” “food loss,” or “food loss and waste” are often used interchangeably without any differentiation.
- Food waste in the FSC can be quantified in three alternate ways – (i) edible weight, (ii) economic value, and (iii) calorie equivalent.
- An estimated 237 thousand metric tons (523 million pounds) of edible food, valued at about $1 billion (1.54% of GDP), is wasted annually in Hawai‘i. On a per capita basis, this is equivalent to 161.5 kg (356 pounds) or $698.36 per person per year.
- Food waste inflicts various adverse effects on society. It is a major source of wasted money for consumers. It also contributes to the misallocation of resources from wasted production inputs, income losses, and higher disposal costs to businesses. It further imposes damaging effects on the environment and degrades overall environmental quality.
- In Hawai‘i, it is a common misconception to associate food availability with the concept of food self-sufficiency rather than food security. It has benefited from food recovery activities organized by volunteers to fight food waste and to feed the hungry.
- Ending food waste completely is unattainable as not all food waste is avoidable. Some portions of food items are not edible or are not amenable to consumer preferences.
- Businesses often choose to engage in surplus stocking to ensure that upswings in their customers’ demand are met, at the expense of higher food waste. Additionally, food-waste reduction is not costless. Transaction, transportation, time, and other opportunity costs are often incurred by individual players in the FSC.
- While the prevalence of household food insecurity in Hawai‘i is relatively low by national standards, the demand for “charity” food is still exceedingly high as suggested by local food advocates.

- Low income residents are typically supported by various federally funded nutrition programs, administered by the state. These programs are complemented by a network of local charitable organizations to feed the needy.
- Low socioeconomic status and income remain key predictors to food insecurity. The high cost of housing, in particular, often forces local households to choose between paying for rent, food, utilities, transportation, and medicine.
- A recent report revealed that residents in Hawai'i are more likely to be living paycheck-to-paycheck than residents in any other state.
- Community-based efforts to combat food insecurity may have to continue to rely on food recovery programs, at least in the short-run. More tangible results are attainable with productivity and efficiency gains in the process of locating, rescuing, and redistributing edible food.

Contents

Abstract

Food wastage is receiving much research and policy attention worldwide, especially during the past decade, due to the environmental, economic, and social implications that it is related to. Prevention of food wastage is a key factor in the battle against starvation on the global scale. If food wastage is halved globally by the year 2025, almost 1 billion more people could be fed, a number that corresponds to the expected global population growth between the years 2010 and 2025. Food wastage is generated in every sector of the food supply chain, namely, agriculture, processing, wholesales-retails, households, and food services. The contribution of each sector differs substantially due to a range of reasons

dependent on the socioeconomic conditions of each country, the culture of the people, the food supply chain, the available food provisioning infrastructure, and policy. In the more developed part of the world, there is growing evidence that the contribution of the households to the food waste problem is particularly significant as the result of multiple behaviors within a household that increase the likelihood or amount of food being wasted. The aim of this chapter is to review the findings reported in peer-reviewed literature published during the past decade. Food wastage is presented in terms of: its amounts generated; its economic, social, and environmental impacts; its dependence on certain sociodemographic and behavioral factors; and finally, its placement in the waste hierarchy context. Food wastage prevention throughout the food supply chain should be among the key pillars of creating a sustainable food system.

Introduction

Food wastage is receiving much research and policy attention worldwide, especially during the past decade, due to the environmental, economic, and social implications that it is related to. In the early 2010s, the Food and Agricultural Organization of the United Nations estimated that approximately one third of food produced for human consumption is either lost or wasted through the food supply chain, from agricultural production and postharvest handling and storage to processing, transportation, distribution, and consumption (Gustavsson et al. 2011). Food wastage puts a heavy burden on the global fight against starvation and famine, and measures have to be taken in order to prevent its generation.

Fig. 1 Breakdown of food wastage classification based on the life cycle stage of the food supply chain

Review of the relevant literature reveals that there is a multitude of terms describing food wastage. Several authors (Gustavsson et al. 2011; Koivupuro et al. 2012; Parfitt et al. 2010) indicate that the food materials discarded during postharvest or processing are often referred to as "food losses." Koivupuro et al. (2012) mention that food wastes are the "food products discarded in retail or consumption." In this chapter (see Fig. 1), we differentiate food wastage between "food losses" and "food waste" in line with the recommendations by Gustavsson et al. (2011) and Parfitt et al. (2010).

Food wastage is generated in every sector of the food supply chain (FSC), namely, agriculture, processing, wholesales-retails, households, and food services. In terms of the contribution of each sector in the generation of food waste, according to a study for food waste in the EU-27, households produce 42% of the total amount of food waste, the manufacturing sector 39%, and the food service – catering sector 14%, while the retail-wholesale sector produces approximately 5% (European Commission 2010).

From a global point of view, the contribution of each FSC sector to food wastage differs substantially due to a range of reasons dependent on the socioeconomic conditions of each country (European Commission 2010; FAO 2013). Moreover, the amount of food that people from different countries waste depends also on their culture, since different parts of the foods are edible in different parts of the world, while other parts are thrown away (Thyberg and Tonjes 2016). Besides cultural and societal reasons, food wastage in each part of the globe also depends on the food supply chain, the infrastructure, and the policy (Neff et al. 2015). However, despite the aforementioned specificities, generalizations are possible based on the degree of industrialization and GDP of each geographical region: Parfitt et al. (2010) stated that in developing countries food losses are higher at the immediate postharvest stages, while in industrialized and developed economies they are higher for perishable foods after they have been prepared for market or, in fact, sold to the consumer; "*for affluent economies, post-consumer food waste accounts for the greatest overall losses*." A recent analysis of the FSC sectors by geographical region showed that wastage occurring at consumption level is much more variable, with wastage in middle- and high-income regions, but much lower in low-income regions (FAO 2013).

The chapter is based on the findings reported by the authors of peer-reviewed literature, published during the past decade. The chapter is compiled as follows: after the introduction, the reported figures of the food wastage generation in different parts of the world are presented. Then the environmental, economical, and social impacts of food wastage are presented, in their respective sections. In the sections that follow, the effects of consumer behavior and sociodemographic characteristics are described. Finally, the chapter ends with the placement of food wastage management options in the EU waste hierarchy.

The Problem in Numbers: How Much Food is Wasted?

Moving on to the actual figures reported for food waste by notable international organizations, FAO of the United Nations estimated that the per capita food waste generation in Europe and North America is 95–115 kg/year (Gustavsson et al. 2011). The European Commission reports an even higher value of 179 kg/person/year as the average total amount of food waste generated in the EU-27 (European Commission 2010). On the global scale and a calorific basis, Kummu et al. (2012) report that around one quarter of the global food crops supply are lost or wasted, a number that corresponds to 1.46 10^{15} kcal/y.

However, specific data referring to countries, even the developed ones, are very scarce and not easily comparable, as there is a wide diversion in definitions and assessment methodologies (Lebersorger and Schneider 2011; Schneider 2013a). For instance, in Europe, the average amount of avoidable food waste reported for Finland was 63 kg/household or 23 kg/person (Koivupuro et al. 2012). Back in 2009, WRAP estimated that consumers in the UK throw away 31% of the food they purchase for consumption (WRAP 2009). Again in the UK, Quested et al. (2013) reported that 7.2 MMT of food and drink waste were generated in households in 2010, of which 4.4 MMT were avoidable. This avoidable waste corresponded to 160 kg per household and was equivalent to 12% of the food and drink entering the home (Quested et al. 2013). Beretta et al. (2013) reported that roughly one third of the edible calories produced for Swiss consumption are lost over the whole food supply chain. Finally, food waste generation in Greece has been quantified, by means of a diary, to 98.9 kg/person annually, of which 29.8 kg/person is avoidable (Abeliotis et al. 2015, 2016).

In the USA, Venkat (2011) reported that the total avoidable food waste at the distribution, retail, and consumer levels amounts to over 55 MMT/year, representing nearly 29% of the annual production by weight, while Thyberg and Tonjes (2016) stated that Americans dispose over 0.6 pounds (approx. 272 g) of food waste per person per day, without any distinction made between avoidable and non-avoidable. Again from the USA, Neff et al. (2015) reported that 31–40% of the postharvest food supply goes to waste; this lost nutritional value represents an estimated 1,249 calories per capita per day.

In South Africa, Nahman et al. (2012) reported that the annual food waste generated is 1.44 MMT, of which 1.16 MMT (approx. 81%) being edible, i.e., avoidable.

The Environmental Impacts of Food Waste

There is strong evidence that the most environmentally damaging form of human consumption is eating (Ehrlich 2011). Figure 2 outlines the main environmental impacts generated at each stage in the FSC life cycle. In a life cycle perspective, energy and/or material resources are added to the FSC in each one of its stages. Therefore, food wastage generated in the latter stages of the FSC (e.g. consumption) generates more environmental impacts compared to food wastage in the earlier stages (e.g. agricultural production). Overall, the environmental impacts of food wastage do not only depend on the quantity but also on the type of food, where in the FSC food is lost or wasted, and how it is recycled or disposed of (Beretta et al. 2013).

Regarding the assessment of the environmental impacts of food wastage, most of the published reports focus on GHG. Food wastage contributes to GHG emissions in two ways: (i) from the embedded emissions associated with its production, processing, transport, and retailing; and (ii) via the decomposition of the food waste after disposal in landfills (Venkat 2011). Overall, GHG emissions associated with

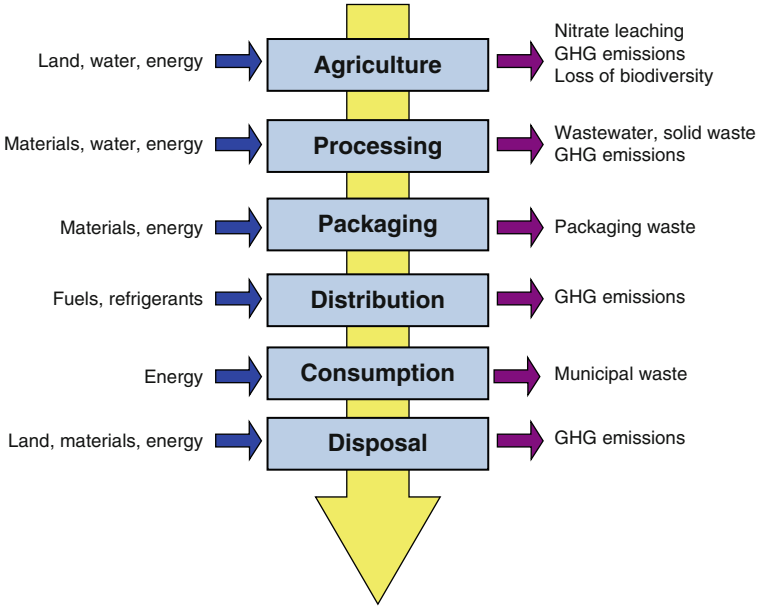

Fig. 2 Outline of the environmental impacts during the life cycle of food

food that is wasted are considered as "wasted emissions" or "emissions in vain" (FAO 2013). In terms of the GHG values reported, Venkat (2011) estimated that the production, processing, packaging, distribution, retail, and disposal of the avoidable fraction of food waste in the USA resulted in GHG emissions of at least 113 MMT CO_2e per year, which corresponded to 2% of the US national emissions. The calculated emissions were subject to an uncertainty of ±20% due to cooking assumptions. In the UK, Quested et al. (2013) reported that the 160 kg per household of avoided food waste for 2010 was estimated to contribute 17 MMT of CO_2e in GHG emissions annually and account for the total water footprint of the UK. Moreover, food waste makes up 30% of the general waste stream from UK households (Quested et al. 2013). In Greece, Abeliotis et al. (2015) estimated that a total of 5,672.5 Gg CO_2 eq. of GHG emissions per year are associated with food wasted. This figure corresponds to approx. 5.3% of the total GHG emissions (with LULUCF) in Greece for 2012.

The Economic Impacts of Food Waste

Food waste prevention is associated with economic impacts, such as business and consumer savings (Nahman et al. 2012). For example, Venkat (2011) estimated, with an uncertainty up to ±15%, that food waste costs to US businesses and consumers $190 billion per year. Consumer waste alone amounts to $124 billion, or nearly 63% of the total value, which works to about $1600 per year for a family of four. Again in the USA, Neff et al. (2015) reported that food lost from harvest to consumer in 2010 costed $161.6 billion; losses at the consumer level averaged $371 per capita or 9.2% of average food spending. In a similar report, Nahman et al. (2012) estimated that the costs of food wasted by households in South Africa are in the range of 21.2 billion rands annually. This equated to approximately 0.80% of South Africa's GDP or 9.63% of the value of retail sales by food, beverage, and tobacco in South Africa.

The Social Impacts of Food Waste

Besides the association of food waste generation with significant environmental and economic impacts, it is also related to social impacts, such as the global food and water security (Koivupuro et al. 2012; Kummu et al. 2012). FAO estimated that almost 11% of the global population is food insecure (Thyberg and Tonjes 2016). Food waste is also associated with the expanding dimensions of malnutrition, in both undernourishment (Nahman et al. 2012) and obesity terms (Parfitt et al. 2010). Therefore, food waste has a strong ethical dimension, since people in many parts of the world face the threat of food insecurity. Kummu et al. (2012) estimated that if the target of the European Parliament to halve food losses and waste by the year 2025 in the EU (see "Policies and Protocols" section) were to be applied globally, almost 1 billion more people could be fed. This number of people is equal to the

expected global population growth between 2010 and the year 2025, based on the medium variant of the UN estimation (Kummu et al. 2012).

From a sociological point of view, Evans (2012) states that food waste is an outcome of food-related behavior. This means that people who provide food for their households are more interested in the freshness and the nutritional quality of the food items (Stefan et al. 2013; Evans 2012). Therefore, in some instances, food waste generation at households is taking place because of the need of people to provide the best for their loved ones. In this case, the guilt about wasting food maybe smoothed away by collective and individual pride in reiterating norms of food safety and freshness (Waitt and Phillips 2016). As a result, food that does not (or is not perceived to) meet the aforementioned freshness criteria, including leftovers, ends up as waste.

The Effect of Consumer Behavior in the Generation of Food Waste Generation by Households

There is growing evidence that the contribution of the households to the food waste problem is particularly significant (Sharp et al. 2010; European Commission 2010). For instance, in EU-27, households are responsible for 42% of the total amount of food waste generated (European Commission 2010). Therefore, food waste generation at the consumption level is becoming an increasingly significant global issue, and household food waste mitigation is becoming a priority.

More specifically, the generation of food waste is the result of multiple behaviors within a household that increase the likelihood or amount of food being wasted (Visschers et al. 2016). These behaviors relate to many different aspects of the food's journey into and through the home: planning, shopping, storage, preparation, serving, and consumption of food (Quested et al. 2013).

Figure 3 presents the flow diagram of food reaching home. Solid lines denote the normal flow of food, while dotted lines denote food diverted to waste.

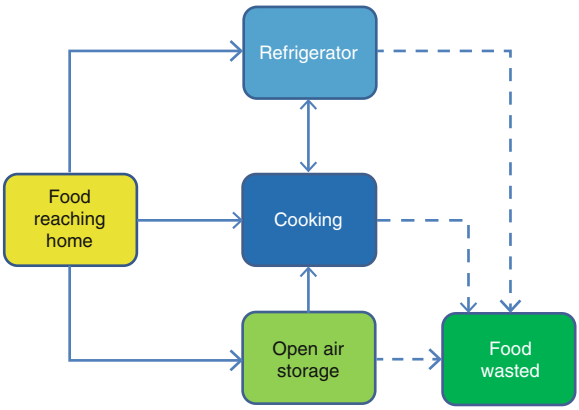

Fig. 3 Outline of possible routes of food arriving at households

More specifically, food reaching home can go directly to cooking, or to the refrigerator, or to open air storage. Food from the refrigerator can be directed to cooking; vice versa, cooked food can be directed to the refrigerator for preservation or deep freezing. Similarly, food from open air storage can be directed for cooking.

Cooked food can take the road to waste if it is served in large quantities or from other situational factors, such as the presence of young kids in the household. Food stored in open air can take the road to waste if it is rotten due to poor management. Food from the refrigerator can end up in the waste bin if it is refrigerated for a very long time, or if it past its "use before" date, or if it past its "best use before" date.

Note that both cooking and refrigeration add energy to food. Since energy results in GHGs emissions to the atmosphere and has financial cost for the household, food wasted after refrigeration and/or cooking is environmentally and economically worse compared to food wasted right after entering home.

More specifically, there is a large number of behaviors that can have a positive impact on food waste generation and, consequently, to the efforts toward food waste prevention (WRAP 2009). Such behaviors include meal planning, cupboard checking and list making before going for food shopping, proper storage of food items, use of food leftovers, cooking and serving the right amount of food, and careful use of expiration date labels (WRAP 2009; Abeliotis et al. 2014, 2016; Koivupuro et al. 2012; Stefan et al. 2013; Quested et al. 2013).

Besides human behavior, studies also indicate that technological factors of food provision such as packaging also affect the generation of food waste (Langley et al. 2011; Evans 2012; Williams et al. 2012). Effective packaging can reduce food losses, both directly and indirectly (Williams et al. 2012). Provision of the correct packaging size (e.g., for families) to the consumer has a direct negative effect on the generation of food waste. Moreover, packaging provides information to consumers regarding the "expiration date" and the "best before date." Correct comprehension of these two dates by the consumers has also an indirect negative effect on the generation of food waste by the consumers. On the other hand, packaging has a direct negative effect on food waste generation when it is used for unnecessary "multipack" promotions.

The Effect of Sociodemographic Characteristics on Food Waste Generation

At the household level, food waste generation is strongly associated with certain socioeconomic parameters (age, income, marital status). Koivupuro et al. (2012) showed that in Finnish households the amount of food waste is correlated with the size of the household, the gender of the person who is responsible for grocery shopping, the frequency of buying discounted products, and the view of the respondent to food reduction as well as to purchasing food packet sizes. Again in Scandinavia, Stancu et al. (2016) found that in Denmark lower amounts of food waste were associated with older consumers, fewer members in the household, and lower income. However, note that the amount of food waste generated per capita decreases

with increasing household size (Quested et al. 2013). People in four-person households generated approximately half the amount of food waste per capita compared to single-occupancy homes (WRAP 2009). Also, regarding the age of household occupants, Quested et al. (2013) reported that people over 65 years old in the UK generate less food waste than the rest of the population.

Regarding the effect of household income, Thyberg and Tonjes (2016) report that as incomes rise, people may be wasting food because the associated monetary losses are not a considerable fraction of their income. The concept of saving money has been found in both qualitative and quantitative research to be a powerful motivating factor toward prevention of food waste generation (Quested et al. 2013). For instance, Stancu et al. (2016) found that awareness of the economic impact of food waste has a stronger negative association on the generation of food waste compared to awareness of environmental and social consequences. Neff et al. (2015) reported that among the motivations for US consumers to reduce food waste, saving money topped the list. Jörissen et al. (2015) argue that there are active societal and economic trends that promote the generation of food waste such as the growing GDP, urbanization, and rising number of single households in addition to multiple burdens in work and family life for women. Figure 4 is an attempt to depict the complex network of food wastage implications discussed in this chapter.

Placement of Food Waste in the Context of the EU Waste Hierarchy

Food waste is normally treated alongside the rest of the organic municipal solid waste in mainstream waste treatment methods such as landfilling, centralized or home composting, incineration, and anaerobic digestion, which are known and largely accepted practices worldwide (Khoo et al. 2010; Luque and Clark 2013). Food waste, being organic in nature and therefore highly degradable, is subject to biological decomposition during the waste management chain. Among the management alternatives, landfilling is the worst in terms of environmental impacts because food waste when landfilled generates substantial amounts of methane, a strong GHG. It is estimated that two tons of CO_2 equivalents are generated per ton of food waste (European Commission 2010).

From the viewpoint of circular economy, industrial symbiosis, and green chemistry, food waste is a renewable resource of useful products (Luque and Clark 2013; Mirabella et al. 2014). In the context of these principles, food wastes are used as raw material for new products and applications focusing on the goal of "zero waste" society and economy. For example, chemicals included in food waste are sugars, phenols, starch, pectin, collagen, cellulose, chitosan, lignin, natural dyes, waxes, and hemicelluloses (Luque and Clark 2013). Waste from fruit and vegetable processing contains high concentrations of phenolic compounds, antioxidants, and fibers; waste from meat processing contains recoverable amounts of proteins, collagen, and gelatin, while waste from dairy products is a valuable source of proteins (Mirabella et al. 2014). Valorizing food waste components could lead to numerous possibilities

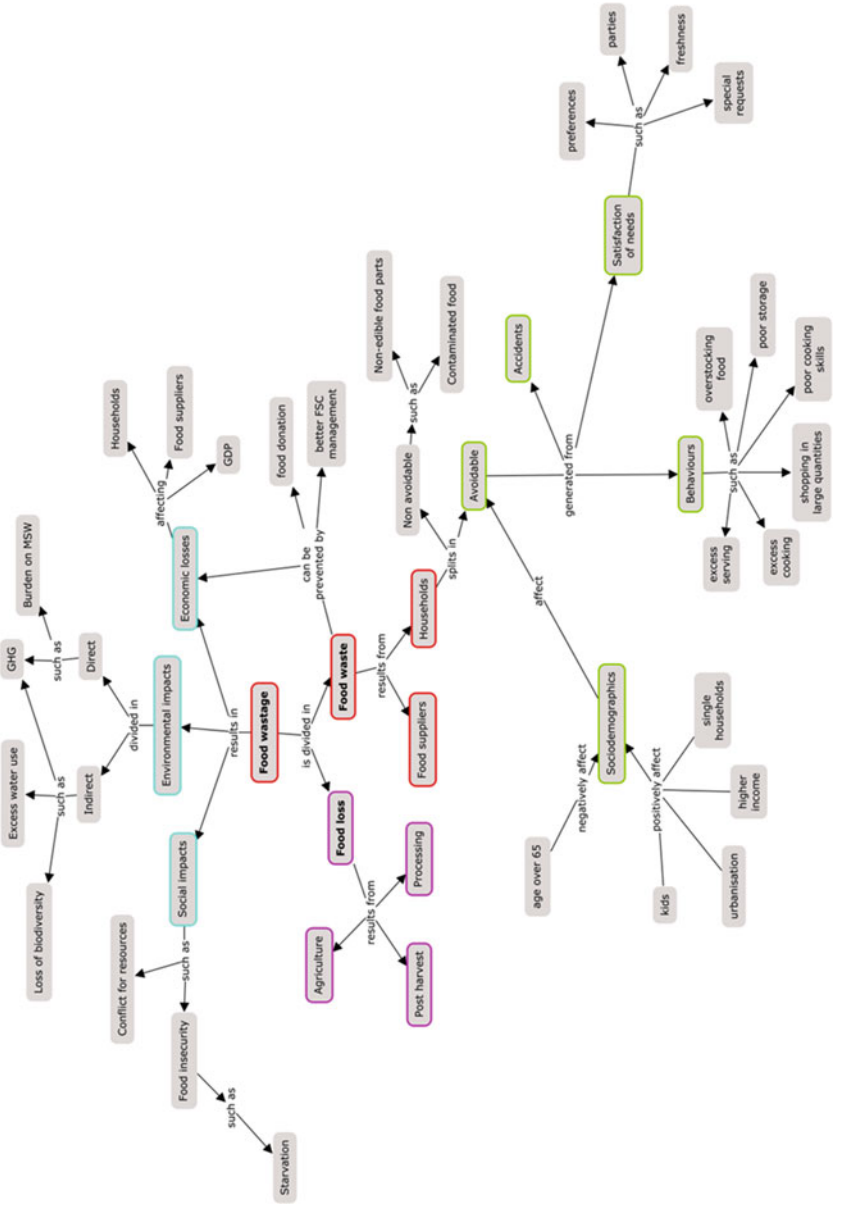

Fig. 4 The complex network of food wastage implications

for the production of chemicals, pharmaceuticals, fuels, and other valuable products (Luque and Clark 2013; Mirabella et al. 2014).

However, prevention should be the preferred management method for food waste (Salhofer et al. 2008). Waste prevention encompasses all the measures taken before a substance, material, or product has become waste, which reduce the quantity of waste, the adverse impacts of the generated waste on environmental and human health, or the content of harmful substances. Food waste prevention must incorporate practices to expand the accessibility of people on still edible foods that are older and/or less esthetically pleasing and those close to their expiration dates (Neff et al. 2015). Food waste prevention, on average, reduces GHG emissions by around eight times more than diverting the same amount of food waste from landfill to anaerobic digestion (Quested et al. 2013). Since the main purpose of food provision is human intake, among the possible food waste prevention alternatives, the donation of food to people in need is a sustainable act par excellence (Schneider 2013b) and must always be the first choice of people that have excess food to provide.

Policies and Protocols

Prevention of food waste generation is among the policy goals set by the UN, EU, and US policy agendas. More specifically:

- The 12th UN Sustainable Development Goal ("Ensure sustainable consumption and production patterns") sets the target to halve by 2030 the per capita global food waste at the retail and consumer levels and reduce food losses along production and supply chains, including postharvest losses (U.N. Sustainable Development Goals 2015).
- Food waste prevention is an integral part of the European Commission's new Circular Economy Package to stimulate Europe's transition toward a circular economy which will boost global competitiveness, foster sustainable growth, and generate new jobs. Moreover, the EU and member states are committed to meet the Sustainable Development Goals (SDG), adopted in September 2015, including a target to halve per capita food waste at the retail and consumer level by 2030, and reduce food losses along the food production and supply chains (European Commission 2017).
- The USDA and EPA have introduced the US Food Waste Challenge. This action calls on entities across the food chain – farms, agricultural processors, food manufacturers, grocery stores, restaurants, universities, schools, and local governments – to join efforts to reduce and better manage food loss and waste in the USA. Among them, the best performing participants are termed as champions. Food Loss and Waste 2030 Champions are businesses and organizations that have made a public commitment to reduce food loss and waste in their own operations in the USA by 50 percent by the year 2030. The Food Waste Challenge inventory of activities will help disseminate information about best practices and stimulate

the development of furher food waste prevention initiatives (United States Department of Agriculture 2017).

Dictionary of Terms

- **Food loss** – "A decrease in mass (dry matter) or nutritional value (quality) of food that was originally intended but is no more suitable for human consumption" (FAO 2013).
- **Food security** – The availability of and access to sufficient and healthy foods and good nutrition.
- **Food waste** – "Composed of raw or cooked food materials and includes food loss, before, during or after meal preparation in the household, as well as food discarded in the process of manufacturing, distribution, retail and food service activities"(EC 2011).
- **Avoidable losses** – Food and drink thrown away that was, at some point prior to disposal, edible (e.g., slice of bread, apples, meat).
- **Possible avoidable losses** – Food and drink that some people eat and others do not (e.g., bread crusts) or that can be eaten when a food is prepared in one way but not in another (e.g., potato skins).
- **Unavoidable losses** – Waste arising from food or drink preparation that is not, and has not been, edible under normal circumstances (e.g., meat bones, egg shells, pineapple skin, tea bags).
- **Life cycle assessment** – A methodology utilized to inform decision-making by identifying changes at every stage of a product's life cycle that can reduce its environmental impact.

Summary Points

- Food wastage is generated in every sector of the food supply chain.
- Food wastage generation is sector and country specific. However, common trends may be identified among countries of similar socioeconomic status.
- Food wastage is associated with social, economic, and environmental impacts.
- Food wastage puts a heavy burden on the global fight against starvation and famine.
- Food wastage has a strong ethical dimension since people in many parts of the world face the threat of food insecurity.
- Households are the major source of food waste in the developed world.
- There is a high level of complexity associated with the behaviors and practices relating to food waste generation at home.
- At the household level, food waste generation is strongly associated with certain socioeconomic parameters. For instance, older people generate less food waste.

- Food waste generation by households has a high variability which depends on the family structure, its eating and consumption habits, seasonality, special holidays, etc.
- The donation of excess food to people in need must always be the first choice.
- In the context of circular economy, food waste is a renewable resource of useful products such as chemicals, pharmaceuticals, and fuels.
- Food waste is a key focus for waste prevention at the household level.
- Food wastage prevention throughout the food supply chain should be among the key pillars of creating a sustainable food system.

of availability and affordability of healthier foods for lower-income families. In addition, lower-income families show considerable anxiety over buying healthier foods, as they are often rejected by children and potentially lead to costly food waste. Lower-income families face multiple stressors that thwart the ability to manage this tension, including economic constraints, the need to buffer stress with positive emotions, and juggling multiple responsibilities. In this chapter, we examine key issues faced by lower-income families and offer research-based solutions.

Introduction

Obesity is a major global health issue, and research supports the assertion that lower income is highly correlated with obesity in industrialized nations (e.g., Drewnowski and Specter 2004). Thus, interventions targeting lower-income families are likely to have a significant impact in addressing this epidemic. However, these families face well-researched obstacles to eating healthier diets including affordability of healthier options and access to healthier foods. Lower-income families also face a wide variety of psychological stressors that push them toward less healthy options, including economic constraints, the need to buffer stress with positive emotions (which can be temporarily accomplished with "comfort foods"), and juggling multiple responsibilities that deplete self-control resources. These factors lead to a fear of food waste in lower-income families, which drives food choices often toward unhealthy options (Daniel 2016; Connell et al. 2016).

Food waste is particularly problematic from a health perspective because fresh, healthy foods (like vegetables) are often wasted; at the same time, most individuals would benefit from increased consumption of these foods (Gunders 2012). Studies show that the average four-person American family wastes approximately $1500 of usable food yearly (Smith 2014). While researchers (and conventional wisdom) suggest that lower-income households should waste less food (see Gustavsson et al. 2011), empirical work has shown that differences in waste are minimal in lower versus higher-income households (Quested and Johnson 2009). Since wasted food equates to wasted money, it may be that the loss of food due to waste is felt more significantly in lower-income (versus higher-income) households.

In this chapter, we examine obstacles that lower-income families face regarding the tension between eating a healthier diet and preventing costly food waste, focusing particularly on obstacles that drive parental food choices for children in the household. Specifically, we examine the roles of nutrition literacy, convenience,

palatability of foods, positive and negative emotions, and potential food safety issues. We provide a review of extant research for each of these tensions, and then offer policy or parental solutions based on this research.

Nutrition Literacy

Nutrition literacy is the knowledge and motivation to incorporate nutrition information into food choices in order to promote health goals and food well-being (Block et al. 2011; Vidgen and Gallegos 2014). Lower-income and ethnic minority individuals may have more difficulty achieving adequate levels of nutrition literacy to promote healthy choices due to constraints on time and/or educational resources (Gans et al. 2009; Kumanyika 1996). Furthermore, lower-income parents must balance a tension between the priorities of good nutrition for the family and value based on economic constraints (Foley an Pollard 1998). Parents' knowledge and beliefs about food, health, and nutrition come from a variety of sources, including formal education from schooling and government agencies, education from healthcare professionals, and information from friends and family members.

Formal education sources to help promote nutrition literacy should be developed in conjunction with and customized to – the target population, such as lower-income parents (Howard-Pitney et al. 1997). Healthcare providers play an important role in promoting nutrition literacy among parents (Parra-Medina et al. 2010). Such education can help increase understanding of the connection between nutrition and downstream consequences (e.g., school performance, type 2 diabetes, etc.; Jyoti et al. 2005). Providers can help parents set concrete learning and food choice goals. Actively involving the parent in the learning and implementation process will increase the likelihood of parental adoption of recommendations by creating a positive stress experience, called eustress. This can lead to more progress toward a health goal (Mende et al. 2017). For example, helping lower-income parents to increase their nutrition literacy can help them to use caloric information to reduce consumption of sugar-sweetened beverages (Bleich et al. 2012).

Family, culture, and tradition may also influence nutrition literacy development among lower-income parents. For example, families who have lived in a food desert for generations may develop traditions around foods that are accessible in the local environment (Davis and Carpenter 2009), without having knowledge about the connection such foods have to downstream health and well-being challenges for the family.

Nutrition literacy uniquely influences parents with limited financial resources at every stage in the consumer experience including acquisition and storage, preparation and consumption, and disposal of food for the family. Lower-income parents want to purchase healthy foods for their families but perceive such foods to be unaffordable (Dammann and Smith 2009). Furthermore, parents may need to learn about how to access a variety of nutritious, inexpensive foods that can be used to prepare healthy meals for the family. At the acquisition stage, parents must be vigilant in distinguishing between promotional messages (e.g., "now with reduced

Table 1 Solutions to address the impact of lower nutrition literacy on food choice and food Waste

Problem	Recommendation
Less healthful food traditions may be learned based on being passed through families over generations	Use traditional educational sources such as healthcare providers, and new sources such as popular press to promote healthy alternatives (e.g., incorporating broccoli into a traditional family macaroni and cheese recipe to improve healthfulness without sacrificing tradition)
Parents may not be aware of what healthy options are available to them, and how to obtain them cost-effectively	Educate parents on how to access and economically prepare a wider variety of fruits and vegetables they may not have been aware of (e.g., providing information on how to obtain seasonal, less-commonly used vegetables)
Lack of food storage literacy may cause parents to consume expired or otherwise unhealthy foods in an effort to avoid waste	Promote the need for the parent to consume healthy options in order to effectively care for the children. Educate parent on food safety options

fat!") and objective nutritional information (Roe et al. 1999). A key aspect of nutrition literacy is understanding guidelines to safe and effective food storage (Connell et al. 2016; Daniel 2016). For example, understanding the nutritional content of fresh and frozen vegetables may help to save parents time and money. Although some frozen fruits and vegetables foods may have added sugar as part of their processing, frozen foods can be stored longer and can at times be convenient to prepare (Szocs and Lefebvre 2016). Families experiencing greater levels of poverty may seek shelf stable convenient foods that do not require refrigeration, which in turn limits the variety of foods that are available (Curtis and McClellan 1995).

Lower-income parents may be concerned about wasting food (Daniel 2016) and information on how to prepare and store meals in advance might help minimize the amount of usable food that is discarded. A parent might mitigate the stress of wasting money on discarded, usable food by, say, consuming items beyond listed expiration dates themselves. An understanding of the distinctions of use-by, sell-by, and best-before, and other information may influence heuristics parents use. Table 1 provides some solutions to help address the impact of lower nutrition literacy among parents.

Preparing own Meals or Buying Convenience Foods

Prepackaged or prepared healthier foods tend to be costly. For example, a Southwest grilled chicken salad costs $4.79 at McDonald's, whereas two cheeseburgers and a side of small fries costs only $3.19 (fastfoodmenuprices.com 2016). Thus, if lower-income parents wish to improve their children's diets, preparing meals themselves is the most viable option. However, many lower-income parents may lack proper cooking facilities, food storage space, and/or the knowledge necessary to cook their own meals (Carraher et al. 1998).

Lower-income families also face time constraints. Because minimum wage employment does not provide a living wage in many locations (Dube 2014), lower-income parents might need to work more than one job to make ends meet. Thus, even if lower-income parents possess adequate knowledge to prepare healthier meals, time constraints will impede their ability to plan and prepare meals. This problem is exacerbated by limited access to retailers selling healthier options such as fruits and vegetables in lower-income areas (Weatherspoon et al. 2013). Additionally, home economics education is no longer a mainstay (Lichtenstein and Ludwig 2010) and research has suggested that cooking is frequently learned from parents, particularly mothers (Carraher et al. 1999). If parents are working multiple jobs and lack time or energy to cook, then the end result is a generation that lacks the skills necessary to prepare healthy meals when they become adults.

In addition, working throughout the day is likely to tax precious regulatory resources, which already tend to be depleted as the day progresses (Baumeister 2002; Boland et al. 2013; Montoya and Scott 2013), and could increase the already difficult and potentially emotionally exhausting task of preparing a healthy meal that children may resist eating (Daniel 2016). If children refuse the meal, then parents are left with the task encouraging consumption and/or wasting food that goes unconsumed (Daniel 2016). Thus, prepared "fast" food is not only an inexpensive option, but an easier and palatable option likely to be preferred when one's regulatory resources are depleted.

A wide body of research supports the assertion that lower-income families urgently need better access to healthy, convenient, and affordable food options. Federal and local governments can provide tax incentives for grocery stores to open locations in urban areas. Because convenience stores still represent the primary food shopping destination for many lower-income families, governments could also provide convenience store owners with tax incentives to offer healthier options, like fresh produce. Governments could further develop programs lower-income families rely on to reflect today's realities. In the USA, perhaps SNAP (Supplemental Nutrition Assistance Program) could be altered so that consumers can use credits for prepared options at restaurants if they meet healthy dietary guidelines. Already, SNAP "dollars" count two-for-one at local farmer's markets, and such incentives should be pervasive.

Because many lower-income parents may lack nutrition-related knowledge, programs need to be put into place or further supported, as preparing meals at home remains an affordable option for healthy eating. As previously mentioned, home economics courses are often not required or offered in primary education (Lichtenstein and Ludwig 2010). We assert that home economics may help increase nutrition literacy, if courses are updated for modern needs. For instance, courses could emphasize understanding of nutrition labels, shopping within a budget, shopping in multiple environments, and how to prepare healthy and easy meals. Adult learning programs that teach the same skills are also necessary.

Involving children in meal preparation is also important as research has shown that when people expend effort in creating something, they develop a greater emotional attachment to the resulting product (Norton et al. 2012). Further, children

Table 2 Solutions to address the labor and convenience tradeoff

Problem	Recommendation
Inexpensive and convenient foods are calorie dense	Tax incentives to food retailers to provide healthy, palatable, and affordable options to lower-income families
Healthier prepared options are expensive	Allow consumers to use programs such as SNAP for prepared options that meet dietary guidelines
Lack of food preparation skills	Increase home economics education in schools and adult learning programs
Children have no vested interest in eating healthier options	Involve children in age-appropriate food preparation tasks

who are involved in growing their own produce and/or assist in preparing meals are more likely to enjoy consuming healthier options (Heim et al. 2009; Kim et al. 1998).Thus, if parents involve children in meal-preparation tasks that are safe and age-appropriate, some of the objections children might have to healthy food options could be attenuated. Solutions to the problems identified here are summarized in Table 2.

Consumption of Preferred Foods or Wasting less Preferred Ones

Empirical evidence supports the notion that the cost of healthful foods (e.g., fresh fruits and vegetables) is higher than the cost of alternatives that are higher in fat, sugar, and salt (e.g., packaged and processed foods; Drewnowski 2010). While research suggests that lower-income families often work to optimize their limited food budgets by selecting less expensive, nutrient poor but calorie rich options (see Drewnowski and Specter 2004), other work shows that careful planning can mitigate the monetary costs of a healthier selection of foods (Carlson and Frazao 2012). Yet lower-income families face additional risks in purchasing healthy foods for children, as children often refuse and waste less preferred, healthy foods (Connell et al. 2016; Daniel 2016). Thus, it is not merely the economic costs of food purchased that drives the decision of lower-income parents regarding what to buy, but also the risk inherent in wasting healthy foods.

Food liking is influenced by many factors. One key factor driving childhood food acceptance is palatability; children prefer sweeter (vs. less sweet) foods. The literature implicates biology (i.e., evolutionary preference) and experience (i.e., lack of exposure to healthy foods in childhood) as drivers (Mannella et al. 2016). Although people inherently prefer sweet and calorie-dense foods, most tastes are learned (Beauchamp and Mennella 2011). The finding that repeated exposure to a novel stimulus increases liking (Zajonc 1968) has been demonstrated in the domain of taste, such that individuals can develop preferences for foods that are not liked on first exposure (Birch 1999; Wardle et al. 2003a, b). Thus, experts recommend repeated exposure to less preferred foods to foster acceptance. Liking for new foods increases between five and ten exposures for two-year-olds (Birch et al. 1982), with more exposures required for older children and adults (Sullivan and Birch 1990).

This technique is effective at increasing the acceptance of a variety of foods and, in particular, increasing children's acceptance of vegetables (e.g., Ahern et al. 2014). Kalat and Rozin (1973) theorize that repeated exposures for novel foods are effective because of "learned safety"; experiencing a less palatable food multiple times without a negative physiological response increases perceptions of safety and, in turn, acceptance (Birch 1999; Wardle et al. 2003a, b).

Despite the known effectiveness of repeated exposure of novel or less preferred foods, research indicates that lower-income parents are not likely to serve children foods that they previously reject (Goodell et al. forthcoming). As discovered by Daniel (2016), a key reason underlying this is fear of food waste; while parents may be aware of the beneficial effects of multiple exposure, their food budgets simply cannot extend to provide (often) more expensive healthy foods that children refuse. Taken together with the structural factors that limit access to healthy foods in lower-income populations (e.g., food deserts with a dearth of fresh foods tend to occur in lower-income residential areas; Hendrickson et al. 2006), this makes the acquisition of such items difficult on a regular basis for lower-income families – and recall that multiple exposures of novel foods are required to establish preferences. While those of greater means may consider food waste stemming from repeated exposures as a necessary buy-in to establish healthy preferences, lower-income family may simply lack the financial flexibility to waste costly food – healthy or not.

Building on the concept of exposure leading to liking (Zajonc 1968; Pliner 1982) lower-income parents might seek out ways to provide multiple exposures of less preferred foods that minimize waste. Food storage may play a role here; foods might be prepared and frozen or canned, for instance, so that multiple exposure can be planned for later dates (as opposed to wasting remaining, perishable foods). Alternatively, less perishable forms of such foods might be purchased (e.g., frozen foods) prior to a child's acceptance so that smaller portions can be used without waste (e.g., cooking a small portion of frozen vegetables and freezing the rest until the next exposure/serving opportunity).

We also suggest that the order in which foods are provided may be intentionally altered to potentially increase acceptance. In terms of vegetables, a category which children tend not to prefer but for which consumption offers myriad benefits (CDC 2014), parents might offer children foods that align in a "risk ladder," in which sweeter foods are introduced and followed by those with increasingly bitter taste profiles (see Connell et al. 2016). This may increase acceptance by children and decrease the waste of less preferred foods. Such a strategy could work with other food categories as well; notably, similar plans are often adopted by parents in cultures where spicy foods are commonly eaten, such that children are given increasing levels of spice with repeated exposures to food to gradually increase acceptance (Rozin et al. 1982). Indeed, support would be needed to communicate the appropriate progression of vegetables (or other foods) for parents who might not possess adequate flavor knowledge to create an appropriate progression.

In addition to exposure, research also suggests that strategies based on associative conditioning may also increase liking for foods (Wadhera et al. 2015). These techniques involve associating a less preferred food with a positive or negative

consequence. For example, sweeteners can be added to items (e.g., grapefruit juice) and, with multiple exposures, children exhibit a greater preference for the item in its natural state relative to those who received multiple exposures to an unsweetened item (i.e., flavor-flavor learning; Capaldi and Privitera 2008). While studies have also looked at the provision of rewards as a basis for increasing liking, the results are mixed, making it unclear if rewards offer additional benefit over merely exposing children to foods repeatedly (see Corsini et al. 2013; Wadhera et al. 2015). However, when exposure is paired with parental modeling of food acceptance (either with or without additional rewards), children's acceptance of disliked foods increases. This supports the idea that parental modeling encourages the consumption of healthy foods and, importantly, may be a cost-efficient way of encouraging healthful eating (Holley et al. 2015).

Food presentation has also been shown to impact the consumption of healthy foods. In a series of studies, Wansink and his colleagues assigned attractive names (e.g., "X-ray Vision Carrots") to vegetable dishes in elementary school cafeterias and compared the percent of students choosing these options over generically named dishes; indeed, more students were likely to select the foods with attractive (vs. generic) names (2012a). Similar research has shown an increase in the selection of apples when they include stickers featuring child-friendly characters (Wansink et al. 2012b). These and other techniques such as serving food in "cute" shapes (e.g., Nenkov and Scott 2014) may serve to increase consumption of less preferred foods. In sum, parents may be able to utilize creativity to alter the appearance of foods as an economical means of increasing the consumption of healthy foods at home while minimizing the likelihood of waste. Solutions to the problems identified here are summarized in Table 3.

Table 3 Solutions to promote acceptance (and minimize waste) of healthy foods

Waste reduction strategy	Parent recommendation
Food storage	Freezing, canning, or otherwise preserving perishable foods
Product form	Purchasing products in less perishable forms (e.g., frozen) so that small portions can be utilized with the remainder stored for future use
Food introduction	Children might be first introduced to healthy foods that they are more likely to accept (e.g., a sweeter vegetable), followed by progressively risker options (e.g., vegetables with more bitter taste profiles)
Food associations	Pairing less liked foods (e.g., grapefruit juice) with preferred tastes (e.g., sweeteners) may generate liking over time with multiple exposures
External rewards	Children may be given non-food rewards for trying new foods or not wasting provided food
Parental modeling	The tendency for children to model their own eating after that of their parents suggests that parental consumption of healthy foods may increase the likelihood of childhood consumption
Food presentation	Foods may be given child-friendly names, associated imagery, shapes, etc. to increase liking and reduce food waste

Healthy Foods or Happy Kids (and Parents)

Indeed, food plays an important role in family life beyond its mere nutritional components that contribute to individual health (Block et al. 2011). Research demonstrates a remarkable connection between food and emotions. Studies show, for instance, that children who regularly eat less healthy foods (vs. healthy foods) are less likely to be unhappy, highlighting a tradeoff between objective (i.e., health) and subjective (i.e., emotional state) well-being (Chang and Nayga 2010). Food is often consumed as a means of consciously generating positive emotions, particularly when more negative ones are experienced, as the phrase "comfort food" suggests (Wood 2010). Foods that bring individuals "comfort" are typically unhealthy ones (e.g., potato chips, ice cream, cookies). Such foods are consumed when people seek to maintain positive emotions or repair negative emotions (Wansink and Sangerman 2000).

Given the tendency for unhealthy foods to generate positive emotions (i.e., to make kids happy), comfort foods might be used by lower-income parents to ease childhood stress that arises from food insecurity and other financial and emotional pressures associated with lower-income households (e.g., inadequate housing, taxing wage work, etc.; Leung et al. 2015; Liu et al. 2014). Unfortunately, this can lead to poor nutrition-related outcomes (e.g., obesity, high blood sugar, etc.); though, notably, experts suggest that stress may itself also lead to weight gain due to resultant hormonal changes (see Adam and Epel 2007). So, while it is important to make healthy food choices, it is also important to identify methods to reduce stress and associated negative emotions via means other than consuming unhealthy comfort foods.

In addition to emotions experienced by children, caregiver emotions can also impact food choice. Research suggests that lower-income parents associate food gratification with good parenting (Kaufman and Karpati 2007) and perceive that saying "no" to a child's request for unhealthy food is an example of failing to show love (often based on their own, recalled responses to being told "no" as a child; Herman et al. 2012). A separate study of lower-income mothers similarly identified the emotional difficulty experienced by the mother in denying children additional food after they had already consumed an adequate serving (Jain et al. 2001).

Additionally, hard-working lower-income parents may consume comfort foods to cope with stresses that spill over from work into home life (Devine et al. 2006). Rather than mitigating stressful work experiences, many lower-income working parents reduce their workload at home, often because they recognize employment instability (Devine et al. 2006). Lower-income parents also often contend with negative emotions resulting from conflicts with other adults in the household who disagree with their strategies to encourage healthy eating (Herman et al. 2012; Jain et al. 2001). Anticipated negative emotional responses from children as well as negative emotions like guilt or stress that may be induced by fellow caretakers may forestall efforts aimed at fostering healthier choices and consumption.

Additionally, family food choices can act as a means of showing affection. A poll by National Public Radio, the Robert Wood Johnson Foundation, and the Harvard School of Public Health (2013) indicates that more than 25 percent of families in the

United States equate food with love. Food and food brands represent key components of individual and family identities (e.g., food traditionally served at holidays or family dinner favorites and preferred brands; Moisio et al. 2004; Motley and Perry 2009; Trump et al. 2015; Wallendorf and Arnould 1991). These identities are based on shared memories and experiences that generate happiness. However, food-derived comfort is a learned association. That is, when a parent attempts to repair negative emotions with food, the hope is that the positive emotions experienced from consuming the food will mitigate negative emotions experienced from stress, frustration, or failure. As mentioned previously, people appear to have an innate preference for foods high in fat, sugar, and salt (Birch and Fisher 1998), which makes introducing healthier options such as fruits or whole grains a tricky proposition for parents. Such an approach would require a widespread public education effort to shift parents' use of unhealthy foods as vehicles of comfort to healthier options. This would likely require significant investments in public service announcements and use of healthy foods as a way of evoking positive emotions in public spaces such as classrooms.

Indeed, positive affect evoked from brands is known to bias people's perceptions of the advertised foods (Connell et al. 2014). Activating health goals has been shown to prompt people to reconsider their judgments and make healthier choices in some cases (Connell et al. 2014; Finkelstein and Fishbach 2010) and have the potential to strip junk foods of the pleasure people anticipate from consuming these foods (Connell and Mayor 2013). Thus, nudging health motivations via public service announcements or via signage or outdoor advertising might serve as effective means of getting people to reconsider their beliefs.

Another important consideration is understanding the multiple stressors that lower-income families face and providing them with a repertoire of behaviors to deal with these stresses (i.e., increasing resilience) that are not related to food. Research on building resilience in children focuses on seven crucial "Cs": competence (enhancing ability), confidence (having positive self-esteem), connection (strong interpersonal relationships), character (moral understanding), contribution (helping others and building community), coping (effectively dealing with stressors), and control (exercising restraint when necessary) (Ginsburg and Jablow 2011). Thus, building resilience should be a priority in our educational institutions so that parents and children have tools other than foods to deal with frequent environmental stressors. Potential solutions to issues related to experienced or anticipated emotions are summarized in Table 4.

Beyond Budget: Perceived Food Safety Impacts Waste

Another factor that likely impacts purchase of healthy foods pertains to food labeling and its impact on perceived food safety. To aid people in evaluating the freshness and safety of items to purchase as well as purchased items, the food industry utilizes a

Table 4 Solutions to reduce the tension between healthy and pleasurable eating

Problem	Recommendation
Indulgent foods are a source of affection	Public education to promote use of healthier foods with sweet flavor profiles (e.g., carrots, beets).
Positive feelings toward food brands and products create biased nutrition judgments	Use outdoor advertising, signage, and public service announcements to activate health goals, which can facilitate reconsideration of beliefs
Lower-income families face multiple stressors that create need for mood repair	Build resilience skills among children and parents via public education

number of cues to convey freshness, including information about when fresh food was packaged, the "sell-by" date indicating that food is still safe to consume, and the "use-by" or "best by" date, indicating a food is at peak quality, and expiration date. However, retailers frequently apply labels inconsistently, and they sometimes put multiple dates on packaged fruit, vegetables, protein, and dairy. Further, people tend not to receive information about what the date on their food label means (WRAP 2011). Consequently, many confuse the "sell-by" and "use-by" dates for expiration dates, and this confusion increases avoidable waste. One explanation for this confusion relates to the "anchoring and adjustment heuristic" in psychology; when people need to make a decision about food freshness, they rely on available information, such as "sell-by," "use-by," or "expiration" dates (Block et al. 2016; Tversky and Kahneman 1975). Indeed, one study indicated that 17 percent of household waste in the United States was due to food products being past their labeled dates (Van Garde and Woodburn 1987). Although "sell-by" and "use-by" dates have no bearing on a product's expiration or freshness, 50 percent of consumers still believed that eating food after their "sell-by" or "use-by" dates posed a significant health risk (Ransom 2005). Reducing the "sell-by" anchor from packaging reduced food waste by 21% in the United Kingdom (The Grocer 2016).

While these are general trends that apply to all consumers regardless of income level, conceivably, these information processing issues are exacerbated among lower-income families who tend to have low nutrition and food literacy and less time to consider whether dates on labels are impacting their eating decisions. Further, given that fresh fruits, vegetables, meats, and dairy take up a larger proportion of a lower-income family's food budget, this tension between determining whether food is fresh or should be thrown out might shift lower-income parents' preferences toward more shelf-stable foods.

When date labels are not present, people may be uncertain as to the range of a products freshness. In these cases, lower-income parents are still likely afraid of purchasing healthier items, like fruits and vegetables, because they are afraid the product will reach its expiration date before it will be consumed (Connell et al. 2016; Daniel 2016). This is consistent with research on risk-attitudes, which attests that as income decreases, concern with food safety and health risks increases (Dosman et al. 2001). Table 5 proposes strategies to overcome concerns of food safety and expiration.

Table 5 Solutions addressing concerns related to food freshness and food safety

Waste reduction strategy	Industry or governmental recommendation
Food date labeling	Remove date marks from food packaging that are unrelated to food safety and expiration (e.g., "sell-by" and "use-by" dates)
Food labeling consistency	Use one, consistent date mark on food labels
Food information	If unable to remove extraneous date marks, educate consumers about what dates on food labels actually mean (e.g., peak-freshness versus expiration)
Food packaging	Offer a range of package sizing so that consumers might pick smaller package sizes to minimize household waste

Conclusion

In this discussion, we have considered some of the unique challenges faced by lower-income parents seeking to feed their families a healthy diet while minimizing food waste – nutrition literacy, convenience, palatability of foods, positive and negative emotions, and potential food safety issues. In doing so, we seek to build on prior research aimed at generating solutions to the global issue of food waste (see Block et al. 2016; Porpino 2016). Acknowledging the complexity faced by low income families, in particular, we recognize that this is not an exhaustive list. However, it is our hope that the issues identified here may be used to generate inquiries that lead to solutions that promote the well-being of families, and may simultaneously address larger societal, economic, and environmental issues.

Policies and Protocols

In this discussion, we discuss unique obstacles faced by lower-income families in preventing food waste and promoting healthier eating, and suggest research-based policies to aid these consumers.

- Efforts to **boost nutrition literacy** by educating consumers about healthy versus unhealthy foods, where to purchase such foods, how to prepare these items, and ways to promote them within the family might promote better food decisions and less waste.
- Policies that make **healthy food more accessible and convenient** include tax incentives for retailers, increased government assistance for consumers, increased home economics education in schools, and other adult learning. Such initiatives may also lead to creative solutions for minimizing waste.

- Techniques aimed at **increasing the palatability of healthy** foods include teaching food preservation techniques (e.g., canning, freezing) and promoting the purchase of foods in less perishable forms. Moreover, children might be exposed to less risky (e.g., sweeter) foods before less palatable ones or preferred tastes might be paired with less preferred ones to increase liking. Foods might also be framed as more fun (e.g., through product naming) and strategies to promote healthy food choices for parents may lead to children modeling parental consumption.
- Given the **emotional nature of eating**, education programs might promote healthy foods, nutrition goals, and strategies for resisting food temptations.
- Polices aimed at **creating an understanding of food safety** include standardizing food dating systems and educating consumers about date meanings. Further, a variety of package sizes might work to reduce food waste.

Dictionary of Terms

- **Eustress** – A stress experience that is positive for the individual. Eustress can lead, for instance, to increased goal engagement.
- **Food desert** – A geographic area defined by a lack of healthful foods, like fresh fruits and vegetables.
- **Food insecurity** – Lacking reliable access to adequate quantities of healthy, safe, and affordable food.
- **Heuristic** – A practical shortcut for decision-making that minimizes effort and time spent in the decision-making process.
- **Nutrition literacy** – The knowledge and motivation to incorporate nutrition information into food choices.

Summary Points

- Key issues lower-income families face in providing healthy diets while avoiding food waste include those related to nutrition literacy, convenience, food palatability, positive and negative emotions, and food safety.
- Many lower-income parents lack basic nutrition literacy.
- Lower-income parents may lack time or food preparations skills to prepare healthy meals at home.
- Healthier foods tend to be less palatable for children, potentially leading to food waste.
- Food is often used as a way to reward, show love, or repair negative mood.
- Concerns over food safety of fresh foods (e.g., expiration dates) can lead to waste or avoiding these options.

- The issues identified and the research-based solutions presented here may be used to generate inquiries that lead to resolutions that promote the well-being of families, and may simultaneously address larger societal, economic, and environmental issues.

Biosocial and Social Aspects, Inequalities, Low Income, Refugees, and Conflict

Applying a Biosocial Perspective to Address Childhood Diarrhea-Related Morbidity and Mortality

21

Nicola Bulled, Merrill Singer, and Rebecca Dillingham

Contents

Abstract

Despite calls for greater attention to the relationship between water access and disease, diarrhea and related malnutrition remains a leading cause of morbidity in children under 5 years. Children are especially vulnerable given their inability to mount an active immune response to pathogen exposure. Social conditions,

including the long-term effects of poverty – reduced nutrition, poor hygiene and sanitation, and diminished home environments – further exacerbate the biological limitations. This chapter offers a syndemic perspective on childhood diarrhea-related malnutrition, specifically examining the consequential interactions between pathogens, as well as pathogenic interactions with other health and social conditions that are disproportionately common among disparity populations. This perspective offers a potential for enriching and extending policy discussions and planning, addressing malnutrition-related diarrheal illness and other health challenges of impoverished populations.

Introduction

Following repeated calls for greater attention to the relationship between poor water access, hygiene and sanitation infrastructure, and malnutrition, the World Health Organization (WHO), United Nations Children's Fund (UNICEF), and the United States Agency for International Development (USAID) jointly prepared the report "Improving nutrition outcomes with better water, sanitation and hygiene," to summarize the abundance of evidence on the benefits of WASH (water access, sanitation, and hygiene) as a means to improve nutrition outcomes (WHO et al. 2015). Diarrhea, spread through contaminated drinking water or food, from person-to-person through contaminated hands, or unsafe disposal of stool, is the leading cause of malnutrition in children under 5 years.

Despite significant advancements in infrastructure and medical technology, diarrhea continues to be responsible for 9% of deaths of children under the age of five in 2015, killing over 1400 children a day, or 526,000 a year (UNICEF 2017). Most diarrhea-related deaths in children occur in those under the age of two in

marginalized communities in South Asia and sub-Saharan Africa (Keusch et al. 2006; Fischer Walker et al. 2013; UNICEF 2017). In these settings, children under age of three experience on average three episodes of moderate-to-severe diarrhea every year (WHO 2013). Diarrhea is usually a symptom of enteric bacteria, viruses, and/or parasitic infection of the intestinal tract. In 2015, rotaviral enteritis (rotavirus) was the leading cause of under-five mortality due to diarrhea globally (146,000 deaths) (Institute for Health Metrics and Evaluation 2017). Death from diarrhea usually results from severe dehydration and fluid loss. The greatest burden of disease occurs primarily in younger age groups, with 72% of deaths from diarrhea occurring in children younger than age two (Fischer Walker et al. 2013). The highest rates of severe diarrheal disease occur at age 6–11 months, as infants no longer receive passive protection from trans-placental and breast milk antibodies and begin to experience greater pathogen exposure from food, water, and their wider environment (Fischer Walker et al. 2013). Risk of diarrhea and diarrheal mortality then decreases with age. However, morbidity (i.e., stunting and cognitive impairment) related to moderate-to-severe childhood diarrhea can have profound implications throughout one's lifetime. Infants and children are more adversely affected because they are more vulnerable to both social and biological factors that facilitate infection, such as the long-term and entwined effects of poverty, malnutrition, and underdeveloped immune systems.

The tendency in existing research and intervention is to look for, and seek to resolve, individual causes of diarrheal disease or use medical treatment technologies to prevent disease or disease mortality. Simple oral glucose-electrolyte rehydration solution (ORS) can reduce diarrhea-related mortality by 93% (Munos et al. 2010), dramatically reducing acute diarrhea-related mortality from 4.6 million annual deaths globally during the mid-1980s to the current estimate of 1.6–2.1 million (Kosek et al. 2003; Keusch et al. 2006; WHO 2013a). The rotavirus vaccine, introduced as part of childhood vaccination schedules in 81 countries (as of May 2016, PATH 2016), has been shown effective at not only reducing hospitalizations due to rotavirus by 88% (95% CI 76–94), but also conferring heard immunity for older children born before the rotavirus vaccine became readily available (40–69% reduction in admission for rotavirus) (Tharmaphornpilas et al. 2017). High-doses of vitamin A supplementation helps to promote and maintain strong immune systems and can reduce all-cause mortality by 24% and cases of diarrhea by 15% (UNICEF 2017). From 2000 to 2015, the total annual number of childhood deaths from diarrhea decreased by more than 50% through these basic interventions (UNICEF 2017).

However, diarrhea is preventable and often does not occur in isolation. Worldwide, one in nine people (783 million individuals) have no source of safe drinking water, and one in three (2.4 billion) lack improved sanitation – numbers that are projected to double by 2025 (Mara 2003; WHO 2013b; The Water Project 2017). Furthermore, 946 million people practice open defecation (WHO/UNICEF 2012a; WHO/UNICEF 2017). Children who suffer from multiple bouts of diarrhea are frequently inflicted with other diseases of poverty, including malnutrition (Bennett 2009), malaria, dengue, measles, and HIV (Singer 2009). Diarrhea-related morbidity

continues to have significant long-term implications, particularly for young children (Keusch et al. 2006; Fischer Walker et al. 2012). Research suggests that diarrhea is not limited to transient illness, but that repeated episodes of diarrhea can cause physical growth impairments (Petri et al. 2008; S.P. Walker et al. 2011). A pooled analysis of nine studies showed that the odds of stunting by age 2 years increased by 1.13 (95% CI 1.07–1.19) for every five episodes of diarrhea (Checkley et al. 2008). Additional research suggests that by age 7, children suffering from multiple bouts of diarrhea can lose up to 8.2 cm in height (Moore et al. 2001). Multiple studies identify the link between repeated episodes of diarrhea and cognitive deficits, with a measured loss of up to 10 IQ points and 12 months of schooling by age 9 (Guerrant et al. 1999; Niehaus et al. 2002; Lorntz et al. 2006). Yet, the causal interactions between disease states and social conditions are understudied.

This chapter offers a syndemic perspective on childhood diarrheal disease, specifically examining the consequential interactions between pathogens, as well as pathogenic interactions with other health and social conditions that are disproportionately common among disparity populations (those suffering disproportionately from poverty, social inequality, and economic and political marginality). We present this perspective in an effort to highlight the potential for a syndemics analysis to enrich and extend policy discussions and planning, addressing malnutrition-related diarrheal illness and other health challenges of impoverished populations. Drawing from available research and current policy agendas, this chapter explores current approaches to diarrheal disease management and considers novel comprehensive disease prevention approaches, consistent with syndemic theory, that are likely to prove effective in generating sustainable and equitable disease prevention solutions. This chapter is an update to our previously published work on the topic (Bulled et al. 2014).

Current Public Health Approaches to Childhood Diarrhea

The international bodies of UNICEF and WHO have guided the global public health agenda on childhood mortality, with a primary focus on the use of biomedical technologies. The *Integrated Management of Childhood Illness* (IMCI), developed in 1995 to reduce under-five mortality, aims for an integrated approach to address the well-being of the whole child. The strategy focuses on three main components: improving case management skills of health care staff for the accurate identification of childhood illness in outpatient settings; making improvements in overall health systems to ensure the appropriate combined treatment of all major childhood illnesses; and boosting community health practices to ensure appropriate care seeking, care management, and preventive practices. The attention is on scale-up and maintenance of health care facilities.

Although the program has been introduced in more than 75 countries, clinical coverage and quality of clinical care for sick children have not reached high enough levels to achieve the expected reductions in mortality or morbidity (Chopra et al. 2012). According to a multicountry evaluation of the impact and cost-effectiveness

of the IMCI strategy conducted in Brazil, Bangladesh, Peru, Uganda, and the United Republic of Tanzania, the IMCI can reduce under-five mortality and improve nutritional status if implemented well (WHO 2016). Furthermore, it costs up to six times less per child than standard of care. However, significant reductions in under-five mortality cannot be attained unless large-scale intervention coverage is achieved (WHO 2016b). According to a study of services provided in 12 countries in sub-Saharan Africa with high diarrhea burdens, the prevalence of "good" care (defined as ORS or zinc provided, fluids given, and feeding continued) was low in all formal and informal health care setting (Carvajal-Velez et al. 2016). A median of 27% of children with diarrhea (range from 17% to 38%) received high quality of care.

Bottlenecks have been a primary impediment to access to and use of biomedical therapies (Gill et al. 2013). These include: inequitable supplies of key commodities and unequal provision within communities through public or private avenues; delayed development of national policies supporting use of certain newer strategies or integration of strategies into national plans (i.e., rotavirus vaccine); limited funding and resources; poor management and coordination of efforts; and inadequate advocacy. For example, despite evidence of effectiveness, the median coverage of ORS has decreased since the late 1980s, with just over 40% of children under age five with diarrhea receiving the recommended treatments of ORS and continued feeding worldwide (WHO/UNICEF 2012b). Use of this treatment is lowest in sub-Saharan Africa and South Asia (38% and 47%, respectively), regions with the most deaths from diarrhea (UNICEF 2017). Furthermore, even a decade after WHO/UNICEF released recommendations for treatment of diarrhea with zinc, global uptake of zinc for the management of diarrhea remains almost negligible, at 4% (Bhutta et al. 2010; UNICEF 2017).

WHO/UNICEF *Integrated Community Case Management* (iCCM) strategy for diarrhea, pneumonia, and malaria launched in 2011 offered a community-level, rather than health care facility, focus for disease prevention and treatment. The aim of this program is to enhance preventive activities such as exclusive breastfeeding for the first 6 months of life, improved vaccine coverage for rotavirus as well as *Streptococcus pneumoniae* and *Haemophilus influenzae* type b (the two most common bacterial causes of childhood pneumonia, measles, and pertussis), ORS usage, and improve water and sanitation access in health care facilities with accompanying hygiene practices.

Despite resurgence in the use of community health workers in the delivery of case management of childhood illnesses, evaluations of these community-based strategies suggest that the quality of services is poor (Strachan et al. 2012; Gill et al. 2013). Contributing factors include: poor incentives to attract or retain workers, inadequate training, no systematic approach to supportive supervision, and limited provision of appropriate treatments such as antibiotics, pre-packaged ORS, and zinc to community health workers despite their skills and access to communities.

The recently announced WHO/UNICEF *Integrated Global Action Plan for the Prevention and Control of Pneumonia and Diarrhea* (GAPPD) offers a more comprehensive approach to addressing childhood diarrhea (and pneumonia) by providing a cohesive policy framework upon which local political and civil society

leaders take the lead in the development of coordinated strategies. In so doing, the GAPPD aims to: close service delivery gaps by bringing together critical services and interventions, promote best practices and proven strategies, and establish healthier environments. The effectiveness of this integrated, multidimensional approach that attempts to speak across sectors is yet to be determined.

One concern with the GAPPD approach is the lack of direct attention to addressing social drivers of disease, including the promotion of poverty alleviation, improvement of water infrastructure, or assessing whether local communities are interested in the approaches suggested and are willing to comply. For example, an analysis of 15 highly cost-effective interventions for the reduction in childhood diarrhea (see Bhutta et al. 2013) published to coincide with the announcement of the GAPPD did not include estimations for broader-based investments in water infrastructure, focusing instead on biomedical/health care facility solutions. A qualitative analysis of the discussions of the multicountry workshop consultations, which ultimately led to the development of the GAPPD, identified limited or no country-level awareness and support for water, sanitation, and hygiene initiatives (Gill et al. 2013). This lack of national engagement in discussions of water and sanitation improvements possibly reflects the perceived magnitude of resources that are needed to develop or upgrade effective water supply and sanitation systems. This lack of conversation also highlights inequities in current geopolitical arrangements as country ministries feel beholden to the priorities of multilateral funders (Gill et al. 2013), resulting in external interests that are quickly implemented and easily monitored being favored over longer-term national priorities, possibly contributing to limited national political will and civic engagement. The result is limited attentiveness to the underlying causes of disease: poverty, inequality, and social marginalization.

Considering the Social Aspects of Disease: The Syndemic Perspective

The term *syndemic* is a portmanteau derived from the Greek work *synergos*, meaning two or more agents working together to create a greater effect than each working alone; and *demos*, or "people," commonly used in public health concept of epidemic, a disease classification that literally means "upon the people." Much like the synergistic effect of multiple drug agents working simultaneously in a system, whereby the total response is more than the predicted sum of the two individual effects, the synergistic interactions of disease conditions that are perpetuated by social disparities generates a syndemic (Fig. 1). The syndemics perspective recognizes that adverse social conditions, including social inequality, marginality, poverty, and other forms of political and economic oppression, play a critical role in facilitating the clustering of both infectious and noninfectious diseases that lead to heightened potential for deleterious disease interactions (Singer 2009).

While the development of a syndemic could indicate less overt inequalities in need of investigation, usually with infectious diseases we are arguing that conditions of poverty or other disadvantages (e.g., malnutrition, trauma, stress, environmental

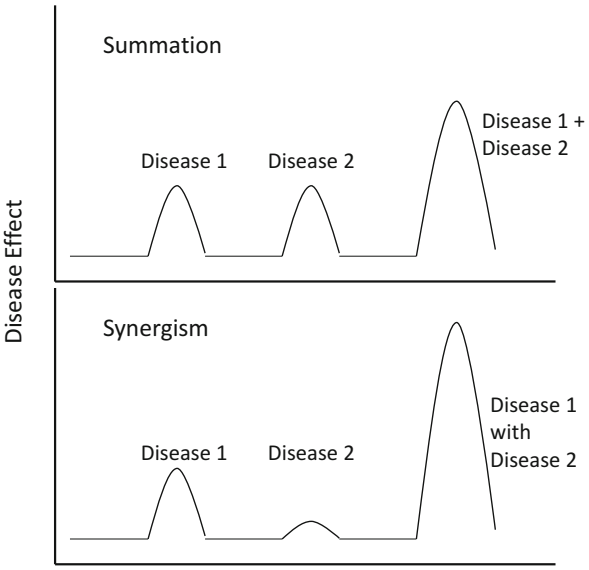

Fig. 1 Summative versus synergistic effects of co-occurring diseases. Under certain social conditions, the clustering of diseases in a specific population may be exacerbated given both micro-parasitism and macro-parasitism relationships

toxins) place bodies at heightened risk for diminished immune capacity, diminished body development and repair, and heightened exposure to pathogens and pathogen clustering interaction. Moreover, disadvantaged populations commonly face multiple infectious agents rather than a high burden of infection from a single pathogen, and these, in turn, often have the capacity to interact within human bodies to multiply their adverse effects. Syndemics theory therefore rests on recognition that health issues are never matters of biology alone but rather involve continuous bidirectional feedbacks between biological and social structure (Singer et al. 2017).

In the case of diarrhea causing enteric infections, the syndemic framework offers an understanding of the complex and dynamic relationship between *micro-parasitism*, the biological proximate causes of disease, and *macro-parasitism,* the human relations that are the ultimate origins of much disease. Globally, diarrhea is of gravest threat to populations already at comparatively high risk for a range of threats to health and social well-being. In this, diarrheal disease both exposes the vast inequities of our prevailing global social structure and the limitations of current national infrastructures to respond effectively and justly to disease.

Syndemic Interactions: Social Conditions

Latest global epidemiological estimates on childhood diarrhea project that only 2% of diarrhea episodes progress to severe disease, with a worldwide case-fatality ratio of 2% (CL Walker et al. 2013). However, diarrhea incidence and case-fatality ratios are much higher within low-income countries than in middle- and high-income countries. Asian and African world regions retain the greatest proportion of severe

diarrhea episodes at 26%. Fifteen countries (Afghanistan, Angola, Burkina Faso, China, Democratic Republic of the Congo, Ethiopia, India, Indonesia, Kenya, Mali, Niger, Nigeria, Pakistan, Tanzania, and Uganda) account for 53% of the total episodes of diarrhea globally and 56% of severe episodes. In 2011, 74% of the total burden of diarrhea mortality in children under 5 years was in these countries. The highest number of childhood deaths due to diarrhea in 2015 occurred in India (117,285) followed by Nigeria (76,980) (WHO 2015).

Infrastructural limitations and poverty conditions significantly increase exposure to diarrhea-causing pathogens. A UNICEF analysis based on 2015 estimates from the WHO and Maternal and Child Epidemiology Estimation Group and the UNICEF global databases from 2016 shows the negative relationship between improved sanitation facilities and under-five morbidity due to diarrhea (UNICEF 2017). However, infrastructural improvements are not enough; even within marginalized communities there are gradations of unhealthy environments that predispose children to increased burdens of disease. In India, for example, where 44% of the population practice open defecation, down from 75% in 1990 (WHO/UNICEF 2017), children are two standard deviations shorter than the reference mean (Spears 2013). Even children in the richest households in India are shorter than the international reference norms (Tarozzi 2008). While this may be interpreted as an inappropriate use of international normalizing standards (Panagariya 2012), Spears (2013) argues that the practice of open defecation creates a disease environment that exposes all residents to disease pathogens, although to varying degrees based on household economic capital and place of residence. In India, recurrent diarrhea and death from diarrhea are much more common among the lowest wealth index (Lahariya and Paul 2010; Avachat et al. 2011) despite somewhat universal exposure to diarrhea-causing pathogens.

Syndemic Interactions: Disease-Disease

Interactions of diarrhea pathogens with other disease states have been well documented (Singer 2010). Concurrent infections with intestinal helminth parasites have been shown to impair host immunity to enteric pathogens (Chen et al. 2005; Weng et al. 2007; Su et al. 2012). Among 30 hospitalized patients with strongyloidiasis (round worm) infections in central Kentucky state, 16 (53%) were found to have extraintestinal infections, with enteric organisms identified in 13 (81%) of these patients (Al-Hasan et al. 2007). Reasons for these relationships are not well understood, but warrant greater investigation.

Children living in diarrhea endemic areas are often at higher risk for other infectious diseases that are likely to have syndemic interactions with other pathogens, such as HIV/AIDS, pneumonia, malaria, tuberculosis, and measles. For example, a study of children under 2 years in Kenya revealed significantly greater episodes of diarrhea in children infected with HIV as compared to those without HIV (van Eijk et al. 2010). Conditions of marginalization increase the likelihood of exposure to diarrhea pathogens and contribute to HIV infection in infants. Barriers to

the prevention of mother-to-child-transmission of HIV in southern Africa overlap with factors that contribute to higher diarrhea burdens, including lower maternal education level, limited health service accessibility, and medical staff shortages (Gourlay et al. 2013).

In addition to HIV, children with measles have a greater likelihood of diarrhea. A prospective study of children in India in the late 1980s found that 25% of those with measles had associated diarrhea, and the diarrhea was significantly more dysenteric in nature (Deivanayagam et al. 1994). A more recent, multicountry study (children in the Democratic Republic of Congo, Ethiopia, India, Nigeria, and Pakistan) revealed a 12–22% reduction in diarrhea cases among children who received the measles vaccine in all countries except Ethiopia (Bawankule et al. 2017). Diarrhea associated with measles has compelled enhanced emphasis on the inclusion of measles vaccines in the GAPPD program.

Syndemic Interactions: Gut Microbiota

Extensive research exists on the dynamic relationships between malnutrition-and-diarrhea and increasingly environmental enteropathy (EE)-and-diarrhea. In isolation, malnutrition is well recognized as a widespread health problem, accounting for 11% of the total global DALYs (disability adjusted life years) (Black et al. 2008). In association with diarrhea, malnutrition is responsible for 53% of deaths in children under 5 years (Kosek et al. 2003). In an elegant study in mice, Coutinho et al. (2008) revealed the synergistic damage of the intestinal architecture caused by malnutrition and diarrheal pathogens, consequently limiting nutrient absorption. EE, the condition resulting from chronic exposure to fecal pathogens, is also marked by alterations in intestinal architecture and increased intestinal inflammation (Korpe and Petri 2012; Lin et al. 2013), and causes alterations in gastrointestinal tract (GIT) microbiota, which contributes to variation in mucosal immunity. Recent study findings indicate that rotavirus and oral polio vaccines are less effective in children who are malnourished and/or experience two or more episodes of diarrhea in their first month of life (Haque et al. 2014). Reasons for this are not well understood, although the findings indicate a complex interrelationship between diseases, immune response, and gut microbiomes, further suggesting the potential importance of syndemic interaction.

GIT microbiota are essential for the development of the gut-associated lymphoid tissue and play a vital part in shaping the immunological repertoire of the GIT (Mayer 2003; Quigley 2008), regulating the epithelial barrier function and GIT motility, and providing support for digestion and host metabolism. Microbiota prevent colonization by pathogens in large part through competition for nutrients and access to adhesive sites and receptors on the epithelial surface (Sekirov et al. 2010). Evidence suggests that GIT microbiota are 3–4 times lower following episodes of acute diarrhea (Albert et al. 1978; Tazume et al. 1990; Tazume et al. 1993). Iatrogenic suppression of GIT microbiota that occurs following antibiotic use, perhaps for repeated episodes of diarrhea or other bacterial and viral infections

including pneumonia and measles, can also disturb the normal mechanisms of GIT microbiota and possibly increase the likelihood of subsequent pathogenic infections (Cryan and O'Mahony 2011). Finally, normal colonization of the gut appears to commence at birth (Palmer et al. 2007). The microbiome of unweaned infants is simple, becoming more diverse and numerous after 1 year of age due to diet and environment (Kurokawa et al. 2007; Palmer et al. 2007). This makes infants and young children especially vulnerable to infection by multiple enteric pathogens, a process further facilitated by weaning from the protective components of breast milk. High-stress environments experienced by children living in marginalized conditions may alter the GIT microbiome sufficiently enough to increase the likelihood of repeated pathogenic infection by various microorganisms causing moderate-to-severe diarrhea in children.

Syndemic Interactions: Pathogen-Pathogen

Diarrhea-causing pathogens may also be interacting with each other in ways that increase the severity of disease symptoms, as co-infections are frequent. Recent findings of the Global Enteric Multicenter Study, a prospective case-control study of hospitalized pediatric patients with moderate-to-severe diarrhea in seven diverse sites in Africa and Asia (Kotloff et al. 2013), suggest that co-infection with multiple diarrhea-causing pathogens is common, at least among children with symptoms severe enough to interact with the formal health system. One or more pathogens were identified in 83% of diarrhea cases (compared to 72% in controls) and two or more agents in 45% of cases (compared to 31% in controls). Similarly in Brazil, 14% of previously collected rotavirus positive samples contained enteric adenovirus or norovirus (Ferreira et al. 2010). In India, diarrheal stool specimen analysis revealed that 63% of specimens had polymicrobial infections (Sinha et al. 2013).

The interactions between enteric pathogens that cause diarrhea are not yet fully understood. However, research is emerging that offers an indication of possible synergistic effects of pathogens in promoting disease. Observational studies suggest that molecular interactions may occur as a result of co-infections that exacerbate disease symptoms. For example, a prospective study of pediatric patients hospitalized for acute gastroenteritis in Rome, Italy, identified co-infection in 18% of patients (Valentini et al. 2013). Co-infected patients experienced more severe clinical presentations. A case-control study of 22 communities in Ecuador found evidence of rotavirus-Giardia and rotavirus-*E. coli* co-infections (Bhavnani et al. 2012). Researchers reported that during co-infection the pathogenic potential of each agent appeared enhanced. Collectively, these findings suggest that moderate-to-severe diarrhea in children may be the consequence of microbial interactions. Of course, these findings might also serve as markers for poor social conditions, whereby multiple pathogens are able to infect children, although not acting synergistically to worsen health outcomes. Additional investigations are needed to tease out the molecular and anatomical level interactions that may or may not be contributing to more severe clinical presentations.

As outlined, these complex relationships between disease states, pathogens, and microbiota suggest an adverse feedback loop involving high-stress environments resulting from social conditions of poverty and marginalization with diarrheal disease. These relationships are accelerated by and accelerate the development of multidisease syndemics that increase the burden of disease and negatively impact the social condition of sufferers (e.g., costs of care, long-term health impacts).

Syndemic Approaches to Childhood Diarrhea Management

Given the syndemic nature of childhood diarrhea, we believe that responses that address both disease and social interactions are likely to prove more effective in the long term. In Brazil, progressive social policies that complement the country's market-oriented reform policies provide a platform for a comprehensive syndemic approach to childhood diarrhea prevention. Policies on poverty alleviation and reduction of inequalities are in line with historical evidence that suggests that improvements in living conditions, not direct biomedical interventions or only improved supplies of water and sanitation services, have a more significant influence on reducing infectious diseases (McKeown 1978; Wegman 2001). Although also attempted in other countries in different ways, Brazil's *Bolsa Familia Program* (BFP) is the world's largest conditional cash transfer program for poverty reduction. Initiated in 2003, BFP distributed funds to over 25% of Brazil's population, or 13.4 million families in 2011, with a total budget of US$11.2 billion (Ministerio do Desenvolvimento Social e Combate a Fome 2013). Cash transfers range from US$18 to US$175 per month, depending on the income and composition of the family (Lindert et al. 2007). The conditional cash transfers require that children are sent to school where they receive at least one meal per day, vaccinations are completed per the Brazilian immunization program schedule (including rotavirus vaccine), routine health check-ups and growth monitoring are maintained per Ministry of Health guidelines, and women attend post-natal care services and receive health and nutritional education. An analysis of the effects of BFP on child survival revealed that under-five mortality decreased as program coverage increased, with the greatest positive impact occurring on poverty-related malnutrition and diarrheal disease (Rasella et al. 2013).

The BFP and other conditional cash transfer programs are not without their limitations and may not be appropriate in all situational contexts, particularly given the significant national investment required and potentials for misappropriation of funds. Nevertheless, the syndemic perspective presented here indicates that greater involvement of diverse stakeholders and strategies with equal or greater investments on improving social conditions can effectively address the biosocial dynamics of childhood diarrheal disease. The success of the BFP suggests that by operating through multiple mechanisms – improving social conditions by decreasing poverty and barriers to health care; improving food access and education; providing biomedical technology that directly addresses specific diarrheal diseases and

disease-disease interactions – as per the syndemic perspective results in significant improvements in childhood diarrhea.

Implications

Given the complex nature of childhood diarrhea including interactions between existing disease conditions, pathogens, gut microbiota, and social environments, the syndemic perspective offers a way forward for potential interventions. Interventions that focus only on technologically advanced biomedical strategies are likely to have only minimal impact or fail completely, as they do not address the social conditions of marginalized populations that promote disease clustering. However, only addressing the macro-level factors influencing childhood diarrhea, bypassing the disease completely, also has limitations. For example, in an effort to improve water distribution, particularly during times of scarcity, the Tanzanian government implemented pilot programs of a form of water "rights and fees" (World Bank 1996). A consistent year-round water supply is necessary for hygiene and sanitation practices and food productivity thereby indirectly reducing exposure to enteric pathogens and preventing malnutrition. The program requires that all commercial water users register with the government and pay a fee to obtain a "water right" which entitles them to an annual value of water resources. Evaluations of this program suggest that this form of government taxation has generated greater income and health inequalities, disproportionately burdening small-scale land owners who cannot afford to purchase the "water rights" (van Koppen et al. 2004).

Improving social conditions among marginalized communities is often considered outside the realm of health care, and consequently infrequently the focus of global public health interventions. Yet, history suggests that approaches that involve both the social and biomedical prove the most advantageous. As noted by Farmer and Becerra (2001):

> epidemic and endemic disease – are not solely biological; neither are they purely social. Yet, conventional studies typically rely on disciplinary approaches and fail to reveal the full complexity of these epidemics. Only by embracing a transdisciplinary, biosocial approach can we hope to describe fully these 'tropical' epidemics, and intervene successfully.

The GAPPD represents an emerging paradigm for global health by emphasizing diagonal financing and structuring (Ooms et al. 2008) (aiming for disease-specific results through improved health systems), with plurality across multiple sectors, collaboration between public and private partnerships, and local ownership. Programs like Brazil's BFP prove that such diverse approaches, although requiring significant national investment and coordination, can have profound effects on improving health conditions of marginalized communities. See Table 1 for an overview of current approaches to addressing childhood diarrhea.

Syndemics represent a critical element in the health profiles of disparity populations and constitutes an important contributor to addressing health inequality.

Table 1 Overview of current approaches to childhood diarrhea in comparison to an approach that considers the syndemic nature of ill health in addressing both disease agents and social factors

	Current approaches to childhood diarrhea			Syndemic approach
Program	*Integrated management of childhood illness*	*Integrated community case management*	*Integrated global action plan for the prevention and control of pneumonia and diarrhea*	*Bolsa Familia program, Brazil*
Aims	• Improving case management skills of health care staff for accurate identification of illness • Improvements in overall health system to ensure appropriate combined treatment of all major illnesses • Boosting community health practices to ensure appropriate care seeking, care management, and preventive practices	Aims to enhance preventive activities: • Exclusive breastfeeding in first 6 months of life • Improved vaccine coverage • ORS usage • Improved water and sanitation access in health care settings with accompanying hygiene practices	Cohesive policy framework aiming to: • Close service delivery gaps • Promote best practices and proven strategies • Establish healthier environments	Conditional cash transfer program requires that: • Children are sent to school • One meal per day at school • Vaccinations are complete per the Brazilian immunization program schedule • Routine health check-ups and growth monitoring are maintained • Women attend post-natal care services
Pros	Costs up to six times less per child than standard of care Improves nutritional status and reduces under-five mortality (WHO 2016)	Resurgence of community health workers in delivery of case management of childhood illness	Integrated, multidimensional approach	Decrease in under-five mortality, with greatest impact on diarrheal disease and malnutrition (Rasella et al. 2013)
Cons	"Good" care is low in high diarrhea burden countries (Carvajal-Velez et al. 2016) Inequitable supply of key commodities and unequal provision, limited funding, poor coordination, inadequate advocacy, delayed national policies (Gill et al. 2013)	Poor incentives to attract or retain community health workers, and limited provision of appropriate treatments (Strachan et al. 2012; Gill et al. 2013)	Lack of direct attention to addressing social drivers of disease, or assessing interest and willingness of local communities to comply (Gill et al. 2013)	Significant national investment and coordination, with potential for misappropriation of funds

The study of syndemics has been termed a "promising new frontier for public health action in response to the critical challenges of our time" (Leischow and Milstein 2006). A *Lancet* Series on syndemics highlights key ways in which the syndemic framework can advance public health approaches to specific diseases like childhood diarrhea (Hart and Horton 2017; Mendenhall 2017; Mendenhall et al. 2017; Singer et al. 2017; The Lancet 2017; Tsai et al. 2017). First, social, political, and ecological factors are recognized as both creating and perpetuating structural vulnerabilities that contribute to syndemic interactions. Second, an understanding of how certain individuals and groups, and not others, are vulnerable to certain syndemics is offered. Third, current strategies of prevention and care are strengthened by considering the full scope of vulnerabilities and intervening at policy and clinical levels to address the root causes of sickness and disease treatments.

Policies and Protocols

- The biosocial nature of diarrhea-related malnutrition must be acknowledged, with any intervention addressing disease combining efforts to address both the biological and social components, including a reduction in poverty and inequality, improved infrastructure and housing, and access to education and health care.
- Interventions targeting diarrhea-related malnutrition must work across government sectors, including health care, economy, housing, and infrastructure to prove effective.
- Marginalized individuals and communities must be encouraged to participate in health maintenance. Supportive social structures can include incentives, such as free meals at school and free access to preventive health care services.

Dictionary of Terms

- **Syndemic** – The adverse interaction of two (or more) diseases or health conditions within a specific population given exacerbating social factors.
- **Syndemic interaction** – The co-occurrence of social and health conditions, including social–psychological, social–biological, and psychological–biological interactions, which worsen the condition of the person or population afflicted.
- **Syndemic perspective** – The recognition that adverse social conditions, including social inequality, marginality, poverty, and other forms of political and economic oppression, play a critical role in facilitating the clustering of both infectious and noninfectious diseases that lead to heightened potential for deleterious disease interactions.
- **Syndemic approach to childhood diarrhea** – Comprehensive and multipronged approaches that address both proximal causes of disease (e.g., improved access to rotavirus vaccine, treatment antibiotics, rehydration solutions, improved sanitation and hygiene infrastructure) and macro social factors (e.g., policies on poverty alleviation, reduction of inequalities, and improvements in living conditions).

Summary Points

- This chapter draws on available research and current policy agendas, to examine current approaches to diarrheal disease management in order to consider novel comprehensive disease prevention approaches, consistent with syndemic theory, that are likely to prove effective in generating sustainable and equitable disease prevention solutions.
- Diarrhea remains the second leading cause of death in children under 5 years. Moreover, frequent bouts of diarrhea result in irreversible limitations on physical and cognitive development, particularly in marginalized communities. Children are especially vulnerable as they are unable to mount an active immune response to pathogen exposure and these biological limitations are exacerbated by social conditions.
- Syndemic theory offers a platform to explore the role of adverse biosocial interactions that increase the total disease burden of diarrhea-related malnutrition in low-resources populations and assess the limitations of recent global calls to action.
- The syndemic perspective describes situations in which adverse social conditions, including inequality, poverty, and other forms of political and economic oppression, play a critical role in facilitating disease-disease interactions.
- Given the complex micro and macro nature of childhood diarrhea-related malnutrition, including interactions between pathogens, disease conditions, and social environments, the syndemic perspective offers a new approach to disease management. While rarely the focus of health interventions, the syndemic approach suggests a coupling of advanced biomedical technologies with economic and political interventions that address the social conditions of disparity.

[one or more of the prerequisites of] security, enabling persons to assume their responsibilities into the society and to enjoy basic rights. A review of the literature published over the past 16 years (2000–2016) was performed to analyze the association between metabolic syndrome and social deprivation. Of the 652 references reviewed for title and abstract, 78 studies were selected and 55 articles were considered. The absence of uniformity in the measures used to assess metabolic syndrome and social deprivation requires some modulation of the results of our analysis. The studies were classified according to the Human Development Index (HDI) of the countries where they took place. The principal risk factors identified for metabolic syndrome are a low educational level (women especially), low income, occupation (specifically an unskilled job or absence from the labor force), and greater socioeconomic deprivation, measured by composite indices. These results are stable according to HDI level.

In conclusion, access to education, the possibility of superior education, and the acquisition of occupational credentials are three themes to prioritize in developing public health policies, irrespective of the country's level of development.

Introduction

The metabolic syndrome (MetS) is a set of disorders that includes elevated fasting glucose, high blood pressure, dyslipidemia, and abdominal obesity and is responsible for an increased risk of all-cause and cardiovascular mortality (Isomaa et al. 2001; Lakka et al. 2002; Hu et al. 2004; Eckel et al. 2005). The pathophysiologic basis of this syndrome is complex, and its first-line management consists of dietary and lifestyle changes, including a reduction in the intake of both calories and atherogenic fat as well as an increase in physical activity (Eckel et al. 2010).

Social deprivation has been defined by J. Wrezinski as "the lack of [one or more of the prerequisites of] security, such as a job, enabling individuals and families to assume occupational, family, and social responsibilities and to enjoy basic rights" (Wrezinski 1987). At the same time, Townsend defined the concept of deprivation as a "state of observable and demonstrable disadvantage relative to the local

community or the wider society to which an individual, family or group belongs." He applied this concept to conditions rather than resources and distinguished between deprivation and poverty (Townsend 1987). He also argued that deprivation is the main cause of inequalities in health and developed an index to measure deprivation over given geographic areas (Carstairs and Morris 1989).

This analysis of the association between MetS and social deprivation is based on a review of the literature published over the past 16 years (2000–2016), identified by a search on PubMed. The keywords used for this search were metabolic syndrome, psychosocial deprivation, economic status, and socioeconomic status. In all, 652 references were reviewed by title and abstract and 78 studies were selected for complete reading. Only the 55 articles with multivariate analyses were considered in this review.

The absence of uniformity in the measures used to assess MetS and social deprivation requires some modulation of the results of our analysis. We report here the different measures used to assess MetS and social deprivation as well as their association. Finally, we also analyze the association between this syndrome and social deprivation together with other factors, such as sex and level of education.

Key Principles

Definitions of Metabolic Syndrome

Its first recognized definition was established by the World Health Organization (WHO) and emphasized impaired glucose regulation in particular (Alberti and Zimmet 1998). Subsequent definitions included one by the National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATPIII) and another by the International Diabetes Foundation (IDF) (Alberti et al. 2005, 2006; Grundy et al. 2004). Finally, in 2009, several international medical federations and societies reached a consensus and established a harmonized definition that enables international comparisons (Alberti et al. 2009). Definitions by the following groups were used in the selected studies, listed in order of decreasing frequency: NCEP-ATPIII, the harmonized definition, American Heart Association (AHA), IDF, and WHO (Table 1). Thirteen studies measured the prevalence of the MetS with at least two definitions.

Measures of Deprivation

Validated tools exist for measuring social deprivation. Some are ecological area measures, by geocoding; the most frequently used are those by Townsend, Carstairs, and Pampalon. The principal individual tool is the EPICES score (Pampalon and Raymond 2000; Townsend 1987; Carstairs and Morris 1989). Among the selected studies, three used the EPICES score, while the others did not use any specific measure of social deprivation. The indicators used in these studies, in order of

Table 1 Definitions of the metabolic syndrome

	WHO 1998	NCEP-ATP III 2001	AHA 2005	IDF 2006	Harmonized definition 2009
Metabolic syndrome	Glucose intolerance, IGT or T2D and/or IR + 2 or more criteria	3 or more criteria	3 or more criteria	Abdominal obesity + 2 other factors	3 or more criteria
Waist to hip ratio and/or BMI	M > 0.90; W > 0.85 >30 kg/m^2				
Waist circumference (cm)		M > 102 W > 88	M > 102 W > 88	Europe: M ≥ 94; W ≥ 80 South Asians/ Chinese M ≥ 90; W ≥ 80 Japanese: M ≥ 85; W ≥ 80	Population- and country-specific definitions
Blood pressure (mmHg)	≥160–90	≥130/85	≥130/85 or med for HBP	sBP ≥130 or dBP ≥ 85 or med for HBP	sBP ≥130 and/or dBP ≥ 85 or med for HBP
Triglycerides mmol/l (mg/dL)	≥1.7 (150)	≥1.7	≥1.7	≥1.7 or med for HTG	≥1.7 or med for HTG
HDL-C mmol/l (mg/dL)	HTG and/or M < 35; W < 39	M < 1.0; W < 1.3	M < 1.0; W < 1.3	M < 1.0 (40); W < 1.3 (50) or med for rHDL-C	M < 1.0; W < 1.3; or med for rHDL-C
Fasting glucose mmol/l (mg/dL)	IGR or T2D, IR	≥6.1 (110)	≥5.6 (100) or diagnosed T2D	≥5.6 or diagnosed T2D	≥5.6 or T2D
Others	μalb ≥20 μg/min or acr ≥ 20 mg/g				

WHO World Health Organization, *NCEP-ATP III* American National Cholesterol Education Program Adult Treatment Panel III, *AHA* American Heart Association, *IDF* International Diabetes Federation, *IGT* impaired glucose intolerance, *T2D* type 2 diabetes, *IR* insulin resistance, *BMI* body mass index, *M* men, *W* women, *sBP* systolic blood pressure, *dBP* diastolic blood pressure, *med* medication, *HBP* high blood pressure, *HTG* hypertriglyceridemia, *HDL-C* high density lipoprotein cholesterol, *rHDL-C* reduced HDL-C, *IGR* impaired glucose regulation, *μalb* microalbuminuria, *ac* albumin/creatinine ratio

decreasing frequency, were educational level, income, occupation category (including nonparticipation in the labor force), social class, and simple or composite indices of poverty.

Association Between Metabolic Syndrome and Deprivation

The studies were classified according to the Human Development Index (HDI) of the countries where they took place. The HDI scores used here come from the 2014 United Nations Development Program (Programme des Nations Unies pour le Développement 2015).

Main Conclusions

The principal risk factors identified for MetS are a low educational level, low income, occupation (specifically an unskilled job or absence from the labor force), and greater socioeconomic deprivation, measured by composite indices. The role of educational level appears to differ between men and women, with a low educational level consistently found to be a risk factor for women but not men. These results are stable according to HDI level.

In countries with a very high HDI [0.800; 1], Lidfeldt et al. included women from 50 to 60 years old at the time of the study. They found that MetS was more frequent among women with low educational level compared with women having a university degree. On the other hand, no association was found between MetS and working status in this population (Lidfeldt et al. 2003). Park et al. performed two cross-sectional studies in 1988–1991 and 1991–1994 in the general population aged 20 years old or above. Low participant's household income in women was the sole factor identified to associate with higher prevalence of MetS. Education was not associated with MetS neither in men nor in women (Park et al. 2003). Carnethon et al. used the education level to explore socioeconomic status among young adults in the Coronary Artery Risk Development in Young Adults (CARDIA) study and found that low educational level was associated with MetS in women only and irrespective of the women ethnic groups (Carnethon et al. 2004). Dallongeville et al. found that MetS decreased with high educational level both in men and women. High household income (estimated by family income tax) and high occupational categories were at low risk of MetS in women only. Finally, tenants were at higher risk of MetS than owners, irrespective of the gender (Dallongeville et al. 2005). Langenberg et al. who included persons 53 years old in 1999 found that least educated people were at higher risk of MetS in men only. No evidence was found for social class irrespective of the sex (Langenberg et al. 2006). Loucks et al. focused their study on civilian non-institutionalized population aged at least 25 years old and showed that low education is related to MetS both in men and women. The research team used the poverty income ratio (PIR), which is the ratio of the midpoint of

observed family income category to the official poverty threshold, and found no significant result (Loucks et al. 2007). Perel et al. included people aged from 35 to 55 years old based on office staff. Education, employment grades, annual personal income, annual household income, and amounts of money the respondent would have if all household assets were cashed and debts all paid were assessed. In men, low employment grades, low annual personal income, low annual household income, and low amount of money were associated with MetS, whereas for women, this association was found for low education only (Perel et al. 2006). La Rosa et al. used the EPICES score to measure deprivation among patients of health examination centers aged more than 16 years old and found that deprived patients were at higher risk of MetS (La Rosa et al. 2008). Lucove et al. included 25- to 50-year-old community-based persons; evaluated education, home ownership, employment status, and occupation; and found that high education level was at lower risk of MetS (Lucove et al. 2007). Park et al. included people age of more than 20 years old in general population and showed that women with high education and upper monthly income were at low risk of MetS, whereas no significant result was found for men (Park et al. 2007). Prescott et al. targeted people aged of at least 60 years old and evaluated duration of schooling, education, longest held occupation, and household income. They demonstrated that high education level was associated with low risk of MetS (Prescott et al. 2007). Salsberry et al. used also the PIR to measure deprivation status and that low PIR was related to MetS in women only (Salsberry et al. 2007). Chichlowska et al. studied family income and neighborhood Z-score in general population aged from 45 to 64 years old, stratifying on gender and ethnicity. For women, both low family income and low neighborhood Z-score were associated with high risk of MetS either in Black or White. For men, in Black only medium neighborhood Z-score was related to MetS and in White only intermediate family income (Chichlowska et al. 2008). Ramsay et al. assessed social class in a cohort at two times and found that manual class was at higher risk of MetS (Ramsay et al. 2008). Santos et al. evaluated MetS in non-institutionalized inhabitants of more than 40 years old in Porto and revealed that low education, housewives, and low social classes were associated with MetS in women only (Ramsay et al. 2008). Scuteri et al. included people aged from 42 to 52 years old and demonstrated that low education level was related to MetS, whereas no significant result was found for yearly income (Scuteri et al. 2008). Manuck et al. assessed deprivation with subjective socioeconomic status by Mac Arthur scale and objective socioeconomic status by education, annual family income, and computed measure by averaging standardized values of the two index variables for each individual. They demonstrated that both subjective and objective socioeconomic status and MetS were associated inversely (Manuck et al. 2010). Phillips et al. performed a study on men who served in Vietnam from 1965 to 1971. They used monthly income, household income in midlife, education, and index of occupational prestige to analyze socioeconomic status. They showed that men in the lower two groups of combined measures were at risk of MetS (Phillips et al. 2010). Riediger et al. explored education and income adequacy in the general population aged at least 18 years old. They revealed that people with high education and the highest income adequacy experienced lower risk of MetS

(Riediger and Clara 2011). Sygnowska et al. performed a study in general population aged from 20 to 74 years old, using education and per capita income with two definitions of MetS. They showed that in women, for the both definitions, higher education level was a protective factor (Sygnowska et al. 2012). Navarro et al. assessed MetS in postmenopausal Caucasian women by calculation poverty index based on annual income of the family. They found no significant results (Navarro et al. 2013). Al-Daghri considered patients of a primary health-care center aged from 18 to 70 years old regarding total monthly household income, occupation, and education. They showed that low income was the protective factor of MetS and that retired men and unemployed women experienced higher risk of MetS. They revealed also that education in women was inversely associated with MetS (Al-Daghri et al. 2014). Keita et al. focused their study on residents in the lower 48 states of the USA aged more than 45 years old and explored socioeconomic status by measuring neighborhood deprivation, education, and total annual household income. In White adults, the most the neighborhood deprivation is, the higher the MetS risk is (Keita et al. 2014). Yang et al. carried a study on person aged more than 20 years old on education, current occupation, equalized gross household income per month, and combined adult socioeconomic status. They revealed that in women, low educational level, manual and inactive, low equalized gross household income, and low combined adult socioeconomic status were associated with higher risk of MetS. On the other side, in men, low education level and manual and inactive were at lower risk of MetS (Yang et al. 2014).

Blanquet et al. used EPICES score on patients consulting in health examination centers aged at least 16 years old. The most deprived persons experienced higher risk of MetS (Blanquet et al. 2016). Gannar et al. used a combined measure based on income, crowding, and education on persons aged 18–75 years old in the general population. They revealed that higher combined measure was a protective factor of MetS in the Spanish population. Opposite results were found for Tunisian men (Gannar et al. 2015). Lim et al. studied education and economic status in patients aged more than 20 years old in a health center and did not found significant results. (Lim and So 2015). Ortiz et al. used the ENRICHD social support inventory and a combined measure of education and income (socioeconomic position) in adult of a former cohort (MESA Latino cohort). They showed that high socioeconomic position was a protective factor of MetS (Ortiz et al. 2015). Martin et al. performed a study on 25–54-year-old permanent residents of the Illawarra region, and they did not found any significant results (Martin et al. 2016). Klijs et al., who evaluated education and household equivalent income in a Dutch cohort aged more than 30 years old, revealed that low education was associated with higher risk of MetS (Klijs et al. 2016). The results are summarized in Table 2.

In countries with a high HDI [0.700; 0.800], Schooling et al. carried a study on persons aged at least of 50 years old and measured education and longest held occupation. They found that high education was a protective factor in women only (Schooling et al. 2008). Erem et al. explored in general population aged 20 years old or above education, occupation, and household income. They showed that education was inversely related to MetS and that housewives were at higher risk of MetS

Table 2 Studies performed in countries with a very high human development index

(Erem et al. 2008). Marquezine et al. measured socioeconomic classes through a population aged 25–64 years old in residents of the municipality of Vitoria. They revealed that the most deprived women experienced higher risk of MetS (Marquezine et al. 2008). Zuo et al. measured education and economic status among people aged 35–74 years old and found that low education level was associated with higher risk of MetS (Zuo et al. 2009). Silveira explored education and family income in persons born in 1982 considering two definitions of MetS. In women, low education was associated with high risk of MetS regardless of the definition, whereas upper family income was a protective factor (da Silveira et al. 2010). Ferguson et al. performed a study in 25–74-year-old people by measuring education and total monthly household income. For men, high education level and also high total monthly household income were associated with higher risk of MetS (Ferguson et al. 2010). Romaguera et al. considered education level of 36–82-year-old women for two MetS definitions and found that high education level was a protective factor when the IDF definition was used (Romaguera et al. 2010). Sidorenkov et al. included outpatient clinic in northwest Russia aged 18 years old or above and measured education and income without any significant results (Sidorenkov et al. 2010). Belfki et al. focused their study on 35–74-year-old persons in the general population and explored education and occupation. They showed that high education level was associated with higher risk of MetS, whereas intermediate occupation was a protective factor in men (Belfki et al. 2013). Gronner et al. measured education and family income in 30–79-year-old urban population and demonstrated that low education was at risk of MetS (Gronner et al. 2011). Tan et al. in 25–64-year-old citizens measured education, monthly household income, location of residence, length of typical work day, and activity involved by work and used IDF and NCEP-ATP III definitions of MetS. They showed that education was inversely associated with MetS, whereas income was positively related to MetS in the pooled sample, irrespective of the definition used (Tan et al. 2011). Ni et al. explored level of occupation and education in the general population aged 18 years old and above. Women with high socioeconomic status have low risk of metabolic syndrome (Ni et al. 2013). Zhan et al. evaluated years of education, personal monthly income, and household monthly income in the general population of adulthood. Women with high education level and high personal monthly income were at low risk of metabolic syndrome (Zhan et al. 2012). Podang et al. carried out a study based on the evaluation of education, monthly income, and types of job in a single enterprise among 25–54-year-old employees. In men, low level of education and low social class were risk factors of MetS. On the other hand, in women low monthly income was the sole factor identified to be at risk of MetS (Podang et al. 2013). Zhao et al. performed in a rural population (18–80 years old) a study measuring education and family economic level. The higher the education level was, the better the protective factor of MetS was. On the contrary, high family economic level was at high risk of MetS (Zhao et al. 2014). Lao et al. compared urban versus rural area in the general population and did not find any difference between these two areas (Lao et al. 2014). Enkh-Oyun et al. analyzed education, monthly income, and social class in Mongolian people aged 40 years old or above and found no significant results (Enkh-Oyun

et al. 2015). Ebrahimi et al. explored, in Iranian population aged 40–64 years old, education and home assets and revealed that education was a protective factor (Ebrahimi et al. 2016). Soysal et al. evaluated education and self-perceived economic status and measured MetS by using two definitions, IDF and NCEP-ATP III. They showed that low education and worst self-perceived economic status were associated with high risk of MetS irrespective of the definition (Soysal et al. 2016).

In countries with a medium HDI [0.550; 0.700] or low HDI (<0.550), Son et al. highlighted that homemakers and retired workers were at higher risk of MetS than unskilled workers in the general population (Son et al. 2005). Khanam et al. performed a study in a rural district of Bangladesh among 60-year-old people. They found that poverty, measured by household assets and housing characteristics, was a risk factor of MetS (Khanam et al. 2011). Kaduka et al. reported, in urban dwellers of Nairobi province aged from at least 18 years old, that high socioeconomic status was associated with higher risk of MetS both for men and women. In men only, higher degree of education was also associated with MetS (Kaduka et al. 2012). Adedoyin et al. measured salary level, annual income, occupation, and education for socioeconomic stratum in the resident of the Ilora community (30–70 years old) and found no significant results (Adedoyin et al. 2013). Binh et al. performed a study in the general population regarding education, occupation, and income and did not revealed any significant results (Binh et al. 2014). Finally, Villamor et al. recruited school-aged children and their family and found that women with high level of education were at low risk of MetS (Villamor et al. 2016) (Tables 3 and 4).

Policies and Protocols

Policies

Regardless of the country's level of development, access to education, the possibility of superior education, and the acquisition of occupational credentials are three themes to prioritize in developing public health policies.

It is also important that these policies do not focus on extreme poverty, which is different from social deprivation, a distinction clearly defined by Wrezinski and Townsend (Townsend 1987; Wrezinski 1987). Socially deprived individuals must be able to receive the appropriate management that they lack, policies of prevention and health promotion specifically designed for them, and the development of their capabilities in the health domain, especially through health literacy (Sørensen et al. 2012).

Protocols

Future research should use the validated composite deprivation indices, geographically coded (Carstairs, Townsend, and Pampalon), which exist or that are based on

Table 3 Studies performed in countries with a high human development index

Reference	Population	Socioeconomic status	Results of the multivariate analysis (ORa)
Schooling et al. 2008 (China)	≥50 years old in the members of a community social and welfare association	**Education** (≤primary school=low; junior middle school=medium; ≥senior middle school=high)	**Women**: (ref low): medium 0.77 [0.66; 0.90]; high 0.59 [0.45; 0.68] **Men**: *ns*

individual measure (the EPICES score) to enable the global comparison of results and to check the nature of the concepts measured – individual or geocoded measures of deprivation that have equivalent predictivity in terms of morbidity and mortality (Pampalon and Raymond 2000; Carstairs and Morris 1989; Townsend 1987; Labbe et al. 2015). This research should also use the harmonized definition so that the identification of risk factors of developing metabolic syndrome is not based on a waist measurement inappropriate to the population studied. This would also make it possible to conduct international comparisons.

As the results appear to differ by sex, it would be appropriate for studies to stratify their results routinely for this variable.

Dictionary of Terms

- **Metabolic syndrome** – a set of disorders including elevated fasting glucose, high blood pressure, dyslipidemia, and abdominal obesity (Eckel et al. 2010).
- **Social deprivation** – social disadvantage related to local conditions for people lacking socioeconomic security but not in extreme poverty.
- **Human Development Index (HDI)** – composite indicator based on three criteria: gross domestic product (GDP) per inhabitant, life expectancy at birth, and educational level.
- **Multivariate analysis** – analysis that simultaneously introduces several explanatory variables in a statistical analysis.
- **Capabilities** – diverse combinations of functioning (states and actions) that a person can accomplish; consequently capability is a set of vectors of functioning that indicate that the individual is free to lead a particular type of life (Sen 1999).
- **Health literacy** – "Health literacy is linked to literacy and entails people's knowledge, motivation, and competence to access, understand, appraise, and apply health information in order to make judgments and decisions in everyday life about health care, disease prevention and health promotion to maintain or improve quality of life during the life course" (Sørensen et al. 2012).

Summary Points

- Most of the studies have been performed in developed countries.
- In countries with very high HDI, 15 studies showed that high education was a protective factor, 9 studies showed that socioeconomic deprivation measured by composite index was a risk factor, and 8 studies revealed that low income was a risk factor too.
- In countries with high HDI, 12 studies identified that low education was a risk factor, and 6 studies found conflicted results regarding income.

- In countries with medium or low HDI, three studies and two studies found discordant results concerning association between education and MetS and poverty index, respectively.
- High level of education was the most frequent determinant identified in women population.
- Income was the most frequent factor identified in men but with conflicting results.
- Regardless of the country, public health policies must be adapted to the deprived and must have as their principal objective of the development of the capabilities of these individuals.

Future research must use as tools specifically validated measures of social deprivation.

Soup Kitchens: Homeless Adults and Gaps in Meeting Their Nutritional Needs

23

Lisa G. Sisson and Deborah A. Lown

Contents

Abstract

Homeless persons have multiple risk factors for malnutrition and have a greater prevalence of chronic diseases. Soup kitchens, where free meals are available to people in need, are the most common source of food for homeless persons and play a crucial role in meeting their nutritional needs. Homeless persons have special nutrient needs. Due to a high prevalence of excessive alcohol intake, smoking, and high body weight from high caloric alcohol intake they

are at risk for protein, vitamin, and mineral deficiencies. The nutritional content of soup kitchen meals does not meet their special nutrient needs. This food tends to be high in fat and sodium and lacking in essential micronutrients, instead exacerbating their chronic diseases. Dietary intake assessments of homeless persons indicate a low intake of fruits, vegetables, and dairy products and consumption of high amounts of fats, saturated fats, and sodium and low amounts of fiber.

These problems cannot be resolved by ad hoc charitable organizations; a systemic policy response to the nutritional status of the homeless is essential to address these issues. Increased allocation of funds for soup kitchens, mandatory nutrition standards, coordination among soup kitchens, educated staff, removal of barriers to enrolling in entitlement programs, and assisting the homeless with applying for benefits are all necessary steps to meet the nutrient needs of homeless persons.

Introduction

Homelessness, described as a state of not having a regular residence and either sleeping outside, or in temporary housing, is an issue all too common in developed industrialized nations (Shelter 2014). Consistent findings from studies of homeless persons suggest an accurate depiction of their health; they have multiple risk factors for malnutrition, including poverty, food insecurity, a high prevalence of substance abuse and smoking, and limited access to health care (Sisson and Lown 2011). Homeless people also have a greater risk for chronic diseases with a reported greater prevalence of hypertension, hypercholesterolemia, and diabetes, which are often under diagnosed and poorly treated resulting in premature death (Cheung and Hwang 2004).

Soup kitchens are locations where free meals are available for on-site consumption to people who do not live at the site, often located within organizations providing other services such as food pantries or shelters (Ohls et al. 2002). They are the most common source of food for homeless persons and play a crucial role in meeting their nutritional needs (Darmon et al. 2001; Johnson and McCool 2003;

Sprake et al. 2014). Homeless persons have a high prevalence of chronic diseases, substance abuse, and poor access to a healthy diet. In this review chapter focused on developed nations, we describe the common characteristics of homeless persons and review the characteristics of typical soup kitchens and the nutrients they provide. The nutrition, health status, and special dietary needs of homeless people are also summarized. The chapter concludes with suggested methods to improve the health and nutrition of homeless persons through improved food quality at soup kitchens and systemic policy changes.

Common Characteristics of Homeless Persons

In developed nations, the prevalence of homelessness is approximately 1% of the urban population (Turnbull et al. 2007). Homelessness affects a wide variety of people of which the majority are minority, single men (Hwang 2001). Single women, mainly older women, make up one quarter to one third of homeless persons. Homeless youth (15–25 years of age) constitute the remainder of homeless people (Hwang 2001). One third of homeless people are chronically homeless, defined as homeless for 1 year or four episodes of homelessness in their lifetime (McQuistion et al. 2014). Compared to first time homeless persons, chronically homeless persons are more likely to receive disability benefits, have chronic physical problems, higher rates of arrest, and higher prevalence of substance abuse without treatment (McQuistion et al. 2014). They are also more likely to be older as compared to first time homeless persons (Goering et al. 2002). A three-nation study found homelessness can be partially attributed to a lack of affordable housing and services (Crane et al. 2005). Differing policies across nations can result in varying economic climates contributing to homelessness. For example, health problems as a contributing factor to homelessness are lower in England with a national health care system, whereas gambling is a greater contributor in Australia due to legal gaming machines creating a greater risk for gambling debts (Crane et al. 2005).

As shown in Table 1 the median age of homeless persons is increasing; presently 30–50% of homeless people are 50 years of age or older (Crane et al. 2005; National Coalition for the Homeless 2009). The aging baby boomer cohort is one factor for the increase in the median age of homeless persons (Crane et al. 2005). Half of older homeless persons (>50 years of age) experience homelessness for the first time after the age of 50. Among older individuals, compounding risk factors for homelessness include chronic health problems preventing employment, financial crises, forced unemployment, mental health issues, substance abuse, lack of family and social support, widowhood, divorce, death of a parent, and prior incarceration (Crane et al. 2005). Older homeless persons in Boston, USA, London, UK, and Melbourne, Australia, were found to be mainly single men. Seventy-seven percent of these individuals experienced their first onset of homelessness between the ages of 54 and 60; 60% were previously employed, and 50% previously lived alone in a rented home (Crane et al. 2005).

The Emergency Food System and Characteristics of Soup Kitchens

Food insecurity, a prevalent problem throughout the world, exists whenever the availability of nutritionally adequate and safe foods or the ability to acquire acceptable foods in socially acceptable ways is limited or uncertain (Anderson 1990). Food insecurity may lead to periods of starvation interspersed with periods of binge eating when food is available (Hampton 2007). Hunger and malnutrition may or may not be present with food insecurity; however, it is positively associated with many adverse physical and mental health outcomes (Vozoris and Tarasuk 2013).

The emergency food system provides food for food insecure individuals and households who cannot meet their nutrient needs. It consists of private and public entities and partnerships, the majority being nonprofit faith-based organizations (Pettes et al. 2016; Ohls et al. 2002). The main types of emergency food providers are soup kitchens, food pantries, food banks, food rescue, or gleaning organizations and emergency food organizations (Ohls et al. 2002). Soup kitchens typically serve a variety of food insecure individuals and families, including immigrants, formerly incarcerated, sex workers, and individuals living with mental illness. However,

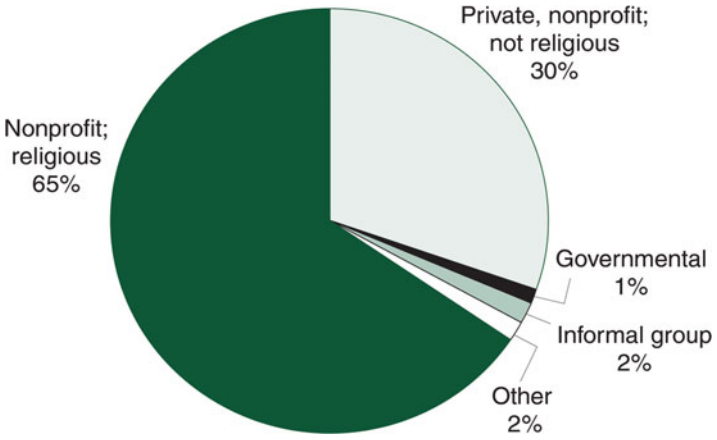

Fig. 1 Types of organizations operating soup kitchens (Ohls et al. 2002)

homeless persons make up the majority of those who utilize soup kitchens (Pettes et al. 2016).

Individual soup kitchens develop organically, while sharing an overarching goal of meeting the immediate food needs of those who utilize their services (Dachner et al. 2009). Soup kitchens are mainly charitable organizations and have limited budgets for food purchases. Most of their food consists of shelf-stable, refined, processed foods (Ohls et al. 2002) sourced through community donations, leftovers from places that serve food, farmers or growers, donations from manufacturers or wholesalers, and food banks. An additional source of food in the USA is The Emergency Food Assistance Program (TEFAP) of the United States Department of Agriculture (USDA), which provides agricultural commodities to soup kitchens (Pelham-Burn et al. 2014) (Figs. 1 and 2).

Soup kitchens are mainly staffed by volunteers with little to no specialized food or nutrition education resulting in meals of poor nutritional quality (Coppenrath 2001). Compounding this problem are the lack of policies relating to nutrition standards. Canadian kitchens often use nutrition standards to guide meal preparation (Pettes et al. 2016), while UK and US kitchens do not (Silliman and Wood 2011; Pelham-Burn et al. 2014) (Fig. 3).

Most soup kitchens are located in urban communities and provide food to an average of 100 individuals per meal. A small percentage of soup kitchens (15%) serve more than 200 people at a single meal (Ohls et al. 2002). Few soup kitchens are open for three meals a day, 7 days a week; most are open only for lunch during the work-week (Dachner et al. 2009; Ohls et al. 2002). According to Pettes et al. (2016) fewer than 65% of the surveyed soup kitchens were open year around and fewer than 50% served meals 5 or more days per week (Pettes et al. 2016). Soup kitchen directors have indicated there is an unmet need for food (Dachner et al. 2009) (Fig. 4).

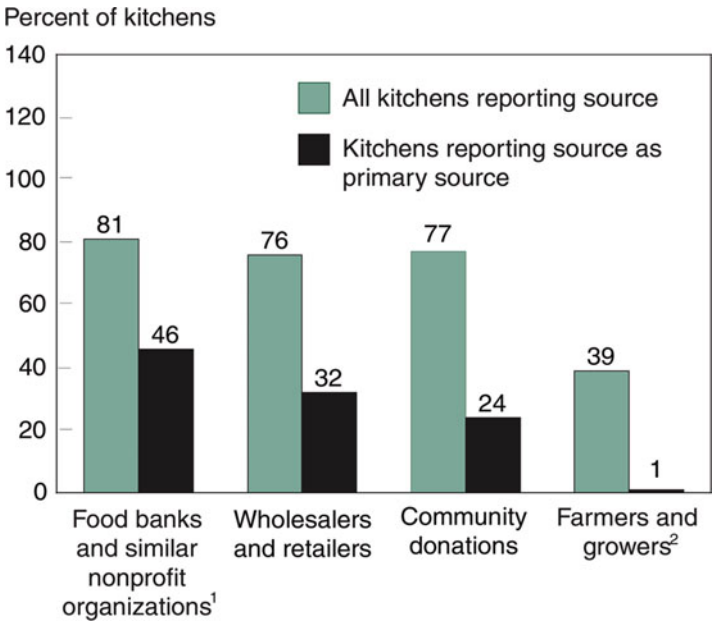

Fig. 2 Sources of food for soup kitchens (Ohls et al. 2002)

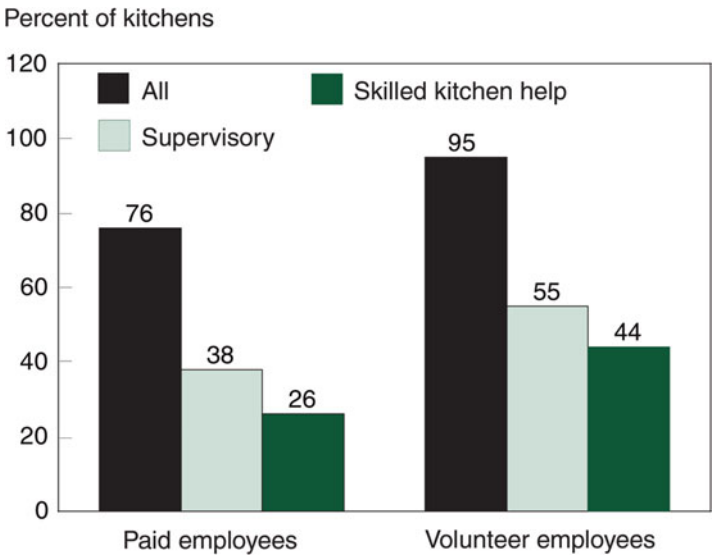

Fig. 3 Uses of paid and volunteer staff by soup kitchens (Ohls et al. 2002)

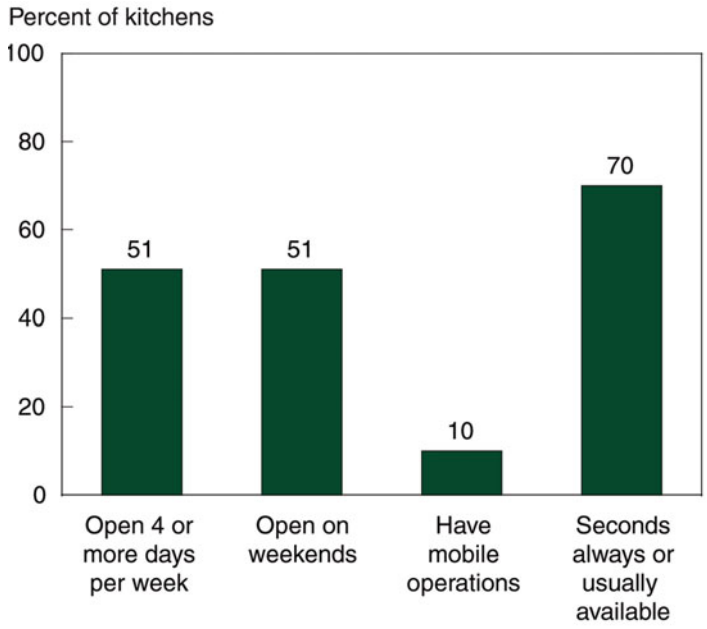

Fig. 4 Selected meal service characteristics of soup kitchens (Ohls et al. 2002)

Common Sources of Food for Homeless Populations

Statistics indicate that homeless individuals reliant on soup kitchens for their meals likely have access to only one meal 5 or fewer days per week. This is consistant with the average reported 1.4–2 meals consumed per day by homeless persons (Malmauret et al. 2002; Ohls et al. 2002). Forty percent of homeless persons, as compared to 3% of low-income households, report not eating for one entire day because they could not afford to buy food (Burt et al. 1999). Twenty-eight percent of American homeless adults as compared to 12% of low-income American adults said they sometimes or often do not get enough to eat (Burt et al. 1999).

Most homeless people obtain the majority of their food from soup kitchens (Darmon et al. 2001; Ohls et al. 2002; Sprake et al. 2014; Popma-Metsaars 2014). Other sources of food for homeless persons include fast food restaurants, convenience stores, community centers, and food purchased with money from panhandling or other income sources. However, these sources of food are seldom used because money is required. Additional food resources include dumpster diving, theft, friends and family, food pantries, and handouts from food sharing organizations (Mahadevan and Fischer 2010). In one study, 93% of homeless women reported eating regularly from dumpsters (Mahadevan and Fischer 2010).

Food assistance programs such as the Supplemental Nutrition Assistance Program (SNAP) in the USA are a potential source of funding for purchasing food; however, their usage is limited among homeless persons. Reports of the use of food assistance by homeless persons is highly variable with Mahadeven (2010) reporting 0% (Mahadevan and Fischer 2010); Obrien (2004), 19% (O'Brien et al. 2004); Martins (2015), 55% (Martins et al. 2015); and Popma-Metsaars (2014), greater than 80%. (Popma-Metsaars 2014). To enroll in food assistance programs, individuals require documentation, access to transportation, and a permanent address, which homeless persons often lack. Distrust of government oversight, bureaucracy, lack of knowledge regarding the programs, and ineligibility are additional reasons homeless persons may not partake in food assistance benefits (Nwakeze et al. 2003; Freedman and Bartoli 2013). Lack of participation results in food insufficiency, placing homeless persons at a high-risk for malnutrition, chronic diseases, and poor health outcomes (Vozoris and Tarasuk 2013).

Nutritional Content of Soup Kitchen Meals

Meals at soup kitchens are derived largely from donated foods which tend to be inexpensive items high in carbohydrates such as pastas, breads, and bakery products. These foods are calorie dense, high in total fat (Sisson and Lown 2011; Pelham-Burn et al. 2014; Silliman and Wood 2011) and saturated fat (Pelham-Burn et al. 2014; Sisson and Lown 2011; Davis et al. 2008), adequate in protein but lacking in fiber (Sisson and Lown 2011; Silliman and Wood 2011; Davis et al. 2008) and many micronutrients. The energy content of soup kitchen meals varies. Some findings indicate that adequate to excess calories are served (Sisson and Lown 2011), possibly contributing to obesity, while others indicate that inadequate calories are provided (Pelham-Burn et al. 2014). Studies found dairy, fruits, vegetables, and fish are unavailable or served in minimal amounts in soup kitchen meals (Ohls et al. 2002; Tarasuk et al. 2015; Davis et al. 2008).

The content of soup kitchen meals contributes to the malnutrition and exacerbates the chronic diseases of homeless persons. These meals commonly do not meet the requirements for vitamin A (Pelham-Burn et al. 2014; Tarasuk et al. 2015), vitamin C (Pelham-Burn et al. 2014; Sisson and Lown 2011), calcium (Silliman and Wood 2011; Tarasuk et al. 2015), zinc (Pelham-Burn et al. 2014; Sisson and Lown 2011; Silliman and Wood 2011; Tarasuk et al. 2015), and magnesium (Sisson and Lown 2011; Pelham-Burn et al. 2014; Silliman and Wood 2011; Tarasuk et al. 2015). Other nutrients found to be inadequate were B vitamins, selenium, and potassium (Pelham-Burn et al. 2014). Sodium was often found in amounts greater than recommended (Sisson and Lown 2011), contributing to hypertension and cardiovascular diseases. Fiber was found to be inadequate in all studies reviewed (Sisson and Lown 2011; Pelham-Burn et al. 2014).

Freedman and Bartoli (2013) found tray waste at soup kitchens indicated a high consumption of satiating protein and carbohydrates with low intake of fruit and vegetable offerings, resulting in inadequate vitamin and mineral intake (Freedman and Bartoli 2013). When surveyed why they consumed low amounts of fruits and

vegetables, the respondents indicated the desire to "fill-up," or they were unfamiliar with the vegetable served or did not like how the vegetable was prepared. Most studies have found that homeless people have a highly variable intake from day to day, often uncertain of when they might eat again, contributing to binge eating when food is available (Sprake et al. 2014).

The Nutritional Status of Homeless Persons

Malnutrition in the presence of obesity is known as the hunger obesity paradox and is commonly found in homeless persons (Sisson and Lown 2011; Koh et al. 2012; Martins et al. 2015). This may be due to a combination of the low nutrient dense, high fat, protein, and carbohydrate food served by soup kitchens and eating behaviors which favor consumption of high satiating foods. Dietary intake assessments indicate a low intake of fruits, vegetables, and dairy products (Martins et al. 2015; Langnäse and Müller 2001; Mahadevan and Fischer 2010) and consumption of high amounts of fats, saturated fats and sodium, and low amounts of fiber. Homeless persons consume inadequate amounts of fat-soluble vitamins A, D, and E (Johnson and McCool 2003; Sprake et al. 2014; Coppenrath 2001; Malmauret et al. 2002). Thiamin, niacin, and riboflavin intake is low even in nations where flour is fortified with B vitamins (Sprake et al. 2014; Darmon et al. 2001; Johnson and McCool 2003). Homeless persons also have inadequate intake of minerals (iron, calcium, and magnesium) and trace elements (zinc, copper, manganese) (Sprake et al. 2014; Coppenrath 2001; Darmon et al. 2001; Malmauret et al. 2002).

The reported calorie intake in homeless people is highly variable, perhaps due the prevalence of a single rather than the usual 3-day 24-h recall method of assessment (Sprake et al. 2014; Malmauret et al. 2002; Darmon et al. 2001). Darmon et al. found 7.3% of French homeless men were underweight compared to 1.7% of nonhomeless French men (Darmon et al. 2001). Whereas Koh (2012) found only 1.6% of homeless persons in Boston were underweight, while 65.7% were overweight and 32.3% were obese (Koh et al. 2012). This reflects the prevalence of overweight and obesity in nonhomeless persons. Langnäse and Müller concluded that the body mass index (BMI) of homeless persons was not solely related to their diet, but also to their chronic illnesses and drug or alcohol use (Langnäse and Müller 2001) (Table 2).

Nutritional Status of Homeless Women

Johnson (2003) found that elderly homeless women had low body weight and that their nutrient intake was less than the recommended amount for all nutrients except iron and phosphorus. These women had adequate protein intake at 52 g per day. But consistent with meals provided by soup kitchens, "less than one-half of the recommended amounts of dietary fiber, vitamins A, D, E and K, biotin, folate, pantothenic acid, calcium and magnesium were consumed. Both zinc and vitamin C were consumed at just slightly more than one-half of amounts recommended"

Table 2 Comparison of weight status by sex in the homeless persons[a]

Weight category %	Males (N = 4535)	Females (N = 1097)	*P* value
Underweight (BMI < 18.5 kg/m^2)	1.3	2.9	<0.001
Normal weight (BMI 18.5–24.9 kg/m^2)	33.4	29.4	0.01
Overweight (BMI ≥ 25 kg/m^2)	65.2	67.7	0.12
Obese (BMI ≥ 30 kg/m^2)	29.7	42.8	<0.001
Grade 1 (BMI 30–34.9 kg/m^2)	18.1	19.2	0.40
Grade 2 (BMI 35–39.9 kg/m^2)	7.3	12.3	<0.001
Grade 3 (BMI ≥ 40 kg/m^2)	4.3	11.2	<0.001

[a]Koh et al. (2012)

(Johnson and McCool 2003, 12). Average daily sodium intake was high at 2700 mg. Most of the women exhibited low body weight, muscle wasting, and/or obesity (Johnson and McCool 2003). Popma-Metsaars (2014) found 31% of homeless women were overweight and 37% suffered from Class III obesity with a BMI > 40 kg/m^2. The median daily fruit and vegetable intake was low, sodium intake was almost twice the recommended amount, and 38.9% of calories were from fat (12.2% from saturated fats) (Popma-Metsaars 2014). This is consistent with the US National Health and Nutrition Examination Study (NHANES) showing greater obesity in females (42.8%) as compared to males (29.7%) (Koh et al. 2012). In HIV, drug abusing homeless women's cultural beliefs and nutritional misconceptions also contributed to their inability to consume a healthy diet (Mahadevan and Fischer 2010).

Homeless pregnant women perceive excessive barriers to prenatal care which are associated with poor infant outcomes. Contributing factors to poor infant outcomes are stressful high risk life-styles (alcohol and drug abuse, smoking) and sexually transmitted diseases (Bloom et al. 2004). Homeless women have a greater number of preterm delivery and small for gestational age babies (Stein et al. 2000).

Special Nutrient Needs of Homeless Adults

Adult homeless persons experience a greater prevalence than housed adults of certain behaviors, physical and clinical problems that can alter their nutrient requirements and nutrient intake putting them at a greater risk for malnutrition. These underlying conditions include smoking, drug and alcohol abuse (Shelton et al. 2009; McQuistion et al. 2014; Magura et al. 2002), obesity (Martins et al. 2015; Koh et al. 2012; Chant et al. 2014), chronic diseases (Gozdzik et al. 2015; Seligman et al. 2010; Shelton et al. 2009), infectious diseases (hepatitis C, HIV, tuberculosis) (Chant et al. 2014; Gelberg et al. 2012; McAdam et al. 2009; Magura et al. 2002), and poor oral hygiene (Figueiredo et al. 2013).

Adult homeless persons have a high prevalence of excessive alcohol intake. In the UK, 35% of homeless persons consume alcohol greater than twice a week (Thorley et al. 2015). Homeless persons who consume large quantities of alcohol are often overweight due to the high calorie intake (Shelton and Knott 2014), but at risk for

protein, vitamin, and mineral deficiencies with low nutrient intake (Ross et al. 2014). Malnutrition also may be due to poor nutrient absorption with toxic damage of alcohol to the gastrointestinal tract (Bujanda 2000). Alcohol metabolism increases the requirements for folate, thiamin, and niacin (Thorley et al. 2015). Blood tests in housed individuals recovering from alcohol and drug abuse indicated 20% were deficient in either iron or vitamin A or both (Ross et al. 2014); this finding is likely similar in homeless persons with substance abuse. As alcohol intake/drug use is associated with smoking, which increases vitamin C requirements, 8% of these individuals have been found to have subclinical scurvy (Ross et al. 2014; Leblanc et al. 2002). Hepatitis which can result from long-term alcohol intake (Bedogni et al. 2007), obesity (Lomonaco et al. 2012), and risky behaviors resulting in virus transmission (Levorato et al. 2017) can lead to fat, fat soluble vitamins (Williams and Sidorov 1971), and calcium malabsorption (Slater et al. 2004).

Homeless persons are at high risk for nutritional anemias through poor intake and decreased absorption of iron, B_{12}, and folic acid. Homeless persons experience a high prevalence of obesity and infectious disease which decrease iron absorption. These inflammatory conditions decrease absorption of iron (Tussing-Humphreys et al. 2012). Older homeless persons, similar to older housed persons, are at risk for B_{12} deficiencies due to atrophic gastritis (Baik and Russell 1999). Homeless persons are at even greater risk due to gastric problems with alcohol abuse, and poor meat intake due to its expense and frequent poor dentition (Sahyoun et al. 2013) (Table 3).

Table 3 Nutrient deficiencies and reasons due to common conditions in homeless adults

Condition	Nutrients	Reasons
Excessive alcohol intake	Protein, vitamins, and minerals especially thiamine, folate, niacin, B_{12}, vitamin A, C, and iron[a]	Poor intake, malabsorption, urinary loss, and increased requirements with alcohol metabolism
Smoking	Vitamin C[b]	Increase requirements with free radicals
Hepatitis	Fat, fat soluble vitamins,[c] and calcium[d]	Decrease in bile production
Obesity/ inflammation/ infection	Iron[e]	Decrease in absorption due to increase in hepcidin production
Atrophic gastritis	B_{12}[f,g]	Low acid-pepsin secretion by the gastric mucosa, which in turn results in a reduced release of free vitamin B12 from food proteins Poor meat intake due to expense and poor dentition

Special Nutrient Requirements of Women of Childbearing Years

As in all adult homeless persons, alcohol/drug dependence was significantly higher in homeless women as compared to housed women (Caton et al. 2000). Additionally, homeless women have a greater rate (75%) of unplanned pregnancies as compared to housed women (Gelberg et al. 2008). These pregnancies increase their nutritional requirements, especially if they are teens who are still growing. Malnutrition prior to and during pregnancy, particularly in the first trimester, impacts the short-term outcomes of low-birth weight, preterm delivery, and future outcomes of increased rates of obesity, cardiovascular disease, diabetes, and hypertension (Fowles et al. 2011).

Policies and Protocols

Policy Recommendations to Alleviate Malnutrition in Homeless Persons

Improving the health and well-being of homeless persons will require a joint effort between agencies that provide food for them and local and federal governments. Soup kitchens alone cannot bear the burden of meeting the nutritional needs of homeless persons. However, there are steps they can take to improve the quality of their food offerings. Soup kitchens that provide one meal a day, or less, should strive to meet the micro- and macro-nutrient requirements of an adult in every meal (Tarasuk et al. 2015). They can achieve this through increasing the amount of nutrient rich foods served, especially fruits, vegetables, and dairy products, without significantly increasing the calorie content (Tarasuk et al. 2015). The use of healthy meal guidelines by soup kitchens and setting nutrition standards for programs that receive government funding has potential to improve the quality of meals served. The city of New York has such guidelines (New York City Health 2014); however, implementation on the national level, as with child care providers and senior meal programs, has not yet occurred. Moreover, implementing standards without improving funding and food sourcing options for soup kitchens may instead have a negative impact by forcing underfunded operations to serve fewer meals.

Mandatory nutrition education standards for staff and volunteers could at a minimum eliminate inaccurate nutrition beliefs held by those preparing food. The use of dietitians/nutritionists for meal planning is suggested by some (Silliman and Wood 2011); however, this is costly and unless the ingredients necessary for healthy meals are available, will have little impact. The use of donated food and foods sourced from leftovers seriously limits the nutritional status of meals that can be prepared. Therefore, increased governmental funding of soup kitchens is indicated to allow for purchasing of hard to resource foods, such as fresh fruits, vegetables, and dairy products.

In the USA and other developed nations, food manufacturers, retailers, and some growers are allowed special tax deductions for donating food to those who serve homeless persons. Changing these deductions in a manner that encourages the donation of healthy foods such as fresh fruits and vegetables and eliminating deductions for unhealthy items such as soft drinks, highly sugared cereals, and candy could positively change the foods that are available to soup kitchens (Fitzgibbon et al. 1996).

Other policies that could enhance the quality of food sourced include developing partnerships between growers, gleaners, and soup kitchens to increase the availability of fresh fruits and vegetables. When charitable meal programs adopt and implement healthy food policies, they see an overall improvement in the nutritional quality of the foods donated which in turn improves the quality of the meals served. These policies can consist of providing lists of nutrient dense foods that are desired, as well as those less acceptable or that are not accepted due to their poor nutritional value. The policies can go further by requiring that donors may only provide foods that meet specific nutrient guidelines or a nutritional balance of donated foods (Shimada et al. 2013; Davis et al. 2008). Targeted food drives for specific healthy foods and provision of educational pieces to potential donors, explaining the needs of homeless people and the goals of the organization providing meals, can change the paradigm of food available.

Coordination among local soup kitchens of meal times and days that allow for daily adequate intake by homeless persons should be undertaken. Additional suggestions to meet the nutritional needs of homeless people include providing specifically designed fortified food products (Darmon et al. 2001), providing nutrition supplements, such as multivitamins with minerals (Coppenrath 2001; Kinder 2004), and take-away snacks (Kinder 2004).

Removing barriers to enrolling in entitlement programs, increasing the amount of money allocated for emergency food programs, and assisting homeless people with applying for benefits such as SNAP is strongly advocated by many (Nwakeze et al. 2003). Others advocate for allowing purchase of prepared foods with SNAP benefits and providing community kitchens and food storage facilities, enabling homeless persons to utilize food from pantries and grocery stores (Davis et al. 2008).

Charitable meal programs have developed out of a need to reduce hunger, but the efforts are uncoordinated and tackle the problem from the position of an emergency need to reduce hunger, rather than a longer-term goal of meeting nutritional needs and reducing or alleviating chronic diseases (Dachner et al. 2009). Unlike homelessness that has been approached as a problem to be resolved by large scale government intervention, hunger of homeless persons has been left to under-resourced charities to solve. Lack of coordination between organizations and lack of adequate funding, nutrition education, and regular trained staff all contribute to the issue of meals that do not meet the specialized needs of homeless persons.

We conclude that these problems cannot be resolved by ad hoc charitable organizations. A systemic policy response to the nutritional status of

homeless persons is essential to address this issue (Dachner et al. 2009; Tarasuk et al. 2015) and will require increased cooperation, funding, and governmental oversight.

Dictionary of Terms

- **Food insecurity** – Lacking access to adequate amounts of safe foods.
- **Emergency food system** – Provision of food to those in need, mainly by nonprofit, faith based institutions.
- **Homeless person** – Someone who does not have a regular place to sleep indoors.
- **Soup kitchen** – location that provides free meals to people in need.
- **Hunger-obesity paradox** – Malnutrition in the presence of obesity.
- **Anemia** – A condition marked by a deficiency of red blood cells or of hemoglobin in the blood.
- **Atrophic gastritis** – A process of chronic inflammation of the stomach mucosa, leading to loss of gastric glandular cells, which impairs the stomach's secretion of essential substances such as hydrochloric acid, pepsin, and intrinsic factor.

Summary Points

- The majority of homeless persons are minority, single males.
- Soup kitchens are the main source of food for homeless persons.
- Homeless persons consume an average of 2 or fewer meals per day.
- Most meals at soup kitchens are calorie dense, high in total fat and saturated fat, adequate in protein but lacking in fiber and many micronutrients.
- Dairy, fruits, vegetables, and fish are served in minimal amounts in soup kitchens.
- The content of soup kitchen meals contributes to malnutrition and exacerbates the chronic diseases of homeless persons.
- Homeless persons consume inadequate amounts of vitamins A, D, and E, thiamin, niacin and riboflavin, minerals (iron, calcium, and magnesium), and trace elements (zinc, copper, manganese).
- Homeless women have a greater number of unplanned pregnancies, preterm delivery, and small for gestational age babies.
- Homeless persons have increased rates of smoking, drug and alcohol abuse, chronic diseases, infectious diseases, and poor oral hygiene that alter their nutrient requirements.
- Soup kitchens should increase the amount of nutrient rich foods served, especially fruits, vegetables, and dairy products.
- A systemic policy response to the nutritional status of homeless persons is essential to meet their nutrition needs and will require increased cooperation, funding, and governmental oversight.

Abstract

Across all countries, the number of food bank users in high-income countries has increased considerably over the years. More and more people appear to depend on the distribution of food donations. Besides being considered economically disadvantaged, the group of food bank users can be described as diverse in terms of educational background, age, gender, and ethnicity. However, mental or physical disabilities, job loss or working poor, living in a large household, an increase in housing costs, living in a nonmetropolitan area, and/or food insecurity are all main reasons for using food banks. While the types of foods offered by food banks vary substantially across countries, the energy of the provided food seems to meet or exceed nutritional guidelines. Nevertheless, often the provided foods lack vitamins and minerals and despite the small number of existing studies, it seems that food bank users do not consume milk and milk products, fruits, and vegetables in sufficient amounts. In the future, the dietary needs of people in need should be considered without jeopardizing the amount of donated food.

Introduction

This chapter will focus on food banks and its users in high-income countries because features and arrangements of food banks differ substantially between low-, middle-, and high-income countries. Many food banks in low-income countries go beyond the donation and distribution of foods and support people in farming or harvesting activities. For instance, food banks in Uganda directly provide seeds and practical training in farming and agribusiness (Watuleke 2015), whereas food banks in high-income countries only sometimes cooperate with local farmers and farmers' cooperatives to expand food contributions (Weinfield et al. 2014).

How donated food reaches its recipients varies considerably. People can collect unprepared food from food banks and food pantries or they receive prepared meals in soup kitchens or homeless shelters. This chapter will cover the former, while (Chap. 23, "▶ Soup Kitchens: Homeless Adults and Gaps in Meeting Their Nutritional Needs" by Lisa Sisson) will discuss the later. Therefore, the term "food bank" here will be used to describe programs that directly distribute foods to the people in

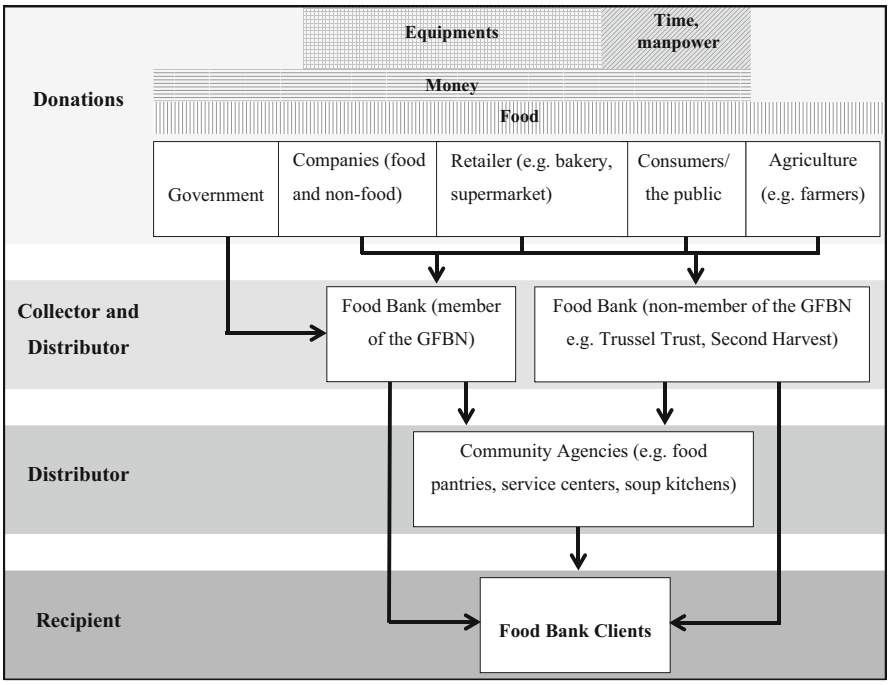

Fig. 1 Food distribution pathway across the different food bank distribution systems

need. However, the terms "food banks," "food pantries," "food parcel programs," and "food aid" are often used interchangeably. In the USA, the term "food pantry" is primarily used for programs that collect food including perishable groceries themselves and directly serve those as parcels to take home for needy clients while food banks go beyond these distribution activities as described in Box 1. In many other countries, no distinction is made and only the terms "food bank" or "local and central food bank" are used. Thus, central food banks usually receive large quantities of foods from the industry, manufactures, and federal or supranational sources such as the European Union food aid and distribute these foods to smaller charitable agencies including soup kitchens and local food banks (or food pantries in the USA). Traditional local food bank programs supply eligible households with predetermined bags of nonprepared food items donated by retailers, manufactures, industries, producers, churches, community members, and other donors. The complex scheme of food banks is described in Fig. 1.

Food Banks and Their Networks

The concept of the first food bank was born in Arizona, USA, in 1966. John Van Hengel, a retired businessman collected foods from a soup kitchen that would otherwise have been wasted and distributed them to people having not enough to

eat (Cotugna and Beebe 2002). The idea of minimizing food waste by giving it to people in need spreads around the world.

The Global Food Banking Network (GFBN)

In 2006, the GFBN was established with the aim to "fight world hunger by creating, supporting, and strengthening food banks around the world" (GFBN 2016a). Currently over 32 countries from all continents, for example, the United Kingdom, Hong Kong, India, or Egypt, are members. The member countries are represented by organizations such as the Feeding America Network, the Arab Food Banking Regional Network, or the European Federation of Food Banks (GFBN 2016b). While the majority of existing food banks are part of the network, not all food banks have so far joined forces, for instance, the Trussel Trust in the UK (The Trussel Trust 2016a), Second Harvest in Canada (Second Harvest 2016), or the Tafel (translated: tables) in Germany (FEBA 2016). More than 6.8 million people were impacted by the network in 2015 (GFBN 2016a). Food banks and their networks generally distribute food, maintain public relations, and share their experiences across organizations, but they also offer other resources such as education programs for people in need as well as volunteers. Nontraditional programs such as rehabilitation programs or community garden projects are also often initiated or supported by food banks.

Box 1 Definition of Food Banks by the GFBN (2016b)
The GFBN defines **food banks** as nonprofit organizations, that "**acquire donated food, much of which would otherwise be wasted, from farms, manufacturers, distributors, retail stores, consumers, and other sources, and make it available to those in need through a network of community agencies.** These agencies include school feeding programs, food pantries, soup kitchens, AIDS and tuberculosis hospices, substance abuse clinics, after-school programs, and other non-profit programs that provide food to the hungry."

USA

In the USA, the food bank and pantry system is highly institutionalized and widespread. Throughout the country, there are over 200 central food banks which distribute large quantities of food to over 46,000 local agencies. More than 67% of these partner agencies represent grocery programs including food pantries which directly provide a predetermined bag of unprepared food to people in need, whereas the others include meal programs such as soup kitchens and other grocery programs such as school pantries (Weinfield et al. 2014).

Local food banks play a significant role in the food environment of low-income population groups in the USA. In 2015, 5.2% of US households reported to have used a food pantry at least once in the previous 12 months (Coleman-Jensen et al. 2016).

Most food banks and food pantries have joined Feeding America; the nationwide umbrella organization that secures donations from national sources such as food manufactures and government agencies, assists food banks in providing education programs and informs the general public about hunger in the USA (Weinfield et al. 2014). The majority of the grocery products distributed through the network are non-perishable foods such as canned products, pasta or rice. Most of the food is donated, but in contrast to most food banks in Europe, U.S. food banks are also allowed to use donated money to buy additional food (González-Torre and Coque 2016).

Canada

In 2013, over 800,000 people in need were provided with groceries through food banks in Canada (Food Banks Canada 2016a). Their umbrella organization is called Food Banks Canada and is comparable to the American network with support of 3000 agencies that help distribute the collected foods. The food and funds donated stem mainly from private companies or other foundations (Tarasuk et al. 2014a). At the Canadian food banks, 38% of provided food is fresh, including milk, eggs, fresh or frozen fruits and vegetables, and bread, whereas 62% of distributed food consists of nonperishable items such as pasta, breakfast cereal, rice, and canned fruits and vegetables (Food Banks Canada 2016b).

Canadian food agencies operate similar to the US food pantries; however, in addition to the provision of prepacked bags containing a certain number of days' worth of food, many smaller food banks also have a grocery store distribution method where clients can select a certain amount of food at no cost or for a nominal cost (Tarasuk et al. 2014a).

Europe

The European Federation of Food Banks (FEBA) with 23 member countries and 4 project partners incorporates around 265 food bank organizations and is estimated to serve 5.7 million people in 2015 (FEBA 2016). Contrary to the food banking system in the USA, every food bank organization works independently and they are not linked among each other. They can vary in structure and distribution system. Some examples are described below:

Half a million Britain have used food banks in the UK (FEBA 2016). One British food bank organization is the Trussel Trust. Although not a member of FEBA, it distributes food through 400 food banks across the country. These food banks are set up as local food banks providing three-day emergency food supply of nonperishable food (Fig. 2) to people in need who were issued a foodbank voucher by care

Fig. 2 Content of a standard bag for one person distributed by The Trussell Trust (With permission from Alexandra Smart, The Trussel Trust)

professionals such as doctors or social workers. Trussel Trust food banks distributed over 500,000 three-day emergency food supplies over the last six months (April to September 2016) of which almost 200,000 emergency food supplies went to children (The Trussel Trust 2016a).

In Germany, the national federation of food banks is the main organization of German food banks (Tafeln), and around 1.5 million people in need were served in 2015 (Bundesverband Deutsche Tafel e. V. 2015). It emphasizes the provision of food as a supplement to the usual food bought in commercial food stores and the existing federal welfare (Bundesverband Deutsche Tafel e.V. 2012). In contrast to most other countries, it has always provided mainly fresh fruit and vegetables (Fig. 3), whereas nonperishable food items are rarely provided. Many Tafeln, in particular those setup as food redistribution centers, are located in parochial facilities (Fig. 4), whereas others, in particular those in a supermarket-style, are operated by other charitable organizations such as the German Red Cross.

Those setups as redistribution centers distribute the foods in predetermined quantity based on household size for a small fee or at no cost, while others use the supermarket like concept with a small shop where eligible individuals can purchase each food product. German food banks are financed mainly by food donations and monetary contributions of companies and the public.

In the Netherlands, currently, 160 locally based food banks and 510 distribution points are part of the umbrella organisation of the "Vereniging van Nederlandse Voedselbanken" which is the Dutch Food Bank Foundation and around 94.000 people were using food banks in the Netherlands in 2014 (Galli et al. 2016). In contrast to most other food bank organizations, clients of a Dutch food bank have to be in contact with social workers to address their food poverty as well as other existing poverty-related problems.

Fig. 3 Typical food distributed by the German food bank system (With permission from Dietmar Gust, Berliner Tafel e.V)

Fig. 4 German local food bank providing fresh produce (Berliner Tafel e.V., Gust D. Pressefotos [press photos] 2017. http://www.berliner-tafel.de/berlinertafel/presse/pressefotos/. Accessed 20 May 2017)

Across all countries, the number of food bank users has increased substantially over the years. For instance, the number of 3-day emergency food supplies given by Trussell Trust food banks in the United Kingdom is currently (2015–2016) almost 20 times higher than in the year 2011 (The Trussel Trust 2016b). In the USA, food pantry user rates have almost doubled from 1999 to 2014 (Baracio and Shaefer

2016). In Germany, while 220 food banks around Germany in 1999 existed, 919 food banks were open in 2014 (Bundesverband Deutsche Tafel e.V. 2016).

Campus Food Banks

One more food bank system should be mentioned. In recent years, campus food banks have been emerging since food insecurity has increasingly become an issue on college and university campuses (Hughes et al. 2011). In the USA, the College and University Food Bank Alliance was founded in 2011. Today, it includes 347 campus food banks. Campus food banks also exist in Canada with 51 campus-based food banks nationwide (Jessri et al. 2014). However, in contrast to people relying on community food banks, the situation of clients of food banks located at universities often differs insofar as students may have better future prospects and the time students need food bank assistance is limited to their student status.

Food Bank Users

Generally, users of food banks can be described as groups of economically disadvantaged populations. These vulnerable populations have certain characteristics in common, such as low- or no income, unemployment or low paid jobs, lack of money (Lightman et al. 2008; Kicinski 2012) and their reliance on welfare assistance. A recent UK study revealed that almost 28% of food bank users indicated benefit delays as primary reason for food bank use, while over 23% indicated a low income as primary reason (Loopstra et al. 2015). Independently of the type of welfare system, there seems to be a strong relationship between receiving federal welfare benefits and food bank usage (Tarasuk et al. 2014b; Daponte and Bade 2006).

However, this is where the commonalities stop. While food bank users are usually adults with or without children, their age range varies across countries, and food banks. Some studies report the highest percentage of users between the ages of 35–49 years (Algert et al. 2006), others report the largest percentage between the ages of 40–50 years (Lyman and Seo 2015; Depa et al. 2015) or 40–59 years (Robaina and Martin 2013). Nevertheless, the mean age in most studies is between 40 and 50 years of age.

Even more diverse is the educational background, and research shows that food bank users report a wide range of educational background starting from no high school education to a completed university degree. Most commonly, with over half of the users, a high school degree or more ranging from 41% to 91% is reported (Lightman et al. 2008). Thus, a low educational level is not predictive of food bank use nor is a university degree protective of becoming unemployed or poor and in need of social assistance. Furthermore, many users are reported to suffer from chronic illness and disabilities (Lightman et al. 2008). For instance, Depa et al. (2015) reported that 64.5% of their food bank participants indicated to have at least one chronic illness. High blood pressure, diabetes, and obesity seem to be the most

common medical conditions (Castetbon et al. 2011; Neter et al. 2014; Martin et al. 2013). Many food bank users also smoke (Depa et al. 2015; Starkey et al. 1998). Despite the observed low energy intake among food bank users summarized below, the large percentage of overweight and obese food bank users, in particular women, is of concern and raises the question of dietary quality of the food consumed by food bank users. Primary reasons for long-term food bank use can be found in Box 2.

Particularly in the United States, minority groups are more likely to use food banks compared to non-Hispanic Whites (Weinfield et al. 2014; Algert et al. 2006) and in Europe, food bank users appear to be more often not born in the country of study (Neter et al. 2014; Castetbon et al. 2011). While in some studies, more single households seem to visit food banks (Martin et al. 2013; Lightman et al. 2008), others report more visits by 2–4 person households (Neter et al. 2014). Households with children, seniors, and particularly single parent households appear to be increasingly using food banks across all countries (Nord et al. 2009; Tinnemann et al. 2012, Nichols-Casebolt and Morris 2002; Bartfeld 2003).

Box 2 Primary Reasons for Long-Term Food Bank Use
Mental or physical disabilities, working poor, living in a large household, an increase in housing costs, living in a nonmetropolitan area, and/or food insecurity (Kicinski 2012; Bhattarai and Duffy, 2003; Biggerstaff et al. 2002; Daponte 2000).

There is one more aspect that the majority of food bank users have in common across various countries; they have been using a food bank not as an emergency short-term service which was the initial intention by food bank founders, but they rely on food banks for support for one year and more (Depa et al. 2015) with many of them visiting a food bank more than once a week (Martin et al. 2013). In general, food insecurity is highly prevalent among food bank users even more so than in other low income households (Coleman-Jensen et al. 2016; Tarasuk et al. 2014b; Castetbon et al. 2011). For example, around 85% of food bank users in the USA are estimated to suffer from food insecurity (Weinfield et al. 2014).

Types of Food Offered

Since the primary source of food as well as of financial capital of most food banks is represented by donations, food banks are highly depend on food surplus and the goodwill of their suppliers. Another important fact regarding the offered food types is the difference in the way food banks collect, provide, and distribute foods between and sometimes even within countries.

Therefore, the dependence on donations makes the amount and types of food to be distributed unpredictable for both food banks and its users. It is, therefore, not surprising that a recent systematic literature review including nine studies from

Canada, the USA, and Australia found large variations in the nutritional quality of the food provided between and within studied food banks (Simmet et al. 2016a). Since most food banks provided bags of diverse sizes depending on the number of individuals in recipient's households, the nutritional value of the supplied food per person also varied between bags of different sizes, even when provided by the same food bank.

Provision of Energy

As reported by the systematic review from Simmet et al. (2016a), the mean provision of energy per day met or exceeded recommendations of the Food and Agriculture Organization of the United Nations for energy intake (given a moderate activity level of 1.75 and an assumed body weight of 60 and 80 kg for women and men respectively (WHO et al. 2004)) in four of six studies. The recent Dutch study also found that the provided amounts of energy were higher than the nutrition guidelines (Neter et al. 2014). However, reviewed studies also revealed that between 33% (Teron and Tarasuk 1999) and 99% of bags (Irwin et al. 2007) provided an amount of energy less than recommended.

Provision of Food Groups

Dairy products were one of the food groups most often provided in inadequate amounts (Table 1), as nearly all studies considered by the review reported an insufficient supply at least for some bag sizes (Simmet et al. 2016a). In contrast, the provision of grains generally was within recommendations, although some food banks provided fewer amounts of whole grains (Nanney et al. 2016).

More heterogeneous were the results for the provision of fruit and vegetables as well as for the provision of meat and alternatives. While the mean provision was found to be adequate for some of the studied food banks, the supply was far away from the national recommended intake for other food banks (Simmet et al. 2016a). The recent Dutch study also found that the mean supplies of fruits and of fish were too low (Neter et al. 2014).

Even if the mean supply was adequate in terms of the number of provided servings, fruit and vegetables were often represented by tomato sauce, canned fruit or vegetables and juice (Starkey 1994; Willows and Au 2006) and only some food banks provide perishable foods such as fresh produce and yoghurt when available (Friedman 1991; Jessri et al. 2014).

Provision of Macronutrients and Micronutrients

As revealed by the systematic review, the supply of macronutrients as represented by the percentage of energy generally met nutrition recommendations, but some food

Table 1 Comparison of mean group intake of food bank users and mean bag content by food groups with national recommendations (Unpublished, adapted from Simmet et al. 2016a,b)

mean bag content	food group	mean group intake
	grains	
	fruit and vegetables	
	vegetables	
	fruits	
	milk products	
	meats and alternatives	

Number of icons represents the number of studies; green icon: mean group intake/bag content was within recommendations; red icon: mean group intake/bag content was below recommendations; green-red color mix: mean group intake/bag content was partly within recommendations (e.g. for one sex or for some bags)

banks provided relatively low amounts of fat (Simmet et al. 2016a), whereas others provided too much saturated fat and protein (Neter et al. 2014).

Among micronutrients, vitamins A and C as well as calcium were the micronutrients which were provided in particularly low amounts (Simmet et al. 2016a). In addition, the provision of iron and zinc was reported to be inadequate at least for some bag sizes. Iron was mostly provided by nonheme beans. While the mean provision of the other micronutrients was mostly within recommendations, large variations were found between different bag sizes, days, and food banks.

Differences in Food Types Offered Across Countries

In most countries, food banks claim to provide a certain number of days' worth of food per person, usually 2 to 4 days (Tarasuk et al. 2014a), but the supply of fresh produce tends to be low (Simmet et al. 2016a). In countries such as the USA, Canada, France, and Australia, donated foods used to come from the food industry's production and distribution channels and included waste products such as damaged containers or mislabeled tins (Campbell et al. 2015). Historically as well as up to now, donated foods therefore have mainly included nonperishable food items.

Recognizing the need of a more comprehensive nutritional evaluation of foods distributed through the food bank systems, some food banks and researchers, for instance in the USA and France, have started to apply a nutrition-profiling system to measure the distributed foods in terms of MyPyramid days (Hoisington et al. 2011) or to use linear programming to identify food items required to mitigate nutritional deficiencies in the food donations (Rambeloson et al. 2008).

Since the food industry has become more efficient, leading to less food waste in the food production and distribution and subsequently to reductions in donations, many food banks sought for new donors and, in particular, food banks in Canada and the USA have started to distribute more fresh fruits and vegetables (Campbell et al. 2015; Handforth et al. 2013). To increase its supply, they have begun to work with local farmers and farmers' cooperatives (Webb et al. 2012; Weinfield et al. 2014), whereas others adopted a "No Soda and No Candy" donation policy (Campbell et al. 2009).

While some food bank managers show concerns in regards to restricting the types of food distributed (Handforth et al. 2013), the provision of more fresh produce and also the implemented policies have improved the nutritional quality of the supplied food (Jessri et al. 2014; Campbell et al. 2009). It requires, however, immense investments in trucks, fuel, refrigerator systems, and manpower to distribute fresh produce which often is close to its best-before-date. Moreover, the provision of fresh fruits and vegetables depends on availability and is usually highly variable.

Diet of Food Bank Users

Energy Intake and Overall Dietary Quality

Users of food banks and food pantries are not only heterogeneous in terms of their demographic characteristics, in particular their educational background, they also differ in their nutrition status.

Another recent systematic literature review by Simmet et al. (2016b) included 11 studies and observed large variations in the nutrition status between users of different programs, countries, and even within user populations.

Despite variations, mean energy intake tended to be below the recommendations of the Food and Agriculture Organization of the United Nations in both sexes and nearly all investigated age-groups (Simmet et al. 2016b). For instance, by using the Healthy Eating Index, one US study assessed the overall diet quality among 48 female food bank users and revealed that 71% of the women consumed a diet that is not health-promoting (indicated by a Healthy Eating Index score below 50 points) (Duffy et al. 2009). The average score was only around 43 points and the majority of women reported no consumption of fruits, whole grains, and dark green or orange vegetables or legumes.

Food Groups

Among different food groups, mean intake of fruits and vegetables and of milk products was below the national recommended intake in nearly all investigated age groups and both sexes (Table 1) (Simmet et al. 2016b). Considering individual intake, many of the studied food bank populations seem to consume fruit,

vegetables, and milk products in amounts lower than recommended. In a recent German study among 267 food bank users, around 50% of them consumed fruit and around 66% of them vegetables less than daily (Depa et al. 2015). Daily fruit consumption was even lower in this sample than in the general German population of low socioeconomic status. Similarly, a French (Castetbon et al. 2011) and an US (Bell et al. 1998) study found food bank users meeting less frequently the national intake recommendation than the general population. Only one Canadian study reported that the percentage of people with an adequate fruit and vegetable intake was higher among food bank users than in the general population (Jacobs Starkey and Kuhnlein 2000). All three studies comparing milk intake between food bank users and the general population found the prevalence of adequate intake lower among food bank users than among the general population (Simmet et al. 2016b).

In contrast, mean intake of meat and alternatives was adequate in all five studies comparing mean intake with national recommendations (Canada, Australia, and the USA) (Table 1) (Simmet et al. 2016b) and a small US study revealed that food bank users consumed more high-fat meat than the general population (Bell et al. 1998).

More heterogeneous were the results for the intake of grains. In two Canadian (Jacobs Starkey and Kuhnlein 2000; Rush et al. 2007) and one Australian study (O'Reilly et al. 2012), mean group intake was within the recommendations, whereas another Canadian (Tarasuk 2001) and one US study (Duffy et al. 2009) found the mean intake of grains inadequate among food bank users. Confirming the heterogeneity, large variations were also observed in the prevalence of inadequate intake, as between 13% and 61% of food bank users had an intake of grains below the national recommended number of servings (Simmet et al. 2016b). In particular, the intake of whole grains was observed to be low (Duffy et al. 2009; Yao et al. 2013).

Macronutrients and Micronutrients

While food bank users' intake of macronutrients expressed as percentage of total energy intake met recommendations, intake of some micronutrients tended to be less than recommended at least in subpopulations of food bank users (Simmet et al. 2016b). Reflecting the low consumption of milk products, calcium seemed to be among the micronutrients which were consumed in particularly low amounts. One Canadian and one US study reported that the mean intake was below recommendations among female food bank users (Bell et al. 1998; Jacobs Starkey et al. 1999). While the mean intake of other micronutrients tended to meet recommendations, one older US study also found that the mean intake of vitamin D, pyridoxine, iron, magnesium, selenium, and zinc was inadequate in women (Bell et al. 1998). Even when the mean intake was adequate, subpopulations of food bank users were reported to consume amounts of micronutrients lower than recommended (Lenhart and Read 1989; Tarasuk and Beaton 1999).

Correlates of the Dietary Quality Among Food Bank Users

Food insecurity seems to be related to the tendency of a less healthy diet while controlling for other variables such as household income and education level (Holben 2012; Robaina and Martin 2013; Tarasuk and Beaton 1999). Given the high prevalence of food insecurity among food bank users, this finding is of particular concern. Moreover, female food bank users appeared to have a higher risk of having an inadequate intake of micronutrients than men (Simmet et al. 2016b). Women's roles in managing family feedings might make them more vulnerable to negative nutritional consequences of food insecurity by neglecting their diet in exchange for a better diet of their children.

Besides food insecurity and the female sex, other characteristics identified to be negatively related to a healthy diet seem to be the frequency of food bank use, smoking, and household size, whereas a higher educational level, born outside the study country, and age seem to be positively related to a healthy diet among food bank users (Jacobs Starkey et al. 1999; Martin et al. 2013; Tinnemann et al. 2012).

Due to the small number of studies, the generally small study samples, and different instruments and methods of data collection, it is hardly possible to reliably compare the nutritional status of food bank users between different countries. It is, however, important to note that across all studied countries, food bank users reported a low intake of milk products, of fruits and vegetables and of calcium.

Given that many food bank users rely on public welfare (Depa et al. 2015; Loopstra et al. 2015; Tarasuk et al. 2014b), it is likely that besides the food provided from food banks and individual correlates, the type and extent of public welfare benefits also impacts the nutritional status of food bank users, but the available data do not allow to verify this assumption.

Intervention Measures to Improve the Nutrition Status Among Those Using Food Banks

Potential intervention measures to improve the nutrition status among food bank users are manifold and should be adapted to the needs of the target population.

Many food bank users desire to receive more meat (Campbell et al. 2011; Greger et al. 2002; Verpy et al. 2003) and perceive their meat intake as less than acceptable (Hoisington et al. 2002) although it actually may be within or even above the recommended level of intake (see Table 1). The introduction of nutrition education tools may assist food bank users to evaluate their own diets. Nutrition education could also serve as a way to improve food bank users' nutrition status since many food bank users do not know how to prepare all the food they receive from the food bank (Greger et al. 2002). More precisely, the provision of cooking classes (Caspi et al. 2016; Flynn et al. 2013) and recipes and forcing self-efficacy (Yao et al. 2013) seem to help these people to improve their dietary quality. As described above, some food bank associations provide valuable platforms to exchange information and

intervention tools to improve the nutrition status and health of food bank users (for instance http://healthyfoodbankhub.feedingamerica.org/).

Food bank interventions that address the complex origins of malnutrition and food insecurity have been conducted so far only in pilot studies (see a good-practice example in Box 3). Another example is the use of local food banks as nontraditional settings for diabetes support given the high prevalence of diabetes among food bank users (Seligman et al. 2015).

Box 3 Good Practice Example of an Innovative Food Bank Model

In 2010, Freshplace was founded in Hartford, USA, by three community agencies to address potential roots of food insecurity and malnutrition. The main differences between the Freshplace model and traditional local food banks include:

- **Client-based choice model**: Clients are allowed to choice the foods from a variety of fresh produce and healthy basic foods to meet the health and cultural needs of their families
- **Individualized case managers**: Clients meet trained case managers monthly who offer individualized case management using motivational interviewing to help clients set and monitor goals for becoming food secure and self-sufficient
- **Additional programs and services:** Cooking Matters classes, exposure to nutrition education, resumé building, and job assistance are provided.

Results: Over one year, Freshplace members were less than half as likely to experience very low food security, increased self-sufficiency, and increased fruit and vegetable consumption by one serving per day compared to the control group of clients of a traditional food bank (Martin et al. 2013).

Practical Implications for Researchers

The observed large variations in the dietary quality along with the high prevalence of overweight and obesity among food bank users highlight the need of future research to gain a deeper understanding of forces and barriers for a health-promoting diet among food bank users.

Very few studies have investigated the impact of food banks on individual dietary intake at long term (Martin et al. 2013). By applying well-planned longitudinal study designs, future studies should also investigate the impact of the assistance of food banks on individual health and body weight.

Unfortunately, very little is also known about the impact of different food bank schemes on users' nutrition status. Whether the clients are allowed to choose foods based on needs and preferences or whether they receive a predetermined bag likely has a substantial impact on the dietary quality and potentially on the

self-efficacy of users, but there is so far only one randomized controlled trial comparing the impact of a traditional and a novel food bank including a choice model as outlined in Box 3.

Since also few studies investigated correlates of the dietary intake among food bank users, future studies are further recommended to identify characteristics associated with the nutrition status. This would allow the identification of subgroups at a particular high risk of unhealthy diets among the diverse populations of food bank users. Moreover, it may assist the development of effective intervention measures to improve food bank user's nutrition status.

Policies and Protocols

Policies to improve the nutrition status of food bank users have to be developed carefully and need to consider the charitable character of food bank organizations, including the dependency on donors.

They should cover three main areas:

- Identification
- Implementation
- Monitoring

Identification Although many food banks in the USA, Canada, and UK claim to provide a certain minimum of days' nutritionally balanced food, they usually lack nutritional standards for a defined food bag provided to food bank users. Given that half of the US food banks still reported to use "common sense" in classifying the nutritional quality of their food inventory (Webb et al. 2012), more food banks are recommended to monitor the nutritional quality of food distributed.

For some food banks, it may be worthwhile to consult researchers how to improve the reliability and validity of their routine data in order to get a more comprehensive picture of their activities, the number of people served, as well as the nutritional quality of the food provided. Moreover, the identification of knowledge gaps regarding nutritional quality by food bank personnel should be made and closed by nutrition experts cooperating with food banks.

Implementation The most obvious short-term solution to improve the nutrition status among those using food banks may lie in the distribution of greater amounts of fruit and vegetables, milk products, and whole grains, although this requires substantial personnel and financial capacities. For smaller food banks, this may, however, be a logistic challenge to distribute perishable foods which are often close to its best-before-date. The initiation and maintenance of local networks likely make it easier, in particular, for rural food banks to gain and distribute more fresh produce.

In the light of the shifting needs of food bank users (e.g., long-term use rather than emergency use), food banks should not hesitate to adopt bans on energy-dense foods of low nutritional quality such as soda, sugar-sweetened beverages, and sweets. Food banks that have already implemented such policies may assist other food banks in doing so and with it, reduce the potential worries of losing much needed donations in any shape and form.

Given the charitable character of most food bank programs, they are hardly able to provide the full range of measures to improve dietary quality. Due to the institutionalization of food banks and their valuable experiences gained over decades, they have, however, an immense potential to play an important role in addressing nutrition-related topics in a population group which otherwise is hard to reach. Moreover, they provide an important setting for other health-related interventions. Food banks and other community resources including health centers, social workers, and physicians as well as research institutions are, therefore, recommended to join forces to address the roots of food insecurity, health risks, and malnutrition.

Monitoring Easy applicable monitoring tools should be developed to control changes in the nutritional quality of food provided as well as the impacts of implemented interventions. Establishing a database of good-practice examples of effective food bank intervention measures may further enhance information exchange and provide a valuable resource for other food banks to learn from.

Outlook

Besides these potential policy concepts, food banks will have to face many challenges in the future. Given the rise of people at risk of poverty and the raise in food banks observed across high income countries, the demand is also increasing. However, the supply seems to decrease while the food industries and particularly the grocery stores have become more efficient and waste conscious. The system in place in the Netherlands that fights food poverty also by offering additional nonfood-related help might become a necessary step to support people in need. For Europe in particular, the current increase in refuges will likely impact food banks substantially further limiting their ability to be effective in relieving people in need.

Dictionary of Terms

- **Central food bank** – A central food bank works as a central warehouse and collects large quantities of food from the industry, (supra-)national sources, and retail and distributes the food to other charitable organizations such as local food banks, soup kitchens, and homeless shelters.

- **Dietary quality** – Dietary quality describes the overall diet and dietary patterns based on current nutrition knowledge with the aim to define people's diet and to provide estimates of national nutritional status.
- **Food bank** – A food bank is a nonprofit and charitable organization that collects food from various sources including but not limited to manufacturers, distributors, retailers, or growers and distributes the donated food to other organizations and people in need.
- **Food insecurity** – Individuals suffer from food insecurity when they are not able to acquire a sufficient amount of food on a daily basis and therefore do not consume enough food each day. As a result, people might suffer from chronic hunger, poor nutrition, and malnutrition.
- **Food pantry** – The term "food pantry" is primarily used in the USA for charitable organizations that operate as local food banks (and collect food from central food banks, retailers, manufactures, and growers and provide the donated food to people in need).
- **Local food bank** – A local food bank is a charitable organization that collects food from central food banks, retailers, manufactures, and growers and provides the donated food to people in need.

Summary Points

- In this chapter, the wide range of food bank programs and the nutrition status among those using these programs was illustrated.
- Food bank programs, their distribution systems, and their funding mechanisms vary widely across and sometimes within countries.
- Food bank users have been described as a vulnerable population groups at high risk of food insecurity, diverse health problems, and a low dietary quality.
- In particular, a low intake of fruits and vegetables, milk products, and calcium can be observed among food bank users.
- Good practice examples show the potential to improve the dietary quality of vulnerable population groups using food banks.
- It is important to develop and implement strategies to improve the dietary quality of people using food banks.

Healthcare, Inequality, and Epidemiologic Transition: Example of China

25

Nan Zou Bakkeli

Contents

Abstract

China has achieved great improvements in population and public health, such as a dramatically lower mortality rate, increased life expectancy, and extensive immunization coverage. However, new health challenges emerge in China today. Noncommunicable diseases such as cardiovascular diseases have become the leading cause of deaths, while there still are serious malnutrition issues among poor segments of the population. New health problems and increased income inequality have both emerged during the period of economic reform and market transition of

Introduction

In the period since the economic reforms started in the early 1980s, China has experienced tremendous growth, and its society has continuously been in a state of rapid transition. The structural changes have emphasized economic development, in terms of the introduction of market-oriented social policies, and the development of infrastructure.

The market reforms have had an ambiguous impact on Chinese society. On the one hand, millions have been lifted out of poverty, people's living standards have been dramatically improved, household and individual income has increased greatly, and the average annual GDP growth has been around 10% for over three decades. On the other hand, income inequality has increased, creating a more divided society. The Gini coefficient is an indicator measuring the degree of inequality in a society. It was around 0.30 in 1980 in China, but had nearly doubled to 0.55 by 2012 (Xie and Zhou 2014). This places China as one of the most unequal countries in the world.

China has achieved great improvements in population health since its establishment in 1949, but is now experiencing several emerging public health problems (Chan et al. 2008). With millions of cigarette smokers, China has become the largest tobacco consuming country in the world; obesity has increased in the population; about 10% of the population is infected with Hepatitis B; the country has experienced a progressing HIV epidemic; tuberculosis (which was previously under control) has broken out again; and in some underdeveloped areas, cholera and other epidemic diseases have been spreading (DRC 2005).

How has the current health situation in China evolved in the reform period, and what contributes to the health challenges? This chapter aims to go through important factors for health situations in China, by asking three questions:

1. What characterizes developments in health and healthcare systems?
2. Is growing economic inequality affecting the health situation in China?
3. How can one understand the interplay between social and health situation, with emphasis on the epidemiologic transition?

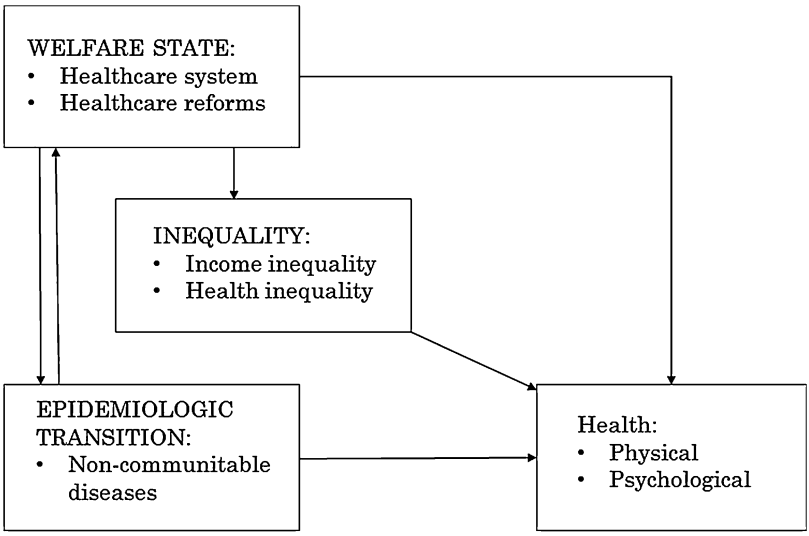

Fig. 1 Relation between welfare state, inequality, epidemiologic transition and health

Healthcare reforms, inequality and epidemiologic transition are three factors that are central to understand population health in China (see Fig. 1). High inequality may lead to negative factors such as lower social cohesion and more mental stress and therefore cause worse health (Wilkinson 1996, 1999). At the same time, market reforms have in many ways given profit-making a high priority. For example, publicly funded mental health rehabilitation facilities were closed down, merged, or down-sized to smaller-scale psychiatric hospitals. For example, only in Shanghai, the number of mental health rehabilitation facilities had decreased by 62% by June 2004, compared to before the 1990s (Liu et al. 2011). This has had a negative impact on Chinese mental health. One study showed that nearly one in five adults had suffered from at least one mental disorder in the past month, that is, roughly 173 million Chinese people (Phillips et al. 2009).

The pattern of type of diseases and leading causes of deaths is also changing. According to the World Health Organization, about 230 million Chinese people (20%) have a cardiovascular disease. The percentages of deaths associated with cardiovascular diseases in urban and rural areas are 20.9% and 17.9% of China's total numbers of deaths per year respectively (WHO 2015). There are also serious malnutrition issues among the poor: the stunting rate among rural children was 22% in 1998, and in some poor provinces, it was as high as 46% (see Park and Wang 2001). The prevalence of underweight among children under 5 years old was 1.8% in cities in 2005, but 8.6% in rural areas (Chang et al. 2006). A well-functional welfare state is not only important to narrow down income and health inequalities, but it is also a central infrastructure to solve health challenges caused by the epidemiologic transition.

Welfare State and Healthcare

The Market-Oriented Healthcare System

The process of marketization and privatization has not only reformed the labor market, but has also affected other social spheres. One example is the changing structure of welfare regime and the social security system.

In the prereform era, there was relatively wide provision of basic healthcare services in China. The state and work units were primarily responsible for offering health care services in cities, and the healthcare services for rural citizens were organized as part of the integrated rural collective commune system. Although rural health benefits were less institutionalized than those in urban areas (Wagstaff and Lindelow 2008), the gap was relatively small, and the general level of social welfare was considered high (Gao 2008; Leueng 2005). Contrary to what many believe in the West, this model of healthcare was widely accepted as successful and it was understood to contribute to better national health (Djukanovic et al. 1975; Sidel 1993).

Overall, the market-oriented economic reform that took place from the early 1980s led to a dramatic reduction in healthcare insurance coverage. In urban areas, healthcare provision was based on which sector people were employed in. Many lost their coverage when they lost their jobs in state enterprises, and only employees with close family members employed in the public sector and state-owned enterprises remained insured (Leueng 2005). By 2003, about 65% of urban residents had to pay for healthcare themselves, and self-financed medical spending had increased 13 fold compared to 1990 (Mok et al. 2010). In rural areas, the de-collectivization of agriculture communities led to reduction of public services, and households became responsible for themselves. As a result, the healthcare system collapsed. There was a fall in health service coverage from about 90% of the rural population in 1980 to 5% in 1985 (Liu and Cao 1992).

One of the major challenges facing the Chinese healthcare system after the economic reforms is that the health services have become heavily hospital-oriented, while primary care has been given low priority (Chan et al. 2008). Before the economic reforms, healthcare delivery was based on a three-tier healthcare system. In urban areas, primary healthcare was provided by the community health units and district hospitals, while municipal and provincial hospitals focused on tertiary medical services. In rural areas, village clinics were responsible for the primary tier, township public hospitals served as the second tier, and county hospitals provided the highest tier for inpatients.

However, as a result of the localization and privatization of health services during the economic reforms, local governments now only provide limited subsidies for health services. Primary care has almost ceased to function. In urban areas, 80% of people visit hospitals for even minor illnesses. In rural China, clinics do not provide preventive care without reimbursement (Chan et al. 2008).

The process of decentralization of welfare provision was combined with a reduction in health expenditure and privatization. Total national health expenditure dropped from 28% in 1978 to 14% in 1993, and health expenditure in rural areas fell

from 20% to 2% (Bloom and Gu 1997). In 2002, the central government required each township to provide only one government-run hospital, while the rest was contracted out or privatized. Healthcare providers such as hospitals and clinics were expected to become "independent accounting units of profit-making entities with independent management," and a revenue-based bonus system was used to increase productivity (DRC 2005).

As a result, healthcare services have been transformed from being institutions responsible for addressing public healthcare needs, to "revenue-maximizing organizations" (Tang and Meng 2004). In order to increase revenue, many hospitals have invested in expensive medical equipment to charge more; they are also recommending unnecessary treatments and selling more expensive medicines.

The government has attempted to regulate drug and healthcare cost, but they have also set prices for new, high-end services above the cost regulation and have allowed a 15% profit margin on drugs. This has prompted hospitals to encourage doctors to prescribe more and costlier medicines, increase expensive high-tech services, and avoid using cheaper medicines covered under regulation (Chan et al. 2008). Among patients who caught a cold, 75% were prescribed antibiotics (Yip and Hsiao 2008).

Aware of these growing challenges, from the beginning of the 2000s the Chinese central government launched several new social programs to extend medical insurance. In urban areas, medical insurance was aimed at covering all urban workers and intended to function as a unified system across different work units. In rural areas, a new medical scheme, launched in 2003, was implemented to cover the whole rural population. From 2005 to 2006, coverage was increased from 600 to 1,433 counties, and by 2008 the program had been implemented in around 95% of all rural counties in China (Zhang et al. 2010).

New Age: Privatizing Public Hospitals in 2010s

Public hospitals in China are the most important healthcare providers and deliver more than 90% of the country's health services. One problem with Chinese healthcare is the lack of primary healthcare services, and the expansion and overuse of secondary and tertiary services. It has led to increased total costs and greater inequality. In 2010, the Ministry of Health started a pilot project to reform the public hospitals. The pilot project was started in 17 cities. The central goals of the reform are to increase equity, affordability, and accessibility (MoH 2010). No practical effort was made to reintroduce primary healthcare. Instead, the important components were to allow for private investment in healthcare, as well as to encourage and support the private ownership and operation of health services.

The 12th Five-Year-Plan for Health was announced in 2012, emphasizing non-public health service providers and an extension of the pilot project to reform public hospitals in other counties and cities (MoF 2014; State Council 2012, 2014b). At least one city in each province was chosen to participate in the public hospital reform during 2014, and over half of the counties will be included in reforming their county-level public hospitals, according to the plans (State Council 2014a).

The main goals have been the same across the cities, but local goals and practices also vary. It seems that most of the governments chose to adapt the market mechanisms and private actors as healthcare solutions. Only four of these cities mentioned goals of providing access to affordable basic healthcare through public and nonprofit hospitals. Some other cities, to varying degrees, shifted their strategies towards market competition and private ownership of public hospitals (Yip and Hsiao 2014). In Hubei Province, the number of new approved private health care institutes increased from 32 in 2012 to 130 in 2013. In Beijing, in just the first two quarters in 2013, 163 new private hospitals and clinics were approved (Chinanews 2014).

If the public hospital reform in China reaches its goal of equal and affordable access to health services, it would lead to efficient and quick treatment of patients, independent of their background. However, to date, most entrants in China have been motivated by profit, including the private hospital chains, pharmaceutical sector, medical equipment producers, and real estate developers (Yip and Hsiao 2014). The opening of the market for private health providers may also reinforce the use of high-tech medical tests and expensive medicines in order to signify high quality of services to patients. This may create an even higher barrier for the poor and for people with poor health, and these developments may be followed by greater income inequality.

Inequality and Health

Inequality in Healthcare System

Notwithstanding these attempts to improve the welfare system, in the middle of the 2000s, the quality of public health care actually worsened (Chan et al. 2008). Medical costs became even more expensive, and reimbursements were low. Many poorer people were thus excluded from access to basic healthcare. About 13% of Chinese households had to pay more than 40% of their disposable income on health, and half of inpatient costs were paid out-of-pocket by an average patient (Ouyang 2013). The share of households' out-of-pocket expenditure in health reached a top of 60% in 2001, with a reduction in the following years. However, health still takes a major part of the health cost. In 2010, households' used 35% of their out-of-pocket expenditure on health accounts (see Fig. 2).

The system was fairly unequal, with rural residents in the lowest income quintile spending the highest share of their income on healthcare (Yip and Hsiao 2009). Further, real income per capita in 2003 was almost double that of 1993, but health expenditure per admission/visit had quadrupled in the same period. On average, the cost of one inpatient hospitalization was 70–80% of an individual's annual income in 1993. In 2003, this had increased to be, on average, twice as high as an individual's annual income.

As a result, illness has become a major contributor to poverty: more than 20% of those living under the poverty line were in this situation because of disease or injury (Liu et al. 2003). Income has become a dominant factor in healthcare utilization: in

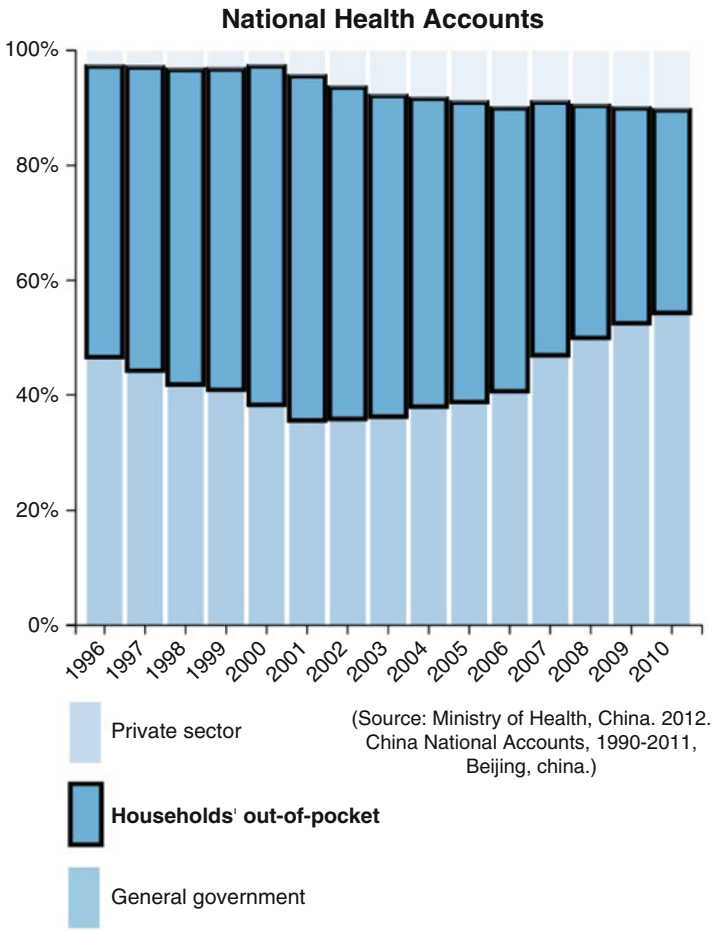

Fig. 2 Share of people in need of hospitalisation that were not hospitalised

rural and urban China, respectively, 24% and 16% of the population refused to be hospitalized due to financial burdens in 2003. Among those hospitalized, 32% of them discharged themselves against medical advice because they could not afford to stay (Yip 2010).

Overall, health inequalities have widened. In 2005, life expectancy was 6 years longer for urban citizens compared to rural citizens and 15 years longer for people living in eastern China compared to those in western China (Chen 2012). The rural to urban ratio of infant mortality rate has increased from 1.5 in 1981 to 2.1 in 1995 (Zhang and Kanbur 2005). Rural mortality was 30% higher than urban mortality among older people (Zimmer et al. 2007), and the maternal and under-five mortality rates in rural areas were about three times greater than those in urban areas (WHO and DRC 2005). In some rural areas, infant mortality even rose in the 1990s (Liu et al. 1998).

At the same time, primary healthcare provision failed in its function to provide preventative care. On average 120,000 new cases of resistant tuberculosis have been reported each year (Shan 2013). In 2012, there were 7 million cases of infectious disease that caused 17,000 deaths (DPES 2005). Some of the previously nearly controlled infectious diseases, such as schistosomiasis, began to spread again (Blumenthal and Hsiao 2005).

The Malnourished

Earlier research has shown that the impact of income inequality on health is strongest for the poorest groups (Fang and Rizzo 2011; Yang and Kanavos 2012). According to the China Family Development Report 2015, the household incomes of the top 20% of households in China are 19 times higher than that of the bottom 20% (NHFPC 2015a). One direct way of measuring the impact of poverty on people's health is to look at malnourishment. During 2005 and 2007, 130.4 million Chinese people were undernourished, accounting for 10% of the total population (FAO 2010). The prevalence of anemia among children aged 6–12 months living in rural China was 35% in 2005, and the corresponding number was as high as 28% when urban children of the same age were included (MoH 2012). Some studies reported prevalence rates of anemia for children living in rural areas in China ranging from 20% to 60%, implying more than 10 million children were affected (Miller et al. 2012). A report from UNICEF referred to an estimation of 12.7 million stunted children in China – that is the same size as the population of Tokyo. The authors found that in poor rural areas in central and western China, one out of 10 children under 5 years old were stunted. In Qinghai Province, the prevalence of anemia among children aged 6 months to 2 years old was above 70% (Liang 2013).

As recently as 2015, malnutrition among adults and children/adolescents in China was estimated to be 6% and 9%, respectively (NHFPC 2015b). Childhood anemia may also impair cognitive development, school performance, and work outcomes and also cause lower socioeconomic status throughout the life course (Stoltzfus 2001).

Inequality and Health in China

Following the process of market transition, many Chinese face greater challenges and pressure. The labor market has become more competitive, stressful, and demanding; job situations are more unsecure since the formerly lifelong employment in the state sectors has been reduced; family obligations lie more heavily on individuals because of the lack of welfare support. The tremendous changes inevitably influence people's daily life, psychological condition, lifestyle, and health-related behaviors and are further embodied in their physical health outcomes (WHO and DRC 2005). Health-related behavior and lifestyle changes such as nutrition, physical activities, smoking, and alcohol have been recognized as important reasons

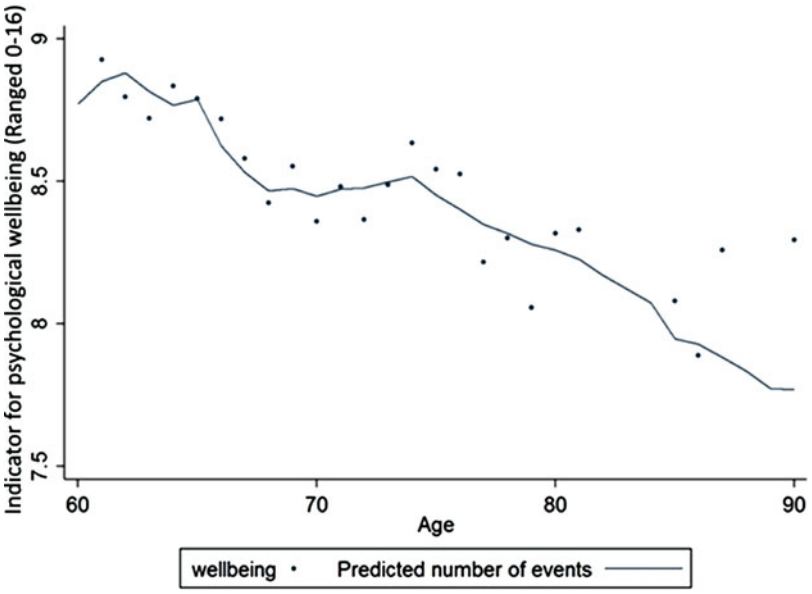

Fig. 3 Correlation between age and psychological wellbeing (Data source: Chinese Health and Nutrition Survey, 2006–11)

for increased health problems (DRC 2005; WHO 1999). By using CHNS 2006 data, Yang and Kanavos (2012) concluded that poorer people are less physically active and less likely to report their health as good or excellent. Using four waves of the same data set from 1991 to 2000, Li and Zhu (2006) found that self-rated health is positively associated with per capita income, but high inequality in a community increases the probability of harmful health-related behavior such as smoking and drinking.

Another vulnerable group is the elderly in China. Subjective wellbeing, as an indicator of psychological health, reduces rapidly with age for people over 60 (Fig. 3). Chinese people born in and before the 1950s have spent more than 25 years of their lives under socialism and experienced a time with rapid social changes, including increased inequality and reduced welfare support.

When considering psychological health, Bakkeli (2016b) found that higher income inequality is associated with lower subjective wellbeing, when studying older adults living in China. This relation is illustrated in Fig. 4. Furthermore, in places with higher degrees of income inequality, poorer individuals may suffer even more from health problems. Chen and Meltzer (2008) found that in rural China, obesity and hypertension are positively associated with increased income inequality in a county, but also with the county's average income. Fang and Rizzo (2011) confirmed that income inequality was negatively correlated with self-reported health, and the effect of inequality on individual health was stronger for individuals from lower income households, compared to those from richer families. Empirical

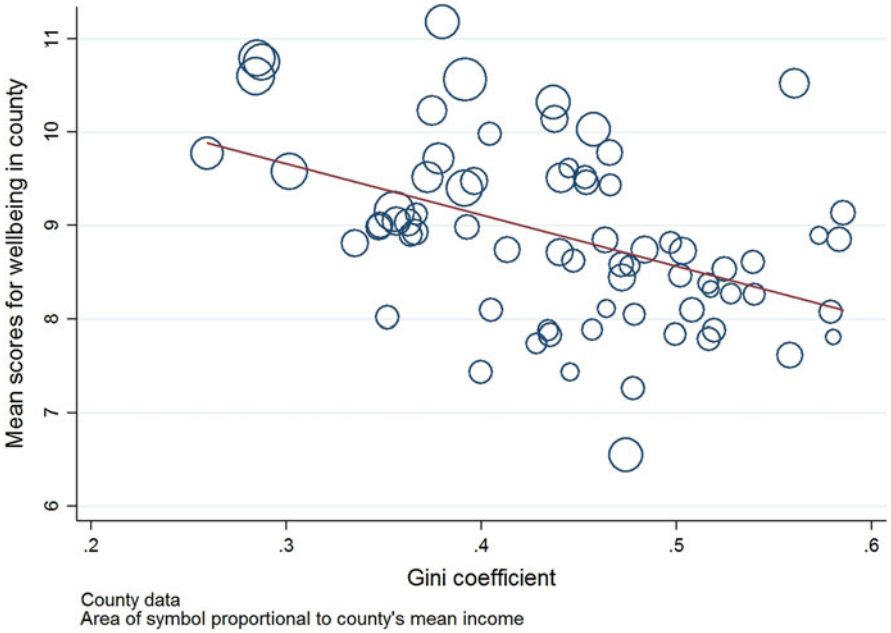

Fig. 4 Correlation between income inequality and subjective wellbeing in China, by counties (Data source: Chinese Health and Nutrition Survey, 2006–11)

studies of the income inequality hypothesis from China are relatively few, and the findings are rather mixed. For example, Pei and Rodriguez (2006) claimed that after adjusting for individual and household variables, the effect of inequality on health disappears. When analyzing longitudinal data sets and defining health using different physical measures, no statistically significant connection was detected between inequality and health outcomes in China (Bakkeli 2016a).

Health Situation and Epidemiological Transition

Recent Health Situation in China

The numbers of Chinese people diagnosed with cardiovascular diseases, hypertension, and obesity increased during the reform period. The Chinese Centre for Disease Control and Prevention estimated that 200 million Chinese people were diagnosed with hypertension in 2010, about one in five adults (CGMH 2011). Accordingly, above 40% of all deaths each year were caused by cardiovascular and cerebrovascular diseases; half of them were caused by high blood pressure. Some official sources have shown that about 24% of those aged 15 or older in China had hypertension. Among youth and adolescents, about 15% of them were

diagnosed with high blood pressure, and approximately 30% of them were diagnosed with obesity (The Central People's Government of the PRC 2013).

Previous studies have recognized occupational and psychological stress, which is a complex biopsychosocial situation, as a major health hazard worldwide; it contributes to different diseases, such as depression, cardiovascular disease, abnormal blood pressure, and even obesity. Similarly, one of the major factors contributing to cardiovascular diseases in China was recognized to be lifestyle and work pressure (Gong et al. 2006). The rising degree of competition, increased income inequality, and labor market stratification in China may also have an impact on people's stress levels, and may cause health problems.

Diabetes has also become an important public health challenge in China. The prevalence of Type 2 diabetes and impaired glucose tolerance was reported to be about 1% in a survey carried out in 1986 for urban citizens aged 25–74 in northeast China (Li et al. 1996). The numbers for the above-mentioned diseases increased to 2.5% and 3.2% in 1994, respectively (Pan et al. 1997). Some other reports found the prevalence of diabetes in the adult population to be much higher than the previously reported results. According to the International Collaborative Study of Cardiovascular Disease in Asia, in 2000–2001, the prevalence of diabetes for Chinese men and women aged 35–74 was as high as 5.2% and 5.8%, respectively (Gu et al. 2003). Furthermore, the rate in northern China was higher than in southern China (7.4% compared to 5.4%) and higher in rural areas than in urban areas (7.8% compared to 5.1%).

Some have argued that when considering noncommunicable diseases (NCDs), familial factors and inherited genetic variants may be more relevant in Chinese people than in Europeans (Ma et al. 2014). Although genetic predispositions may be an important factor in the development of cardiovascular diseases, environmental factors are also of major importance. Epidemiological studies have identified several risk factors associated with the development of cardiovascular diseases, such as overweight and lifestyle, air pollution, environmental noise, and the social-cultural context.

NCDs such as type II diabetes are highly preventable. However, the management rates for such diseases in China are very low: less than half of those who were diagnosed by hypertension and diabetes in China were treated by health care providers in 2008. Because of a lack of prevention information, about 30% of those who had hypertension were not aware of their condition before diagnosis, and 54% had never received blood pressure tests by health providers (Meng and Tang 2013). This may be a reflection of the Chinese healthcare system: despite the fact that the central government in China has started to focus more on wellbeing and human development, local governments have still prioritized economic development.

Phases of Transition

China may be facing a new epidemiological transition today. Epidemiologic transition is the changing pattern of diseases and mortality in a society, and the theory of

epidemiological transition, developed by Omran (2005), focuses on the complex change in patterns of health and disease, and how these patterns are connected to the demographic, economic and sociological determinants. The decline in mortality is closely linked to the process of modernization. While socioeconomic development was recognized as the most important factors for improving living standards and reducing mortality in the western model, medical technologies and public health were considered more important for the accelerated and contemporary model.

Cook and Dummer (2004) attempted to apply the model of epidemiologic transition to China. They documented that before 1949, infectious disease and natural catastrophes such as flooding and drought were the major causes of mortality in China, corresponding to Omran's "age of pestilence and famine." From the 1990s, China experienced an important overall decline in infectious diseases of poverty and underdevelopment, such as cholera, dysentery, hepatitis, and typhoid. In the last decade, China has experience increases in death rates from chronic diseases, including cancers and heart disease. These shifts reflected Omran's model quite well. However, Cook and Dummer emphasized that epidemiologic transition in China is segmented, with large variations between rich and poor, and between urban and rural areas, as well as an emerging "medical poverty trap" that reinforces the widening inequalities of access to healthcare services.

One may argue that income inequality is a component in and unintended consequence of the economic transition and that it further mirrors the ongoing epidemiological transition. However, Wilkinson demonstrated the relation between income inequality and life expectancy in wealthier industrialized countries that have passed through the epidemiological transition and where the cause of mortality has changed from infectious diseases to chronic diseases. Observing that life-expectancies had increased in countries with lower income inequality, while countries with higher inequality had fallen behind in terms of life-expectancies, Wilkinson argued that whereas material deprivation leads to poverty and infectious disease, social disadvantage provokes stress and chronic disease (Wilkinson 1996).

Similarly, Gaylin and Kates (1997) criticized epidemiological transition theory for being overly optimistic about the demise of infectious diseases and argued that it ignored the importance of social inequalities. They suggested that socioeconomic inequality should be brought to the center of the analysis and that epidemiologic differences between population subgroups should be taken seriously.

Epidemiological Transition in China?

This new phase of epidemiologic transition is defined by a shift in the burden of disease to NCDs. Because of economic growth and poverty reduction, the transition is being accelerated by a shift from malnutrition to overnutrition. The population faces a new set of health problems, including diseases of affluence, the impact of smoking and drinking, hypertension, environmental pollution-related health risks, and the rise of infectious diseases (Yang et al. 2013; Zhou et al. 2016).

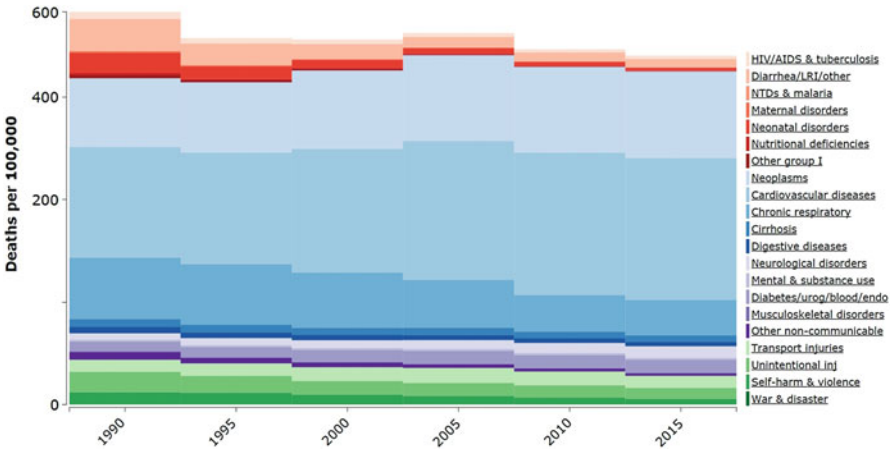

Fig. 5 Leading death causes in China, 1990–2015 (Data source: Institute for Health Metrics and Evaluation (IHME))

See Figs. 5 and 6 below for changes in diseases. Of the 8.3 million deaths in China per year, 7 million are due to NCDs. The leading risk factors for disability-adjusted-life-years in 2010 in China were cardiovascular diseases, cancers, low back pain, and depression. Other risk factors included dietary risks, high blood pressure, tobacco, and air pollution (Yang et al. 2013).

By investigating how patterns of cause of death had changed from 1990 to 2003 in 33 provinces in China, Zhou et al. (2016) show that during this period, life expectancy had improved, the death rate had fallen by almost a third, and that the major causes of mortality had changed. In 1990, the most important causes of death in most provinces were lower respiratory infections and preterm birth complications. In 2013, the leading causes of death were stroke, ischemic heart disease, chronic obstructive pulmonary disease, and lung cancer. Mortality due to infectious diseases, diarrheal disease, and lower respiratory infections had fallen substantially. Throughout the country, an increased proportion of deaths were caused by road traffic injuries throughout the country.

At the same time, challenges related to urbanization and widening social and regional disparities persist. The epidemiological transition is not unrelated to social contexts. For example, Lei et al. (2010) found that hypertension affects all socio-economic classes independently. But people with a better education living in urban China are more aware of their condition, and there is therefore a higher treatment percentage and better control among this group. Further, public healthcare services fail to inform patients of their hypertension status. Yang et al. (2013) interpreted the rapid rise of NCDs as driven by urbanization, rising incomes, and aging. Richard Horton, the present editor-in-chief of *The Lancet*, commented on China's transition and suggested that China needs to place a greater emphasis on building a primary healthcare system, addressing environmental threats, and reducing inequalities (Horton 2015).

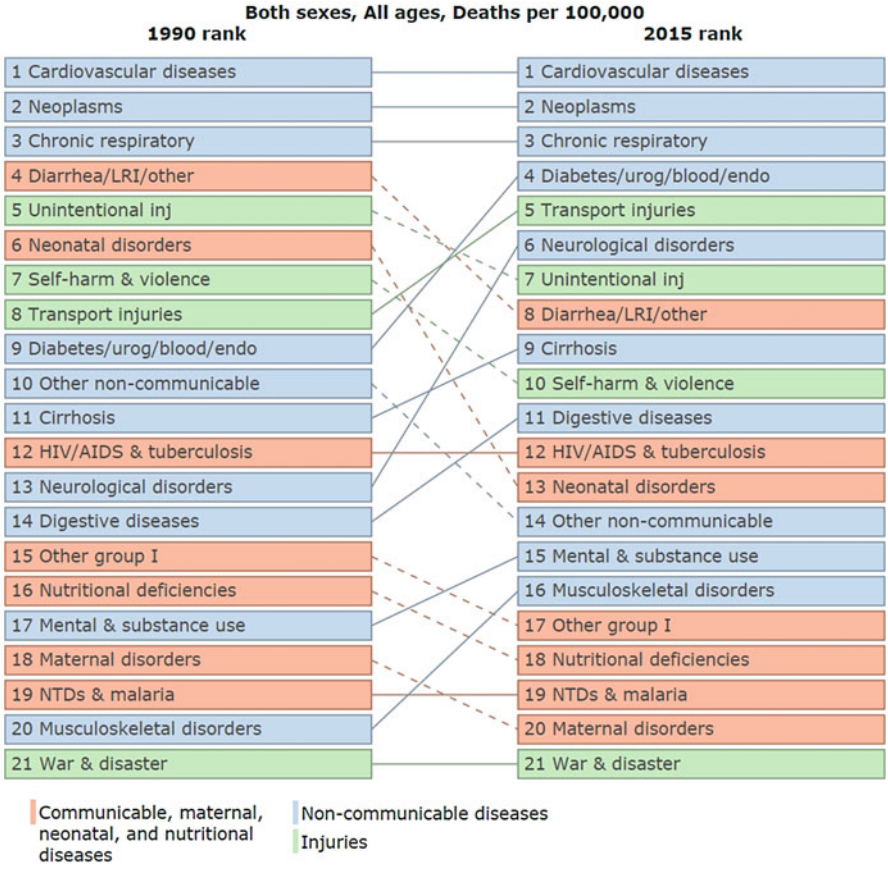

Fig. 6 Ranking of leading death causes in China, 1990 and 2015 (Data source: Institute for Health Metrics and Evaluation (IHME))

Conclusion

There is an increased awareness of the need to not only keep an eye on factors like income inequality or income in itself, but also to have a more nuanced discussion that includes the ongoing epidemiologic transition in China. There is also an urgency to place more emphasis on developing China's healthcare structures, as well as general discussions concerning welfare support. This faces challenges due to China's demographic and epidemiologic transitions. The population is aging rapidly. The increasingly elderly population, one-child families, dual-employed parenthood, and large-scale rural-to-urban migration led to a more fragile family base. At the same time, China has experienced an epidemiologic transition in a much shorter time than many other countries – there has been a shift

in leading mortality causes and behavioral changes such as smoking and lack of physical activity. With 177 million adults already diagnosed with hypertension, 303 million smoking adults, and the emergence of NCDs and chronic diseases, China's healthcare reforms and healthcare institutions face particular challenges.

The challenges include the integration of primary care services with secondary and tertiary healthcare, prevention strategies and treatment for chronic diseases, and public policy support. Further, such policies are integrated with welfare policies for employment, income maintenance, housing, education, etc.

Reducing NCDs is one of the key interventions for a reduction of poverty and social and health inequalities. Therefore, it is important that welfare institutions can also adapt to new challenges caused by the transition.

Policies and Protocols

In this chapter, we have discussed three major factors that have been important for health in China. These are healthcare system and reforms, inequality, and epidemiologic transition. We have discussed the impact of market-oriented healthcare reforms and its possible impact on health inequality and population health. Developing a well-functioning healthcare structure and social policies are important for both users of welfare state, as well as new challenges connected to social, demographic and epidemiological transitions. Following are some of the policy suggestions.

- China needs a broader public policy support with a focus on different social strata. More attention to prevention strategies and treatment for chronic diseases is essential.
- An important challenge for future healthcare reforms is to integrate primary care services with secondary and tertiary healthcare.
- Besides further development of infrastructure, it is urgent to reduce overall inequality in China.
- Reducing noncommunicable diseases is one of the key interventions for poverty reduction and increased equity and equality.

Dictionary of Terms

- **Noncommunicable diseases** – Refers to a diverse set of chronic diseases, including heart disease, stroke, cancer, diabetes, and chronic lung disease.
- **The epidemiologic transition** – Describes changing patterns of different demographic trends. This includes age distributions in a society, mortality, fertility, life expectancy, type of diseases, and causes of death. In this chapter, we focus on the epidemiologic transition in which dominant causes of death has changed from

infectious diseases, malnutrition and war, to noncommunicable diseases, accidents, pollution, etc.

- **The Gini-coefficient** – The Gini-coefficient is a statistical measure of income inequality in a society. It is ranged from 0 to 1, from total equality to maximal inequality. A value placed between these extremes indicates how unequal the income distribution is. As the value rises, the degree of income inequality is higher.
- **Malnutrition** – Primarily refers to both undernutrition and overnutrition. This chapter focuses more on the undernutrition aspect of malnutrition, i.e., individuals who do not consume enough food.
- **Privatization** – Primarily refers to state-owned enterprises passing under private ownership, in addition to the growth of the private sector and private shareholders. Furthermore, the general withdrawal of state or public services in certain areas is a form of privatization, since it reduces state responsibilities and increases the reliance on private service providers.

Summary Points

- This chapter reviews three factors that contribute to health problems in China: healthcare system, inequality, and epidemiologic transition.
- The market-oriented healthcare reforms in China have led to more profit-oriented medical services, while to some extent ignoring the healthcare system's primary function of infectious disease prevention and securing population health.
- The healthcare reforms have led to uneven distribution of healthcare and increased economic burdens for the poor.
- China is facing challenges of increasing health and income inequalities. A higher degree of inequality may also lead to lower psychological and physical wellbeing.
- The ongoing epidemiologic transition requires more policy attention. Reduction, treatment, and prevention of noncommunicable diseases should be given higher priority.

Abstract

Drinking-water deprivation in terms of access, quantity, and quality poses serious health hazards both in the short and long term. This is especially critical in refugee chronic situations that last for decades, such as the Saharawi refugee camps (>40 years). Water access and water quantity improves health, as water is not only needed for direct consumption or cooking but also for hygiene, directly related to health. On the other hand, water quality avoids not only gastrointestinal diseases in the short term, but also other health issues that appear under a long-term exposure. This chapter reviews the history of drinking water and health at the Saharawi refugee camps, showing how water access has improved over the years but still does not guarantee the minimum quantity of 20 l/person/day established by the United Nations High Commissioner for the Refugees (UNHCR). It also shows how water treatment using chlorination has reduced dramatically the diseases associated to microbiological contamination, and how the poor raw water quality that a percentage of the population is still consuming has produced long-term health effects, such as the prevalence of fluorosis and goiter.

Introduction: Water and Health

Why drinking water when talking on starvation or nutrient deprivation? Although discussing on nutrition issues is often directly related to food income, water should be always considered as one of the main sources of nutrients in any nutritional study. As the United Nations High Commissioner for the Refugees (UNHCR) states, "Water is one of the main nutrients, along with fat, protein, carbohydrates, and micronutrients, that the human body needs on daily basis" (UNHCR 2016a). Water is needed for food preparation; therefore, safe drinking water is essential as otherwise it can cause diarrhea, producing loss of nutrients that results in malnutrition. This is especially dangerous for children under five as malnutrition contributes to almost 60% of deaths of this fragile population (UNHCR 1992).

But not only microbial safety is one of the main required characteristics of drinking water, there are also physicochemical requirements to guarantee water safety. Water quality includes also a series of micronutrients that can affect health, by absence or excess, and both are equally risky. Some examples are nitrate presence, fluoride, or iodine, which will be explained further in the next sections. And while microbiological contamination produces short-term health effects, causing diarrhea almost immediately, most of physicochemical components will only show their effects after several years of exposure (long-term effect), which is especially risky in some refugee situations that last for long periods of time (decades).

Finally, the other main challenge is to provide sufficient water quantity to the population, which is not only related to the amount of safe water available for drinking and/or cooking, but to other uses such as hygiene (personal washing, household cleaning) and sanitation, which are directly associated to health benefits. How to decide how much water is needed? In the past, organizations and relief agencies used to have different criteria till the development of the SPHERE Project (The Sphere Project 2011), which defines the minimum requirements for water quality and quantity, along with water access, for emergencies situations. In this line, UNHCR adapted these standards for refugee situations (UNHCR 2017), considering that refugees might stay longer in a camp that an "emergency situation" (Table 1). A minimum of 20 l/person/day of water is established, along with no microbiological contamination and a minimum of 0.2 mg/l of free residual chlorine to ensure water safety.

Guaranteeing drinking-water access at refugee camps is actually a worldwide challenge, especially in situations where the resources are scarce, and also in cases of

Table 1 Water guidelines for refugee situations. Guidelines on water minimum standards for refugee populations defined by the United Nations High Commissioner for the Refugees (UNHCR) (and comparison with the Sphere Humanitarian Charter and Minimum Standards in Disaster Response (SPHERE) Project for emergencies), including water quantity, quality, and access

Parameters	Standard	UNHCR (refugee camps)	SPHERE (emergencies)
Water quantity – basic needs for health and well-being	Average quantity of water available per person/day	>20 l	>15 l
	Water containers per household (average of 5 members)	1×20 l, 2 × 10 l, 2 × 5 l	2 of 10–20 l
Water quality – prevention of health risk	Number of fecal coliform organisms at distribution point (microbiological content)	0 per 100 ml of treated water	0 per 100 ml of treated water
	Free chlorine residual concentration in disinfected water	0.2–0.5 mg/l	0.5 mg/l
Water access	Distance from farthest dwelling to water point	<200 m	<500 m
	Number of persons in each water point	80 to 100/tap 200 to 300/hand pump/well	250/tap500/hand pump 400/well

chronic crisis, the "protracted refugee" situations (Loescher et al. 2008; UNHCR 2009). According to UNHCR, "6.7 million refugees were in a protracted situation by the end of 2015," plus 5.2 million Palestinian registered with the UNRWA, about 12 million in total (UNHCR 2016b). Among the longest refugee camps, there are the Palestinian population in Gaza, Jordan, Lebanon, and the West Bank (1948, >65 years), the Sudanese in Ethiopia (since 1950), the Burundians in Tanzania (1971) and the Saharawi camps in Algeria (1975, >40 years). In these long-term cases, the effects on health from an inadequate nutritional intake, including an appropriate drinking-water source, are always more serious, not only because of the long-term effects of malnutrition, but also because the population keeps depending on international external assistance for fulfilling their basic needs, for an indefinite period of time, staying in a "limbo" situation.

This chapter reviews the case of the Saharawi refugee camps in Algeria, describing their challenges for a clean drinking water source, and the health effects that the deprivation of safe drinking water has produced in the refugee population since the early days of the camps.

Drinking-Water Access at the Saharawi Refugee Camps

Saharawi refugee population from Western Sahara is one of the "forgotten" international conflicts that remain in a protracted situation. After 40 years, there are still about 165,000 refugees – according to local authorities and the estimations of the Government of Algeria – that live under the harsh conditions of the Sahara desert, with very limited access to basic needs, including those related to health, energy, and water. Meanwhile, there has not been any significant advance in the peaceful political conflict resolution and most of the refugee population still live in very precarious conditions.

The refugee camps were established in 1975 in the initial stages of the international conflict in Western Sahara. At present, they are composed by one institutional center (Rabouni) that comprises the administrations, and five refugee camps located near Tindouf (Algeria). These refugee camps are divided into five "wilayas" (Fig. 1): El Aiun, Awserd, Smara, Dahkla, and Boujador (Boujador is near Rabouni, not shown in the Figure). Each wilaya is organized in smaller communities called "dairas." Most of the population live in tents ("jaimas") or rudimentary houses made of adobe, made with a mixture of sand and water ("mud-houses"), with no direct access to water neither electricity (Fig. 2).

Drinking-water access has been one of the main concerns since early days of the refugee situation, starting with "survival" emergency shallow handmade wells, then building deep groundwater wells, and finally incorporating water treatment using reverse osmosis and/or chlorination; 100% water supply in terms of quantity and quality has not yet been achieved. This evolution corresponds to the natural change from an initial "temporary" settlement (emergency) to a more permanent one (prolonged crisis). Three stages on the water supply access can be differentiated (Fig. 3):

Fig. 1 Situation of the Saharawi refugee camps. Map of Western Sahara (UNHCR 2006) and detail of the Saharawi camps area, showing the different wilayas. Data are from UNHCR (2006), with permission from Publishers

Fig. 2 Overview of Saharawi refugee camps. Overview of the Saharawi refugee camps. Tents and adobe houses constitute the dwellings of most of the population. Picture is from the authors

Stage I (1975–1993) – Shallow Groundwater Wells

In 1975, the drinking-water supply was set up as an "emergency" solution to the Saharawi population that fled the Western Sahara region to Algeria. It consisted of traditional handmade shallow groundwater wells and superficial ponds dug at El Aiun and Dakhla. They supply 75% of the population, up to 20 l/person/day, which is above the minimum standard given by the Sphere Project (15 l/person/day) (The Sphere Project 2011) or the WHO (WHO 2011a) for emergency situations. Water quality was originally good, although contamination was a main risk and water quantity was seriously limited.

Stage II (1994–1999) – Deeper Groundwater Wells

In 1994, after already almost 20 years of settlement without any significant evolution in the water supply access, unusual strong rains caused devastating floods that contaminated the shallow wells mainly due to the lack of a sanitation system in the camps, originating a cholera epidemic at El Aiun. This led to a considerable change in the water supply as the shallow wells were no longer a safe solution.

Deeper groundwater wells of about 100 m with automatic pumping were created followed by a chlorination stage (only microbiological treatment). Water supply was centralized in these new wells rather than in the immediate vicinity of the households as for the previous traditional wells, and then water distribution was operated by tanker trucks to the different camps. Another important aspect was the introduction of the first water microbiological analysis from that moment onwards (*E.coli* and total coliforms analysis). These improvements guaranteed safer drinking-water access, but the available water quantity per person decreased dramatically to

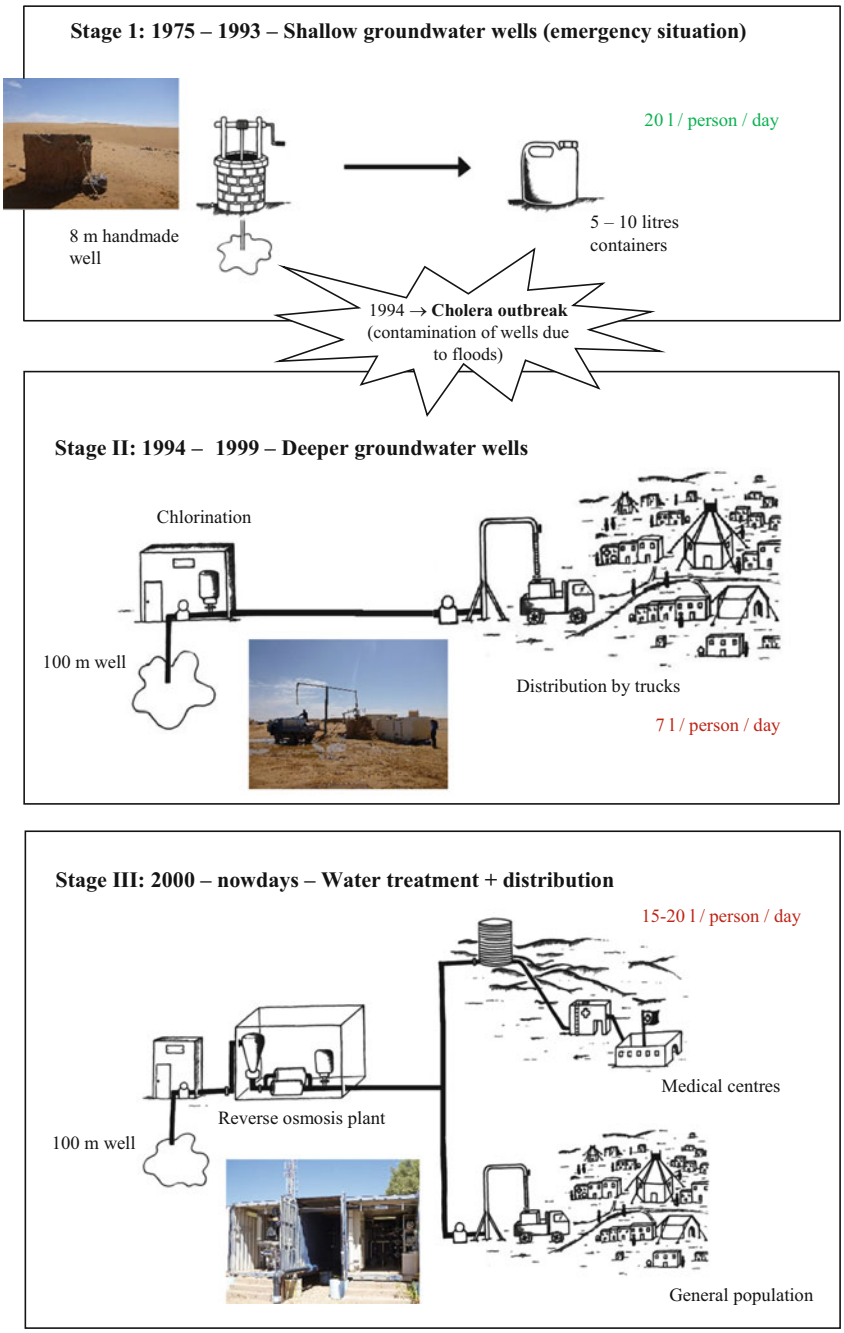

Fig. 3 Water access at the Saharawi camps over time (1975–2016). Different stages and the water supply access characteristics of each of them: a) Stage I (1975–1993): shallow 5–8 m deep hand-made wells, b) Stage II: 1994–1999: deeper groundwater wells (~100 m) plus chlorination and

7 l/person/day, below the minimum standards of 15 l/person/day given by the Sphere Project. Simultaneously, the associated costs increased notably.

Stage III (2000–Currently) – Water Treatment and Distribution

After a more than 25 years in the camps, and with no significant advances in the resolution of the political conflict, the Saharawi authorities and UNHCR decided to further improve the current water supply facilities. The main improvements included: (a) raw water treatment using reverse osmosis, (b) water quality control (physicochemical and microbiological analyses), and (c) expansion of water distribution networks. Now, general drinking-water supply at the camps is organized in three zones that include one or several wilayas:

- *Zone 1: El Aiun, Awserd*. Water supply consists of groundwater wells and a reverse osmosis plant for both wilayas. The treated water quantity in the plant is not currently sufficient to supply continuously the population in these two wilayas so each wilaya receives treated water in turns of 20 days.
- *Zone 2*: *Smara, Rabouni, Boujador*. Groundwater wells and two reverse osmosis plants working alternately provide continuous treated water to the zone.
- *Zone 3*: *Dakhla.* This wilaya is located about 140 km far from the rest of the refugee camps, so it has a dedicated water supply which consists of a groundwater well followed only by a chlorination stage due to the good quality of the raw water.

Water Quantity and Health

The different uses of safe drinking water are directly linked to health effects on the population. First, the main use of water is for human consumption, which includes drinking and cooking. As stated by WHO and Kleiner (Kleiner 1999; WHO 2003a), "Water is a basic nutrient of the human body and is critical to human life. It supports the digestion of food, adsorption, transportation and use of nutrients, and the elimination of toxins and wastes from the body." The immediate consequence of not having access to an adequate quantity of safe drinking water is dehydration, which can cause diarrheas. As an indication established by WHO, the volumes of water required for maintaining hydration are of 2.2–2.9 l/day for adults and 1.0 l/day for children.

Regarding cooking, water is needed for the preparation of foodstuffs, and quantities can vary significantly depending on the diet, although a minimum water quantity must be always included to be able to prepare the basic food basket of a

Fig. 3 (continued) water distribution by trucks, c) Stage III: 2000 - nowadays: groundwater wells followed by reverse osmosis, wider water distribution including also medical centers. Data, drawings and pictures are from the authors

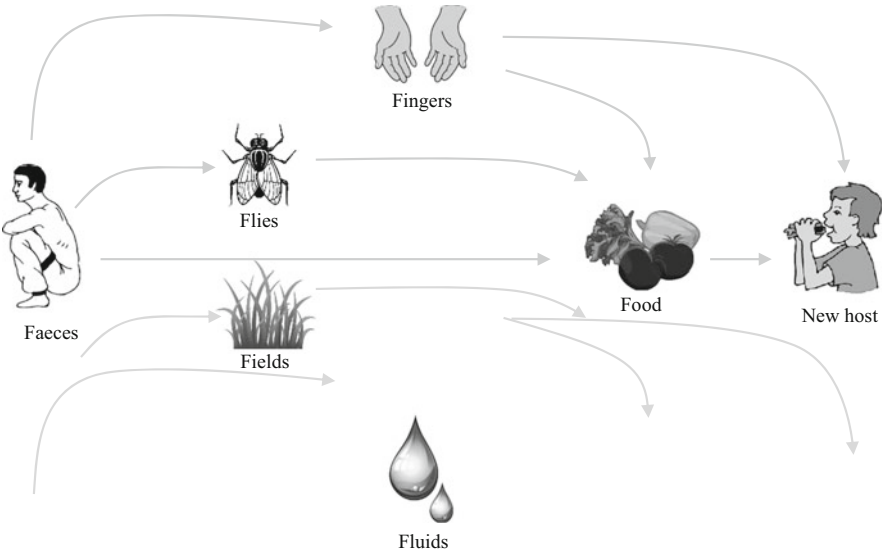

Fig. 4 Fecal-oral route for transmission of diseases, showing the importance of personal hygiene (requiring a sufficient quantity of safe water). Scheme from the authors

family. Additionally, it is important if the milk is provided as powder or not, as this would increase the required quantities of water.

The other important use of water that is related directly to the health status of a population is hygiene, including personal washing and domestic cleaning. Within personal washing, one critical aspect is handwashing, as an inadequate habit of handwashing can accelerate cases of diseases transmitted through the fecal-oral route (it is necessary to hand wash before eating and cooking and after defecation), such as diarrhea and skin and eye diseases (Fig. 4). In many developing regions, the main reason behind an inadequate personal hygiene is the lack of an appropriate quantity of water (WHO 2003a).

As defined by UNHCR, the minimum water quantity in a refugee situation should be at least 20 l/person/day. Recent data on the quantity of water supplied to the Saharawi people report that it is currently of about 15–17 l/person/day in all the settlements (below the UNHCR standard) excepting Dakhla that reaches 20–25 l/person/day (Vivar et al. 2016), although other sources (AECID 2015) report even lower quantities: 15–20 l/person/day in Dakhla, Smara, and Boujador and only 9–11 l/person/day in El Aiun and Awserd camps. UNHCR also reported in 2015 an average quantity of potable water distribution for the Saharawi refugees around 18 l/person/day (UNHCR 2015). In conclusion, the quantity of water provided to the population is currently insufficient and improvements on the service should be implemented to guarantee the minimum amount of water established by UNHCR.

Another important consideration regarding water quantity is the reliability of the service, or in other words, the water supply continuity. One of the problems of the

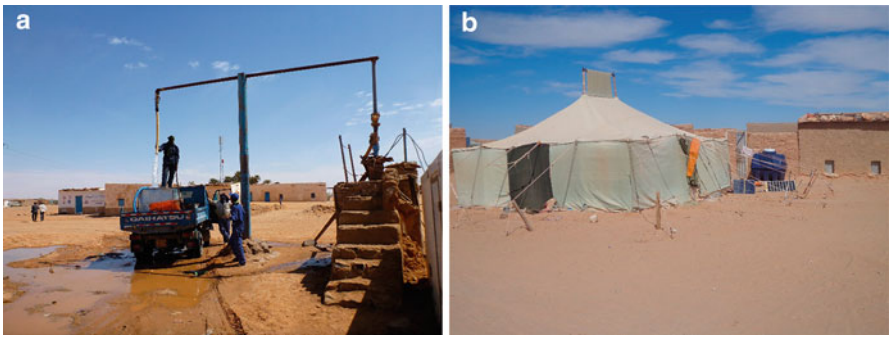

Fig. 5 Water distribution at the Saharawi camps . Example of water distribution network at the Saharawi camps: a) main water supply point in Dakhla using trucks for distribution to households; b) typical tent in the camps, with a water tank in the vicinity (in this case it is adequate for human consumption, vs. other tanks made of metal or other non-food grade materials). Photos from the authors

Saharawi water distribution system is that is based on trucks that transport the water to the different wilayas (Fig. 5). According to the latest reports, the condition of the fleet is not adequate and the trucks are in very poor condition, which often results in the fact that they are not able to adhere to the distribution calendar, producing shortcomings of water in the population (WFP and UNHCR 2013). Although in some cases the amount of water might reach the minimum requirements, often these quantities are not provided continuously, with periods of time with insufficient water to cover the basic needs.

Finally, the other important issue in the Saharawi camps is the variations of demand of water over the year. WFP and UNHCR conducted a survey in 2012 and found that the quantity of the water distributed during the winter (December–February) was considered sufficient to meet the needs of households, while in the summer months (June–August) the demands for water increased due to the high temperatures in the desert (>50 °C) and it was not sufficient (WFP and UNCHR 2013).

Water Quality and Health

Water quality is essential to guarantee a healthy status of any human being. An inadequate water quality has not only immediate effects on health (usually associated to gastrointestinal diseases), but the continuous consumption of water with inappropriate chemical content can origin other diseases in the long-term.

Short-Term Health Risks: Microbiological Content and Nitrates

In general, the effects of short-term ingestion of contaminated water are more widely known, as they produce rapid and acute effects on health such as watery diarrheas

that often lead to death in developing countries (mainly due to the lack of safe water to prevent dehydration during diarrhea), especially in children under five. These gastrointestinal diseases transmitted by water might have their origin in the microbiological content of water: microorganisms that are pathogen for the human, such as bacteria, viruses, and protozoa. These microorganisms have their optimum growth temperature about 37 °C, which is the average normal human body temperature, so when they are in the human organism they can proliferate rapidly.

The most common bacteria related to fecal microbiological contamination of water (Fig. 4) are *Escherichia coli*, *Intestinal enterococci*, and *Clostridium perfringens*, which are used as indicators of water contamination. These bacteria are present in the normal intestinal flora of humans and animals, where they can live with no harm for the host. The problem arises when they enter in other parts of the body via ingestion of water where they can cause infections.

Another group of bacteria that is used as an indicator of water contamination after it has been disinfected is total coliform bacteria, which should be absent immediately after disinfection, so their presence indicates inadequate treatment or contamination problems in the distribution network.

Finally, one of the most common groups of bacteria in epidemics in developing countries associated with water contamination is *Vibrio*, with pathogenic species such as *V. cholerae*, producing cholera, with symptoms that include fulminating and severe watery diarrhea. To guarantee microbiological safety of water, WHO standards (WHO 2011a) indicate that the content in water of any of the *microbial indicators* must be *0 in 100 ml of water*.

There are also a number of chemical components that at high concentrations can produce immediate effects on the human body posing serious hazards. Despite the general understanding that inadequate physicochemical properties of water show their effects in the long term, there are chemicals such as nitrates (NO_3^-) that are especially dangerous for the infant population, for those being fed with artificial milk ("bottle-fed").The hazard appears when water from ground wells containing high concentration of nitrates is used for the preparation of milk. When the water is ingested by the infant, large quantities of nitrates are converted into nitrites (NO_2^-) that react with hemoglobin in the red blood cells and forms methaemoglobin, blocking the oxygen transport. It is commonly called the "blue baby syndrome" because of the blue-gray skin color. The disease can evolve rapidly causing coma and death if not treated adequately (WHO 2011b).

As today, the standard limit given by WHO is 50 mg/l of nitrates in drinking water.

Long-Term Health Risks: Fluoride and Iodine

Other chemical compounds that might be present in the water will show their health effects only after several years of exposure. These are long-term health risks and are especially relevant for the case of chronic humanitarian crisis. For the case of the Saharawi camps, the main chemical contaminants naturally present in water are fluoride and iodine:

- Fluoride

Fluoride (F^-) in high concentrations can appear in groundwater, usually in areas with naturally fluoride salts. While at low concentrations fluoride is used as protection against dental caries and it is added to toothpastes, gels, or even drinking-water, higher concentrations than >1.5 mg/l if ingested during years can lead to important diseases as dental fluorosis and skeletal fluorosis. Fluoride is absorbed by the bones, and with time it can increase the possibilities of bone fractures and produce chronic pain. Fluorosis in teeth in children usually produces a characteristic "mottled enamel" aspect that in some cases can cause physical damage to the teeth (WHO 2003b).

WHO standards for fluoride in water is 1.5 mg/l.

- Iodine

Although WHO does not establish a direct relationship between iodine in drinking water and associated health effects due to either deficiency or excess of iodine, it does give an indication of the total dietary requirement for adult humans, ranging from 80 to 150 μg/day. This number includes all the nutritional sources that compose the dietary intake, not only the drinking water, but in many parts of the world, the water is an important source of deficiency or excess of iodine, and it affects directly the total iodine daily ingestion. Iodine is an essential element for the synthesis of thyroid hormones and, in inadequate quantities, can lead to severe adverse effects on health, including hypo and hyperthyroidism, goiter, and neurological development.

Only the Chinese legislation establishes standard values to evaluate the iodine concentration in water: adequate (10–150 μg/l), inadequate (high iodine zone >150 μg/l), and iodine excess goiter zone (>300 μg/l) (Pichel and Vivar 2017).

Water Quality and Health at the Saharawi Camps (1991–2016)

The relationship between water quality and health at the Saharawi camps can only be understood following the evolution of water quality along the years and the water supply infrastructure improvements (section Drinking-Water Access at the Saharawi Refugee Camps). This is especially important when studying diseases with origin in long-term exposures to certain substances.

- Microbiological content

The main epidemic related to microbiological contamination of drinking water at the Saharawi camps is the cholera outbreak in 1994 after unexpected floods contaminated all the shallow groundwater wells. These wells were closed and water from deeper groundwater wells followed by a chlorination step was used from then onwards. Although there has not been any other report on problems associated to gastrointestinal diseases from unsafe water, recent data from 2016 (Fig. 6) show that

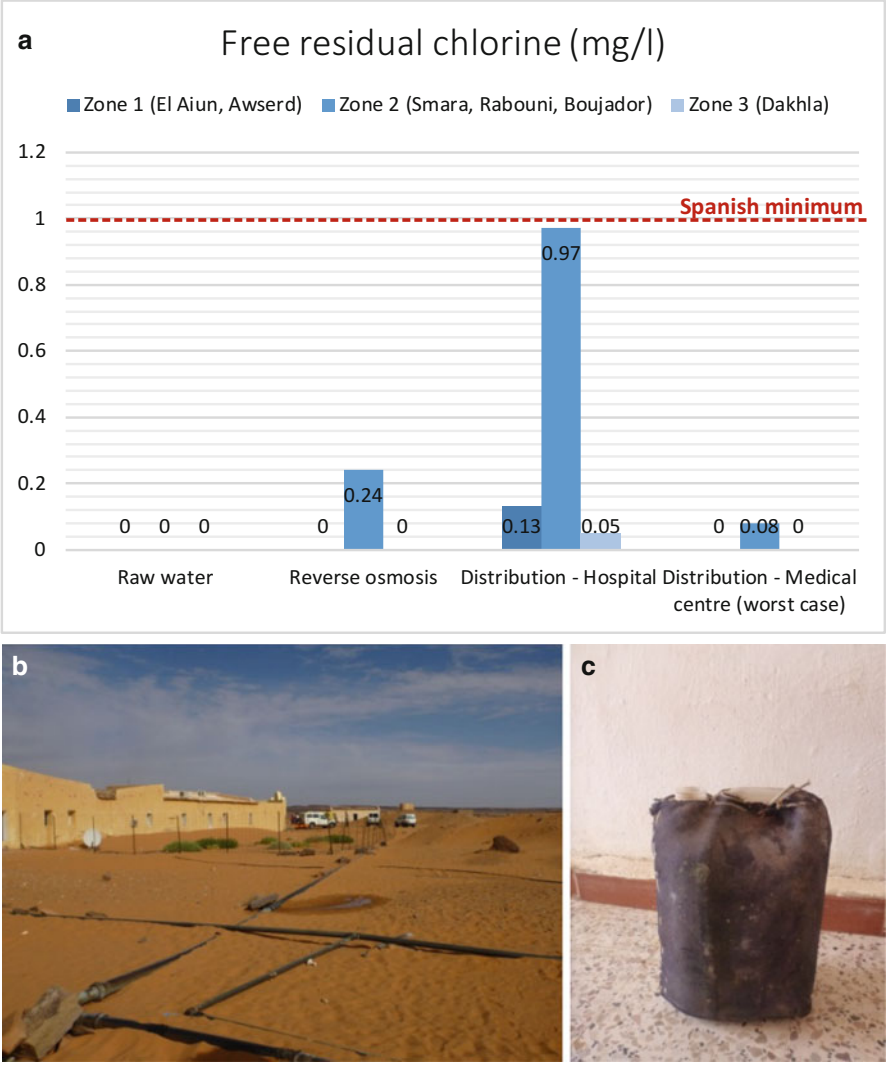

Fig. 6 Sources of microbiological contamination. (a) Free residual chlorine (mg/l) from sampling at different water supply and distribution points at the Saharawi refugee camps in 2015, (b) points of potential contamination due to failures in the distribution network; and (c) 10 l containers showing total coliforms contamination. Data and photos from the authors

the free residual chlorine levels in distribution points (tanks and taps sampled) do not reach the minimum values established by the Spanish legislation (Spanish RD140/2003 2003) neither by WHO guidelines, detecting total coliforms, especially in 10 l containers. Some distribution points also presented turbidities above 5 NTU, probably due to contamination in the distribution network, indicating potential microbiological contamination (Vivar et al. 2016).

- Nitrates

As of today, no published study has reported cases of blue-baby syndrome within the population of the Saharawi camps, but the reality is that nitrate levels have been high in the past, posing a health risk until the water started to be treated. On the other hand, maternal breastfeeding has been always promoted as the main lactation method for infants, thus reducing the use of water to prepare baby milk.

High levels of nitrates in water at the camps were first reported 2001 by Docampo (2006), and 3 years later, in 2004, another Spanish team (Docampo 2006) reported once again the same high levels of nitrates affecting the drinking water quality at El Aiun and Smara.

In 2007 two reverse osmosis plants were built in Smara, and several years later, in 2010, another reverse osmosis plant was commissioned to provide water to El Aiun and Awserd. As the raw water quality in Dakhla was adequate, only a chlorination stage was included as water treatment. These reverse osmosis plants reduced the high levels of nitrates. As of 2015, current nitrate levels (Fig. 7) in raw water in Smara were of 125.5 mg/l, decreasing to 15.9 mg/l after the osmosis. Smara water supply is the best regarding quality in distribution within the refugee camps, as it is always treated water from one of the two available reverse osmosis plants, vs. El

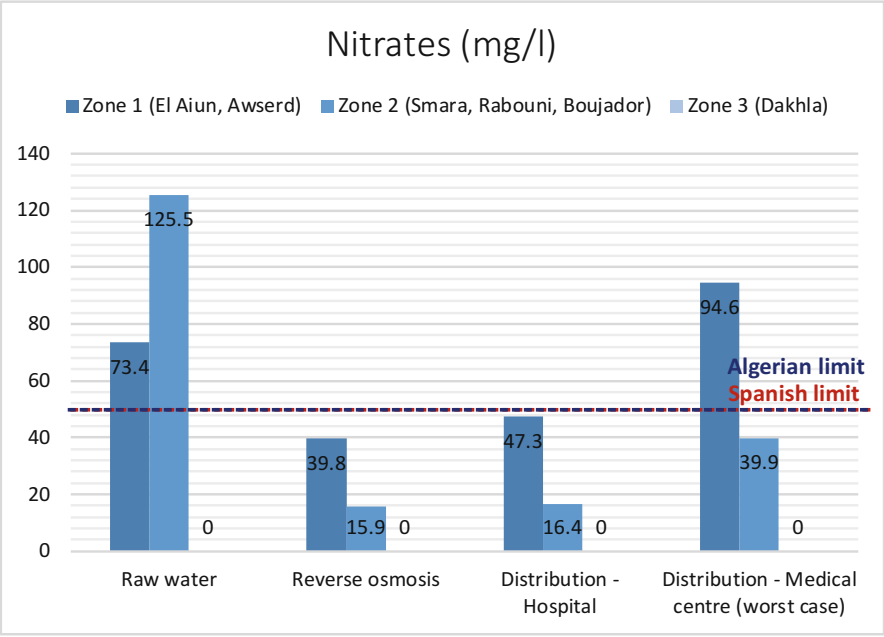

Fig. 7 Current levels of nitrates in Saharawi drinking water. Nitrate levels in water (mg/l) from sampling at different water supply and distribution points at the Saharawi refugee camps in 2015. Spanish and Algerian (Algeria 11–125 (2011)) legislation limits are shown as reference. Data are from the authors

Aiun and Awserd, which receive treated water only in turns of 20 days, receiving treated water and raw water directly alternatively. In this case, latest levels of nitrates in raw water are of 73.4 mg/l, well above the recommended limit of 50 mg/l given by WHO, posing a health risk for the infant population if bottle feeding is used. Finally, levels of nitrates in Dakhla are low, 8.88 mg/l, so there is no health risk associated (Vivar et al. 2016).

- Fluoride

Dental fluorosis can be directly observed nowadays in the population of El Aiun and Awserd in their brown spotted enamel, especially in those who have already been born in the refugee camps (young population) and have been exposed to fluoride since birth. The most detailed study on the dental status of the refugee children at the Saharawi camps is the conducted by Almerich-Silla et al. in 2008 (Almerich-Silla et al. 2008). They already associated the unbalanced diet, poor oral hygiene habits, and high concentration of fluoride in drinking water (~2 mg/l) to the current dental status. They worked with the refugee camps of Smara, El Aiun, and Awserd, and they observed that among the 6- to 7-year-old children, 36.9% were free of fluorosis, 15.6% presented moderate fluorosis, and 7.8% presented severe fluorosis. Among the 11- to 13-year-old children, only 4.2% were free of fluorosis, 30.2% exhibited moderate fluorosis, and 27.4% presented severe fluorosis. They also studied decayed permanent teeth and caries prevalence, and they concluded that these were higher on children affected with severe fluorosis, suggesting that it could increase the susceptibility to dental caries (Fig. 8).

Regarding fluoride content in water at the refugee camps over time, in 1991, Díaz-Cadórniga et al. (2003) reported already values of fluoride in water exceeding the recommended standard limit (1.5 mg/l) of 1.6 mg/l, which were reported again in 2000, ranging from 0.7 to 1.5 mg/l in the camps. In 2001, "Aguas de Sevilla" (Docampo 2006) conducted a more detailed water analysis at the camps, obtaining also high fluoride values at El Aiun and Smara (1.4 and 1.8 mg/l, respectively). Three years later, in 2003, another Spanish team (Docampo 2006) analyzed the water, reporting once again the same high values for fluorides in water at El Aiun and Smara.

Another study from the Norwegian College (Akershus University College 2008) in 2008 conducted a series of water analysis after the reverse osmosis at Smara was designed and set-up and their results reflected this improvement. While El Aiun continued to present high fluorides values, Smara water supply dramatically reduced them, from 1.8 mg/l to 0.16 mg/l.

Latest available data correspond to 2015, with the reverse osmosis plant of El Aiun and Awserd already in function. In this case, raw water quality still presents high values of fluorides (1.95 mg/l) that although are reduced to 0.23 mg/l after osmosis, still critical because the population uses this source of raw water as drinking water in turns of 20 days. On the other hand, despite the high values of raw water in Smara (1.8 mg/l), all the population in this camp receives treated water (0.12 mg/l), so no posing any health risk. Once again, Dakhla presents low values of fluorides (0.6 mg/l), not requiring any water treatment in this regard (Vivar et al. 2016).

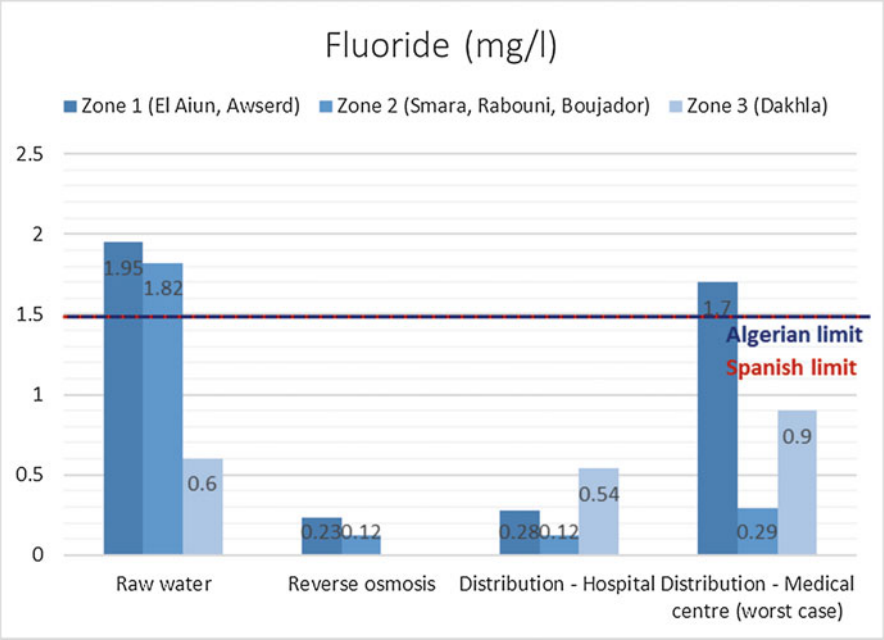

Fig. 8 Current levels of fluorides in Saharawi drinking water. Fluoride levels (mg/l) from sampling at different water supply and distribution points at the Saharawi refugee camps in 2015. Data are from the authors

- Iodine

The Saharawi refugee camps have been considered as an endemic goiter region (more than 5% of the individuals presenting goiter) since the first studies in the 1990s reported significative percentages of the population presenting goiter. For example, Prezzino et al. (1998) results showed 28% of a school children population with palpable goiter prevalence, and in the year 2000, Díaz-Cardóniga et al. (2003) reported even a higher value for goiter prevalence in the same age range population, 58%. Both studies associated prevalence of goiter with excess iodine in drinking water, with values up to 934 μg/l in El Aiun.

Another group of studies in 2007 by Henjum et al. (2010, 2011) and Barikmo et al. (2011) showed again high prevalence of goiter among school children (6- to 14-year-old) and women (15- to 45-year-old), with values of 11% and 18%, respectively. These studies also attributed excess iodine in the daily intake to drinking water, but also showed that iodine content in milk was very high (70–13,071 μg/l), so not only drinking water could be the cause of the excess iodine in the diet. Later studies by the same research group in 2007 and 2010 (Aakre et al. 2015a, b) on iodine and goiter at the camps reported also high prevalence of goiter

and continued to associate it to drinking water, although iodine concentrations in water decreased to values of 80–254 μg/l on average in 2007, vs. iodine content in animal milk of 1175–2049 μg/l, much higher, up to 20 times. Water iodine concentration continued to decrease in 2010, with an average of only 58 μg/l, but the thyroid dysfunction diseases continued to be as high as 34.1% in the surveyed population.

Overall, the iodine concentration in drinking water was strongly reduced from the high average values of 638 μg/l in 1998 (corresponding to an endemic goiter region according to the Chinese legislation, >300 μg/l), to adequate levels of iodine in water in 2010, with values of only 58 μg/l.

Latest analysis conducted by Pichel and Vivar in 2015 and 2016 (Pichel and Vivar 2017) show only high iodine concentrations in raw water before the reverse osmosis plants at El Aiun and Smara, with concentrations of 193 μg/l and 357 μg/l, down to 81 μg/l and 95 μg/l after the water treatment. On the other hand, iodine content in drinking water in Dakhla was of 108 μg/l. Average iodine in drinking water in the camps ranged from 81 μg/l to 139 μg/l, considering that the values are higher for El Aiun and Awserd that receive treated water each 20 days. According to Chinese legislation, water iodine concentration below 150 μg/l would be adequate for human consumption. As a reference, this study also shows the iodine concentration in Madrid (Spain), in an area of adequate levels, reporting values of 66 μg/l for mineral water and 57 μg/l for tap water. Finally, the study concludes that although iodine excess seems to be the cause of prevalence of goiter in the Saharawi refugee camps and drinking water has been associated directly to this goiter since the first studies on the matter, it would be convenient to analyze the entire dietary intake of the population to detect other potential sources of iodine, especially after iodine content in water has been dramatically reduced in the last years and after animal milk has shown high values of iodine in the latter literature studies (Fig. 9).

Policies and Protocols

Water Guidelines on Access, Quality, and Quantity for Refugee Situations

In this chapter, the importance of water in refugee situations has been described along with the effect of unsafe water in the Saharawi population, both under short- and long-term exposure. Guidelines on water access have followed the recommendations given by UNHCR, guidelines and policies on water quantity (>20 l/person/day) have also followed UNHCR and WHO standards, and water quality in terms of microbiological (0 CFU/100 ml), nitrates (<50 mg/l), fluorides (<1.5 mg/l), and iodine content (<300 μg/l) have followed the WHO guidelines for drinking water as well as the Algerian and Spanish legislation. For the case of iodine, the Chinese legislation has been also considered.

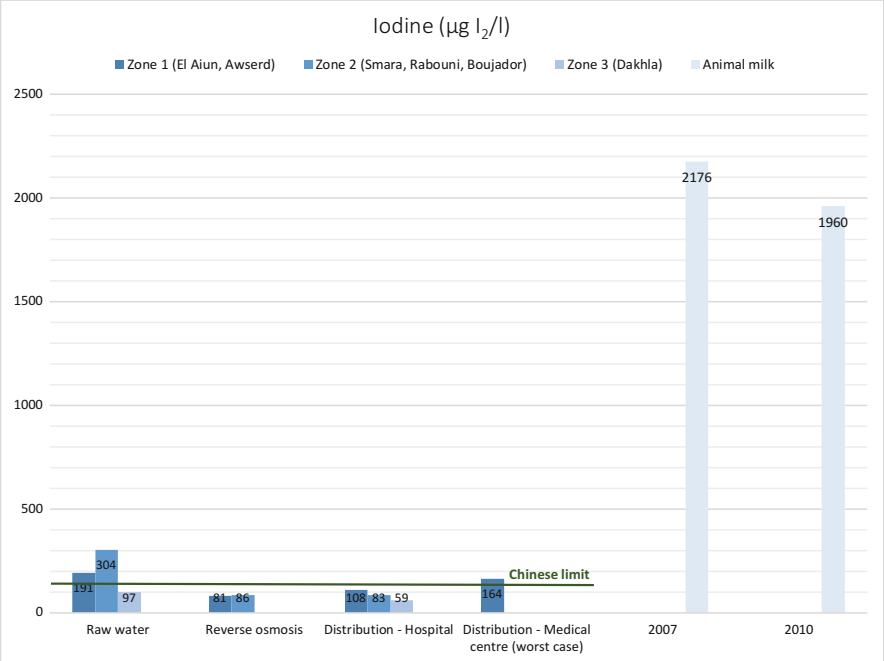

Fig. 9 Current levels of iodine in Saharawi drinking water and animal milk. Iodine levels (mg/l) from sampling at different water supply and distribution points at the Saharawi refugee camps in 2015. Iodine concentration in animal milk from the studies of 2007 and 2010 is shown as comparison and potential source of excess iodine. Data on water are from the authors, data on milk from referenced studies

Water Quality Analysis

Field-measured parameters included temperature and dissolved oxygen, pH, conductivity, and turbidity. Residual-free chlorine, total iodine, and fluoride were measured daily after sampling. Microbiological analyses were conducted using 3M Petrifilm plates with chromogenic *E.coli* and total coliforms culture medium, incubated 24 h at 37 °C. Quantification limit was of 1 CFU/ml.

At central laboratories in Spain, water samples were analyzed for different parameters according to the "Standard Methods for the Examination of Water and Wastewater" (APHA 2005): pH, conductivity and redox potential, alkalinity, total phosphorous, total nitrogen, organic content, major ions including chloride, nitrate, nitrite, phosphate, sulfate, fluoride, sodium, ammonium and potassium; and single elements such as iodine, chrome, manganese, iron, nickel, copper, arsenic, cadmium, lead, mercury, antimony, boron, aluminum, and selenium using ICP-MS (inductively coupled plasma mass spectrometer).

Dictionary of Terms

- **Blue-baby syndrome** – Disease that is common in babies under 3 months that have been ingesting water with high levels of nitrates, which react with the hemoglobin in the red blood cells and blocks the oxygen transport. It is called "blue baby syndrome" because of the blue-gray skin color.
- **Daira** – A smaller urban administrative area similar to a district or suburb. A wilaya can be composed of several dairas.
- **Fluorosis** – Fluoride that is present in drinking water is absorbed by the bones, and with time it can increase the possibilities of bone fractures and produce chronic pain.
- **Goiter** – Disease caused by a thyroid dysfunction, which causes the enlargement of the thyroid gland.
- **Protracted refugee situation** – Populations of at least 25,000 refugees who have lived in exile for at least 5 years in developing countries.
- **Wilaya** – An administrative region within the Saharawi urban organization, similar to a town.

Summary Points

- This chapter focuses on the relationship between deprivation of drinking water and health issues at the Saharawi refugee camps.
- The Saharawi refugee camps were established in 1975 and are one of the oldest chronic refugee crisis.
- Drinking-water deprivation in terms of access, quantity, and quality poses serious health hazards both in the short and long term.
- Water access at the camps has improved from the first emergency handmade wells to deep groundwater wells combined with water treatment via reverse osmosis.
- Water quantity is still insufficient in the camps, 18 l/person/day, below the minimum standard of 20 l/person/day established by the United Nations High Commissioner for the Refugees (UHNCR).
- Raw water quality has been an issue since early days at El Aiun, Awserd, and Smara, with high values of nitrates, fluorides, and iodine that pose a health risk.
- Currently, water treatment via reverse osmosis has reduced the hazards of raw drinking water, although El Aiun and Awserd still consume raw drinking-water in 20 days turns.
- These parameters have affected the population that after a long exposures how dental and skeletal fluorosis and goiter problems.
- Microbiological water content has been reduced since the cholera outbreak in 1994 when handmade wells were closed and chlorination water treatment was introduced.

- But the levels of residual-free chlorine at the distribution point and maintenance problems of the distribution networks still pose a health risk.
- It is necessary to extend the distribution of treated water with adequate quality for all the population and to increase the available water quantity in order to improve the refugees' health status.

Impact of Transnational Migration: Underweight and Obesity in Contemporary Europe

27

Sylvia Kirchengast

Contents

Abstract

Periods of famine and starvation have been major push factors of migration since prehistory. From Paleolithic times onward, a lack of available food forced *Homo sapiens* and their ancestors to move to new habitats. This behavior continued until now. At the beginning of twenty-first century, however, transcontinental migration is only seldom the result of long periods of starvation. Nevertheless migration is often associated with profound changes in dietary habits. In the present review, the weight status of Indian and Turkish immigrant women in Austria is focused on. As typical of immigrants in Europe, immigrant women in Austria suffer seldom from undernourishment. In contrast the main problem of transnational and transcontinental immigrants in European countries is the high prevalence of obesity and associated disorders. In Austria, female immigrants from India but also from Turkey show

extraordinary high rates of obesity. This is especially true of women and children. As the main reason, the rapid transition to Western lifestyle is discussed.

Introduction

Migration to new habitats is widely found in nature. Long-distance movements, which are typical of birds, fishes, and mammals, are mainly triggered by climate factors, mating behaviors, seasonality, and changes in the availability of food and water resources (Mascie-Taylor and Lasker 1988). Among humans and their ancestors, migration can be assumed since the emergence of hominids. Transcontinental migration starts with the dispersal of *Homo erectus* out of Africa to Eurasia about 1.8 million years ago. Our own species *Homo sapiens* evolved in Africa about 180,000 years ago and moved out of Africa 70,000 years ago. 30,000 years later, *Homo sapiens* had spread across Australia, Asia, and Europe. 20,000 to 15,000 years ago, *Homo sapiens* reached America, and by 2,000 years ago, most of the Pacific Islands were colonized (Henke and Hardt 2011). Consequently *Homo sapiens* has a long history of migration, and migration is clearly not only a recent phenomenon. Today rural urban migrations, transnational migration, and even transcontinental migration are widely found and triggered by push and pull factors which force people to leave their homelands and move to new areas. First of all war but also economic, political, and environmental push factors influence a person's decision to migrate. Especially important push factors are harsh environmental conditions, such as drought and famine which cause starvation and hunger; these factors however induce only seldom transcontinental migrations. In contrast affected people try to move to better areas nearby – a behavior which was typical for more than 99% of our history when the subsistence of *Homo sapiens* was based on hunting and gathering. It can be assumed that hunter-gatherer suffered repeatedly from food shortages of few days (Pentice 2005); longer periods of starvation however have occurred seldom. This is mainly due to the fact that hunter-gatherer societies consisted of few members and followed a mobile lifestyle. Their reaction of an acute food shortage was to move to new hunting and gathering grounds (Pentice 2005). This kind of lifestyle was typical of our ancestors until the so-called Neolithic transition, which started about 10,000 years BC. Even today the few remaining hunter-gatherer societies suffer very seldom from periods of starvation. Consequently from the

viewpoint of evolutionary anthropology, we can assume that to move away and to migrate are adapted strategies of *Homo sapiens* to avoid starvation. Since the Neolithic transition, however, the frequency of famines and periods of starvation increased drastically. The domestication of animals and plants and the adoption of agriculture changed the lifestyle of our ancestors. They became able to produce a surplus of staple foods and to create contingency stores to buffer future food shortages. As a consequence populations started to grow, and they gave up their mobile lifestyle. Permanently settled villages and later towns emerged. This new lifestyle patterns however created new vulnerabilities because this new system relies more or less on constant and predicable climatic conditions but also on the absence of intra- and interpopulation conflicts (Larsen 1995). Consequently droughts and flood waters, wars, but also periods of epidemic diseases caused catastrophic famines often accompanied with mass mortality. Mainly environmentally induced famines are documented for nearly every ancient culture (Keys et al. 1950; McCance 1975) but also for medieval, premodern, and modern Europe (Lucas 1930). The Little Ice Age during the seventeenth and early eighteenth century caused starvation in many European regions and forced waves of migration (Engler et al. 2013). The most prominent example of starvation-induced mass emigration is the Irish Potato Famine also called "The Great Famine" starting in September 1845. English winds had carried an airborne fungus called *Phytophthora infestans* to Ireland, wiping out the potato crop and causing a horrible period of starvation. Many people died or emigrated, and the Irish population decreased by 1.6 million people or about 17% of the total population. Without their main food crop to rely on, a large number of Irish citizens emigrated from their country to escape starvation (Daniels 2002). The large population of Americans and Canadians of Irish descent can trace its ancestry to this period (Daniels 2002). During the twentieth century, both world wars, but first of all World War II, caused periods of famine and severe starvation in Europe such as the Siege of Leningrad (1941–1944) and Dutch famine (1944–1945) (Young 1943; McCance 1975). After World War II especially during the time of the so-called *Wirtschaftswunder*, famine and periods of mass starvation disappeared in Europe as in all first world countries. Nevertheless, famine and starvation are present in many parts of the world and force migration mainly to Europe but also other first world areas. Migration is a worldwide phenomenon in 2017, and it has a profound impact on nutritional habits but also on the prevalence of underweight, overweight, and obesity of immigrants.

The aim of this paper is to review the impact of transnational and transcontinental migration on weight status of immigrants. The main focus lays on the situation of Turkish and Indian immigrant women in Austria.

Starvation and Malnutrition Worldwide

The FAO defines starvation as a severe deficiency in caloric energy needed to maintain an organism's life. Starvation represents the most extreme form of malnutrition (FAO 2015). According to the Oxford English Dictionary (1971), the term

hunger has three meanings: the uneasy or painful sensation caused by want of food, the want or scarcity of food in a country, and a strong desire. A lack of sufficient food supply results undernourishment. Although often used as synonyms, malnutrition and undernourishment are not the same. While malnutrition refers to all deviations from adequate and optimal nutritional status, including undernourishment but also overnutrition and therefore obesity, undernourishment describes a generally poor nutritional status mainly characterized by underweight (Shetty 2006). The term underweight describes a weight status too low to be considered as healthy, usually defined as a body mass index below 18.50 kg/m^2. Undernourishment and underweight are primarily caused by an inadequate intake of dietary energy (Shetty 2006). Underweight and undernourishment are caused by exogenous factors such as an inadequate availability of food as a result of famine, war, conflict, or poverty but also endogenous factors such voluntary reduction of food intake, i.e., anorexia nervosa, intestinal disorders, parasitic infestations, organ failure, neoplasm, or infections (Shetty 2006). The consequences of undernourishment are weight loss, loss of body fat, wasting of muscle mass, and the atrophy of visceral organs (Shetty 2006). Inadequate food supply or starvation, especially during intrauterine development and childhood, causes fetal growth restriction, stunting, poor health, first of all an increased prevalence of infectious diseases, but also general weakness, low-energy levels, and reductions in mental functioning (Victoria et al. 2008). In this way starvation can lead to even greater poverty by reducing people's ability to work and learn, thus leading to even greater hunger (Victoria et al. 2008). During the last 25 years, the prevalence of undernourishment was reduced markedly worldwide. According to the United Nations Food and Agriculture Organization (FAO), about 795 million people (10.9% of the world population) were suffering from chronic undernutrition in 2014–2016. Nearly all the chronically starving people, 780 million, live in developing countries, i.e., 12.9% of the population of developing counties. About 11 million people are undernourished in developed countries (FAO 2015; Rosen et al. 2016). In developed countries undernourishment is mainly caused by endogenous factors such as psychic or somatic diseases but only rarely by poverty. Famines affecting food supply do not exist in developed countries.

As to be seen in Table 1 even in developing countries, the prevalence of undernutrition decreased drastically from about 23% in 1990 to 12.9% in 2014. This was especially true of Southeast Asia, but also in sub-Saharan Africa, the prevalence of undernourishment is felt from 33.2% in 1990 to 23.2% in 2014.

Obesity Worldwide

Malnutrition characterized by obesity is mainly seen as a very recent phenomenon, because it can be assumed that at population level obesity was largely unknown up to the 1950s (Brown 1991). In 2008, however, for the first time in the long history of *Homo sapiens*, the number of obese people on earth exceeded the number of people suffering from starvation and undernourishment (FAO 2008). In 2014, 39% men and 40% of women aged 18+ were overweight (BMI $\geq$ 25 kg/m^2) and 11% of men and

Table 1 Prevalence of undernourishment 1990/1992 and 2012/2014 (Source: FAO 2015)

Prevalence	1990/1992	2012/2014
Worldwide	18.6%	10.9%
Developed countries	<5.0%	<5.0%
Developing countries	23.3%	12.9%
Africa		
Sub-Saharan Africa	33.2%	23.2%
Asia		
Eastern Asia	23.2%	9.6%
Southeast Asia	30.6%	9.6%
Southern Asia	23.9%	15.7%
Latin America	14.7%	5.5%
Oceania	15.7%	14.2%

Table 2 Prevalence of overweight in 2014 according to WHO regions (Source: WHO 2016)

	Overweight (BMI > 25.00 kg/m^2)	
	Male	Female
African region	22.9%	38.6%
Americas	62.8%	59.8%
Eastern Mediterranean region	43.8%	50.1%
European region	62.6%	54.9%
Southeast Asia	19.3%	25.3%
Western Pacific region	34.7%	31.2%

15% of women were obese (BMI ≥30 kg/m^2).This means that more than 1.9 billion adults, 18 years and older, are overweight. Of these over 600 million correspond to the definition of obesity (WHO 2016). Prevalence rates of overweight among adult people (>18 years) are presented in Table 2.

This high prevalence of obesity is a matter of concern because obesity is associated with premature mortality, morbidity, and a markedly reduced health-related quality of life (Ford and Mokdad 2008; Wang et al. 2011). Once considered a condition typical of affluent societies of developed countries, overweight and obesity rates are now fast growing in poor neighborhoods of developed countries but also in many developing countries, too (Hossain et al. 2007; Pijl 2011). The main reason of this trend is the globalization of increasingly obesogenic environments characterized by rapid urbanization, mechanization of jobs, improvement of transportation services, the availability of food of high-energy density, and reduced physical activity (Popkin 2001; Popkin and Gordon-Larsen 2004; Poston and Foreyt 1999; Ulijaszek and Lofink 2006; Ulijaszek 2007). Many developing countries have achieved a remarkable improvement in nutrition status in the past decades, and consequently obesity rates increased. Nevertheless the prevalence of undernourishment is still a serious problem. The double burden of obesity and underweight-induced malnutrition exists in almost all developing countries (Abdullah 2015).

In societies of economic and nutritional transition, the paradox situation can be observed that malnutrition and obesity rise parallel (Chatterjee 2002). One example is India which has a population of over one billion. Seventeen years ago, India was considered as one of the poorest countries in the world mainly suffering from undernourishment (Krishnaswami 2000; World Bank 2001). Since that time India has undergone a rapid economic development and is increasingly faced by a rising epidemic of obesity (Singh et al. 1995; Krishnaswami 2000; Garg et al. 2009; Florentino 2002; Bhadra et al. 2005; Yoon et al. 2006; Ackerson et al. 2008; Khokhar et al. 2010; Masoodi et al. 2009). Obesity in India is associated with modernization, rapid urbanization, and a transition in lifestyle and nutritional habits. Besides a rapid rise in rates of overweight and obesity, a consequent rise in noncommunicable diseases such as type 2 diabetes is found. This trend is observable among several societies of transition. A very fast variant of transition takes place as a result of transnational and especially transcontinental migration. The transition from a lifestyle typical of developing country to a life in a Western society is accompanied by modernization and sometimes acculturation. Both affect nutritional habits, physical activity patterns, and consequently weight status (Green et al. 2003). The present investigation focused on the weight status of two different immigrant populations in Austria. In detail the weight status of Indian women originating from Punjab and Turkish women in the Austrian capital Vienna was analyzed.

Weight Status of Refugees and Immigrants Worldwide

Recently, starvation-driven migration is mainly found in sub-Saharan Africa, where political conflicts and climatic change-related drought result in famine (Grijalva-Eternod et al. 2012). Only a few hungry refugees had enough energy to migrate long distances through the Mediterranean Sea to Europe; most of them reach refugee camps in neighboring areas only. As to be expected, in these camps, first of all in Ethiopia but also in Western Africa, high prevalence rates of underweight, stunting, and wasting are found among young children, adolescents, and women (Jemal and Haidar 2014; Kelati et al. 2015), although overweight and even obesity have been documented among women of reproductive age from Western Sahara in Algerian refugee camps (Grijalva-Eternod et al. 2012). A recent study focusing on refugee children mainly from Somalia, Iraq, and Burma in the United States showed that nearly one-half of these children had at least one form of malnutrition (44.9%). Refugee children were affected by wasting (17.3%), stunting (20.1%), overweight (7.6%), and obesity (5.9%) (Dawson-Hahn et al. 2016).

In contrast to refugees, immigrants in developed countries suffer only very seldom from undernourishment. Contrary, numerous investigators have demonstrated that migrant status increases the risk of overweight or obesity dramatically. This is true of Hispanic immigrants in the United States (Kaplan et al. 2004; Park et al. 2009), as well as of immigrants originating from Mediterranean countries or the Middle East in Central and Northern Europe (Brussard et al. 2001; Hoppichler and Lechleitner 2001; Uitewaal et al. 2004a, b; Fredriks et al. 2005; Kirchengast and

Fig. 1 Migration increases obesity rates. Transnational and transcontinental migration is often associated with a change from a traditional society into an obesogenic environment, characterized by a surplus of energy dense food and a lack of physical activity. This process of modernization and acculturation often results in increasing obesity rates among immigrants

Schober 2005; Misra and Ganda 2007; Dijkshoorn et al. 2008; Wolin et al. 2008). A high prevalence of overweight and obesity (3.6–49.4%) is also found among immigrants from Northern Africa in Europe. The highest frequency of physically inactive or lightly active people among immigrants was observed in first-generation Sudanese and Moroccans in Amsterdam (males, 57.1%; females, 74.2%), with increasing rates in second-generation females (Toselli et al. 2014). Especially high rates of overweight and obesity are found among children of immigrants (Kirchengast and Schober 2005). This observation seems to be mainly due to the fact that most immigrants hope for better lives for themselves and their children and interpret energy dense food, characterized by a high amount of sugar and fat but also physical inactivity as a luxury lifestyle (Green et al. 2003; Hosper et al. 2007; Lawrence et al. 2007). Immigrants adapted very fast to an obesogenic environment in Europe or the United States. They and their children are confronted with advertisements and opportunities to purchase food that is relatively cheap and of low nutritional quality. Therefore, immigrant obesity is interpreted as the result of an unhealthy assimilation of immigrants (Van Hook and Balistreri 2007; Faskunger et al. 2009; Park et al. 2009; Ujicic-Voortman et al. 2009) (see Fig. 1).

Immigrants in Austria

Up to the period shortly after the end of World War II, Europe was mainly a continent of emigration and not of immigration. After World War II, many parts of Europe experienced a period of enormous economic growth but also political stability and increasing food security. Consequently Europe turned from a continent of emigration to a continent of immigration. Since the 1960s, an increasing number of people originating from Southern European countries but also from Turkey and Northern Africa moved to Central and Northern European countries such as Austria. Austria, a small country in the center of Europe, has about 8.5 million inhabitants; 21% of them have a background of migration, which means that at least one of their parents was born outside Austria (Statistik Austria 2016). The majority of these people settled in

Vienna, the capital of Austria. Today Turkish people and people from Former Yugoslavia, who have been actively recruited as migrant workers, represent the largest groups of immigrants in Austria. The social status of many immigrants, especially those originating from Turkey, is significantly lower than that of the Austrian majority. Furthermore the health status of many immigrants is quite poor. People with a background of migration show higher rates in morbidity and mortality in comparison with their Austrian counterparts, although the public health system in Austria is highly developed and enables Austrians as well as immigrants access to health service centers and medical treatments free of charge (Hoppichler and Lechleitner 2001; Statistik Austria 2016). During the last 10 years, even before the great waves of immigration took place in 2015 and 2016, increasingly people from the Middle East, Asia, Africa, and Latin America migrated to Austria. The main push factors of these migration waves to Austria were mainly conflicts, political factors, and economic problems in the countries of origin but very seldom famine and starvation.

Weight Status of Indian Immigrants in Austria

The Indian community is a quite small one in Vienna. According to Statistik Austria (2016), about 3,600 immigrants from India live in Vienna. For comparison, about 700,000 people with a background of migration, mainly originating from former Yugoslavia and Turkey, live in Vienna in 2016. The Indian population in Vienna was chosen for this analysis because – as pointed out above – a marked nutritional transition leading to increasing rates of obesity has taken place in India during the last 20 years. Indian immigrants in Europe and in the United States, however, also experience an extremely fast transition in lifestyle and nutritional habits resulting in increasing rates of obesity (Bhatnagar et al. 1995; Landman and Cruickshank 2001; Abate and Chandalia 2007).

In the present study, weight status and nutritional habits of 50 Indian women aging between 19 and 58 years ($x = 38.2 \pm 10.8$) living in Vienna have been analyzed. All women originated from Punjab area in India. Punjab is a state in the northwest of India. According to the "India State Hunger Index 2008," Punjab has the lowest level of poverty in India. But due to educational differences, there is still a large disagreement in living conditions, following women rights and health conditions between the people living in rural areas and in cities. For comparison 65 women aging between 17 and 80 years ($x = 39.1$; ± 16.8) living in rural and urban areas of the district of Jalandhar in Punjab were enrolled in the study.

Weight status was determined by using the body mass index (BMI) kg/m^2. To define overweight and obesity, the BMI cutoffs for South Asians were used (WHOEC 2004) (BMI < 18.50, underweight; BMI 18.50–22.99, normal weight; BMI 23.00–24.99, overweight; BMI > 25.00 obese). As presented in Table 3, underweight among Punjabi women was much more prevalent in India than in Vienna, while in contrast overweight and obesity were significantly ($p < 0.01$) more prevalent among Punjab women in Vienna.

Table 3 Weight status of Indian women in Vienna and in Punjab (Source Kirchengast and Singh 2011)

Weight status	Indian women in Punjab	Indian women in Vienna
Underweight BMI < 18.50 kg/m^2	18.5%	6.0%
Normal weight BMI 18.50–22.99 kg/m^2	47.7%	14.0%
Overweight BMI 23.00–24.99 kg/m^2	9.2%	26.0%
Obese BMI > 25.00 kg/m^2	24.6%	54.0%

While more than 18% of Punjabi women in India were classified as underweight, this was only true of 6% among Indian women in Vienna. Furthermore a high prevalence of overweight and obesity (nearly 35%) was documented for Punjabi women in India; among Indian women in Vienna, 80% were classified as overweight and obese (Kirchengast and Singh 2011). This observation is in accordance with the results of numerous studies which showed high rates of obesity among immigrant women in Europe (Misra and Ganda 2007; Kilaf and Kirchengast 2011; Park et al. 2009). The high prevalence of overweight and obesity among Punjabi women in India, however, seems extraordinarily high for a developing country, although the National Family Health Survey III in India (2010) revealed that nearly 30% of Indian women living in urban areas and nearly 9% of women living in rural areas are obese. This is especially true of Punjab region (Garg et al. 2009; Ackerson et al. 2008; Khokhar et al. 2010). Therefore the results of this Viennese study are in accordance with the general trend of weight status among Indian women. There is no doubt that this high obesity prevalence in India is due to an extremely rapid economic development accompanied by a dramatic transition in lifestyle and dietary patterns (Ramachandran 2004). As a consequence the prevalence of obesity among Indian women increased from 10.6% in 1999 to 12.6% in 2006. Despite this trend, about 35–40% of the Indian population still lives below the poverty line, and more than 30% of Indian women of all age groups are underweight and suffer from malnutrition, anemia, and deficiencies in micronutrients and vitamins. Underweight is mainly found among women of low socioeconomic status and low education level, while overweight and obesity are most frequently found among women of high socioeconomic status living in urban areas (Ackerson et al. 2008).

Turkish Immigrants in Austria

The second immigrant sample considered in this review represents the second largest immigrant group in Austria. According to National census, about 250,000 Turkish immigrants live in Austria (Statistik Austria 2016). As presented in Table 4 from early childhood onward, Turkish girls exhibit a high prevalence of overweight and obesity, while the prevalence of underweight was extremely low (Kirchengast and Schober 2005).

Extraordinary high prevalence rates in overweight and obesity were also found among adult Turkish women aging between 18 and 56 years living in Vienna (Kilaf

Table 4 Weight status according to age group among Turkish immigrant girls and adult Turkish women living in Vienna (Source: unpublished data from Kirchengast, Kilaf & Schober)

Weight status	Turkish girls 6 years	Turkish girls 10 years	Turkish girls 15 years	Turkish women 18–50 years
Underweight (<10 Perz)	3.3%	5.1%	2.9%	2.3%
Normal weight (10–90 Perz)	71.8%	64.8%	70.3%	42.4%
Overweight (90–97 Perz)	12.7%	16.7%	14.1%	32.3%
Obese (>97 Perz)	12.2%	13.4%	12.7%	23.0%

and Kirchengast 2011). As demonstrated in Table 4, the prevalence of underweight was extraordinary low in this sample (2.1%), while more than 55% of the women were classified as overweight or obese according to the BMI categories of the WHO (1995).

In European countries immigrants originating from Mediterranean region and from Near East and Middle East show an extremely high prevalence of overweight and obesity (Papandreou et al. 2008). This is especially true of children and adolescents as well as women (Ömer et al. 2004; Dijkshorn et al. 2008; Dinc et al. 2006; Tanyolac et al. 2008). The results of the present study corroborate these reports. 23.4–30.2% of Turkish children in the Netherlands were classified as overweight or obese (Fredriks et al. 2005). Dijkshorn et al. (2008) found a prevalence of overweight/obesity of more than 80% among Turkish immigrants in the Netherlands. Obesity is also a major health concern in Turkey (Erem et al. 2001, 2004; Gültekin et al. 2009). According to Iseri and Arslan (2008), 56% of the adult Turkish population is overweight or obese. Oguz et al. (2008) reported a prevalence of overweight of 36.0% and a prevalence of obesity of 30.4% for the adult Turkish population. Nearly all authors reported higher obesity rates for women than for men. The prevalence of obesity has significantly increased among Turkish women over the past 20 years from 28.5% in 1990 to 44% in 2010 (Erem 2015). This trend is mainly due to a transition in lifestyle, changing nutritional habits and increased physical inactivity, which is found in Turkey as well as in host countries (Hosper et al. 2007; Lawrence et al. 2007; Papandreou et al. 2008). Underweight and undernourishment represent only a marginal problem among young girls and adult Turkish women in Turkey but also in European countries.

Weight Status Among Immigrant from the Viewpoint of Evolutionary Anthropology

What are the reasons for these extremely low rates of underweight and high rates of overweight or obesity among immigrants in Austria and general in Europe? From the viewpoint of evolutionary anthropology in the high prevalence of obesity and overweight associated with migration to new cultural settings, acculturation and modernization may be interpreted as a result of a maladaptation of recent *Homo*

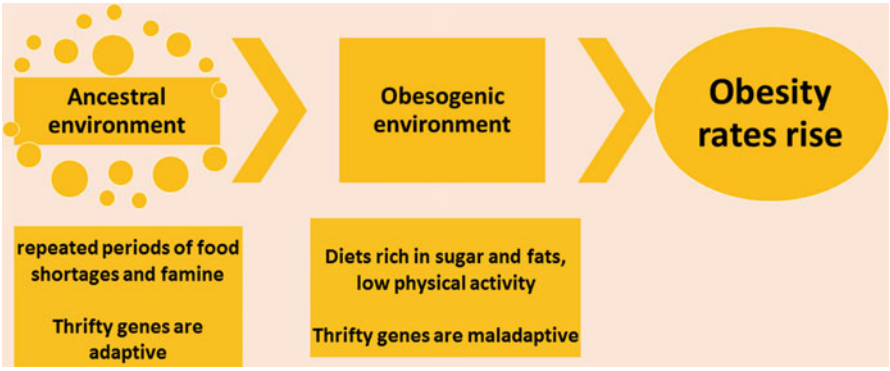

Fig. 2 Thrifty gene hypothesis. Our ancestors are adapted to an environment characterized by frequent food shortages, a diet poor in sugar and fat, and a high degree of physical activity. Thrifty genes are adaptive in this environment. In contemporary societies this thrifty genes are maladaptive because they prepare the body for starvation periods which never occur. Therefore obesity and type 2 diabetes rates increase

sapiens to postmodern environments. As early as 1962 James Neel proposed the thrifty gene hypothesis to partially explain the rise in type 2 diabetes and obesity in the twentieth century (Neel 1962). The central premise of his theory is that natural selection has favored the ability to store and utilize energy efficiently because our ancestors went through a cycle of feast and famine. Individuals whose energy storage or utilization was increased were more likely to survive and reproduce during periods of starvation. Consequently efficient energy storage was a beneficial adaptation. In our recent obesogenic environment, however, efficient energy storage turned to be maladaptive resulting in obesity and all associated problems (see Fig. 2). During the 1980s and the early 1990s, an alternative hypothesis to explain the high rates of obesity and type 2 diabetes was introduced. The British epidemiologist David Barker developed a theory of prenatal programming of later life diseases based on in utero nutritional deficiencies Barker 1999). According to Barker, life course plasticity was the key to explain obesity epidemic. In particular low birth weight newborns respond to their low level of nutritional intake in early life through alterations in growth and metabolism, which increase the risk of obesity and type 2 diabetes in later life (Barker and Clark 1997) (see Fig. 3). Barker postulates that low birth weight newborns have metabolically thrifty mechanisms for fat storage and glucose sparing with reduced rates of glucose oxidation in insulin-sensitive target tissues (Barker 1999). Furthermore poor nutrition in early childhood is suggested as an important driving factor behind the rising obesity rate in most developing countries. Indian and Turkish women were adapted to periods of food shortage up to recent times. Economic change but also the migration to new environments has improved the food supply and decreased physical work load, and consequently obesity rates are rising. As a result underweight rates drop down and obesity rates rise dramatically with the process of modernization and westernization, especially among immigrants.

Fig. 3 Thrifty phenotype hypothesis. Poor intrauterine environmental conditions result in intrauterine growth restriction, low birth weight, and a thrifty phenotype. The organism is prepared for poor food supply and energy stress. Improved environmental conditions during later life increase obesity rates

Policies and Protocols

In this chapter the impact of transnational and transcontinental migration on weight status was focused on. Research limitations: The studies reviewed have some obvious limitations. The number of immigrant women enrolled in the studies is quite small because the recruitment of participants is difficult among minority groups. The Viennese immigrant study population has been recruited in cooperation with the Viennese Fond of Integration, the Viennese school authority, and members of the Indian community in Vienna. Policy should cover three main areas: intensive cooperation between government and NGOs, improvement of education of immigrant women, and the inclusion of school authority, teacher, and parents to avoid excessive weight gain among immigrant children.

The assessment of weight status is problematic. BMI categories defined by the WHO are widely used; however, these weight status categories have met a lot of criticism. Although body composition analyses would yield more precise data, in the field it is often not possible to collect reliable body composition data. Therefore the BMI is still the most practicable indicator of weight status. For South Asian populations, separate categories have been defined. In the present studies, weight status categories defined by the WHO were used for the adult Turkish sample; South Asian weight status categories were used for Indian women. Weight status of children and adolescents have been classified by BMI percentiles according to sex and age group.

Dictionary of Terms

- **Migration** – means the movement of people from one place to another with the intentions of settling, permanently in the new location.
- **Malnutrition** – refers to all deviations from adequate and optimal nutritional status, including undernourishment but also overnutrition.

- **Obesogenic environments** – means living conditions characterized by rapid urbanization, mechanization of jobs, permanent availability of food of high-energy density, and reduced physical activity.
- **Modernization** – means the progressive transition from a traditional to a "modern" society.
- **Acculturation** – means the process of cultural change that results following meeting between cultures.
- **Thrifty gene hypothesis** – is an attempt by James V. Neel to explain in an evolutionary manner why certain populations today are prone to obesity and diabetes type.
- **Thrifty phenotype hypothesis** – suggests that early-life metabolic adaptations help the organism to survive by selecting an appropriate trajectory of growth in response to environmental cues.

Summary Points

- Starvation and famine have been major push factors of migration since prehistory.
- In 2008 the number of overweight or obese people surpassed the number of undernourished one for the first time in history.
- The prevalence of periods of starvation and consequently undernourishment is rapidly decreasing through the process of modernization.
- The double burden of obesity and underweight-induced malnutrition exists in almost all developing countries.
- The prevalence of overweight and obesity is high among immigrants in First World countries.
- Indian women and Turkish women in Austria show extraordinary high rates of obesity.
- Underweight is extremely seldom among immigrant children and women in Austria.
- Thrifty gene and thrifty phenotype hypotheses try to explain the high rates of obesity from the viewpoint of evolutionary anthropology.

Adult Undernutrition in Rural Post-conflict Northern Uganda

28

Stine Schramm and Morten Sodemann

Contents

Abstract

This chapter outlines the prevalence and high-risk groups for adult undernutrition and discusses the social, behavioral, and structural mechanisms that can lead to food insecurity and undernutrition in a post-conflict setting like northern Uganda. In summary, adult undernutrition is higher in the post-conflict area of Uganda compared to areas that did not experience the war. Undernutrition varies by gender and age groups, higher among men than women, with young men and elderly being most likely to be underweight. Social and behavioral risk factors for undernutrition specific to post-conflict areas, such as substance use, and disruption of traditional values and norms will be discussed. The high prevalence of undernutrition among men may be a result of a "syndemic" interaction between

mental illness, HIV, substance abuse, and undernutrition itself, which further interacts with the social and structural conditions such as gender inequality, stigma, stress, feelings of disempowerment and shame, poverty, and limited access to health care. Focusing on conventional target groups in health interventions and failure to adapt to the local context may have contributed to disruption of existing family and social structures and created other risk groups for undernutrition that are not targeted.

Introduction

The health of populations in post-conflict settings is determined by both direct and indirect effects from war, including trauma and injuries during the war, long-term poverty, and collapse of basic infrastructure. All aspects of human security, including food security, are further affected by disruption of families and social networks, land

conflicts, and continued ethnic clashes. When a peace agreement is signed, most humanitarian organizations pull out, while the governmental systems often do not yet have the capacity to take over. As a consequence, some public health indicators may be worse in post-conflict period than during the conflict. Hence, the real and tough battles to sustain peace and rebuilt society begin after the war. Nutritional status is a good indicator for the general health status of the affected populations. Based on published data from both epidemiological and ethnographic studies from northern Uganda, this chapter outlines the prevalence and high-risk groups for adult undernutrition and discusses the social, behavioral, and structural mechanisms that can lead to adult undernutrition and poor health in a post-conflict setting like northern Uganda.

Historical Background of Northern Uganda: Internal Displacement and Distributions of Food Rations

The population of northern Uganda experienced two decades (1986–2006) of armed conflict between the rebel movement Lord's Resistance Army (LRA) and the Government of Uganda's (GoU) military, the Uganda People's Defence Forces (UPDF) (Fig. 1). The population of the North was subject to torture, sexual violence, murder, and mutilations. Children and youth were abducted and forced to become soldiers, laborers, and brides (Branch 2008; Finnström 2008). In response to the insecurity, protected camps or internally displaced persons' (IDP) camps were created by the government and guarded by the UPDF. Most camps were established around preexisting villages or military detaches. They were created to protect civilians, but also to achieve military victory over LRA by separating civilians from rebels. While some families moved to the IDP camps voluntarily, many were forced by the UPDF to leave their homes and livelihoods and move into IDP camps (Branch 2008; Finnström 2008; Whyte et al. 2014). At the peak of the conflict, over 1.8 million people (approximately 90% of the population affected) lived in IDP camps (IDMC 2010). The camp size range from 5,000 to 65,000 people that lived in mud brick huts with thatched roofs (Whyte et al. 2014) (Fig. 2). Although the camps were "protected" and guarded by the UPDF, the IDPs were subject to traumatic experiences and human rights violence in the camps from both rebels and UPDF soldiers (Roberts et al. 2008; Nibbe 2010; Whyte et al. 2012). Camp residents did not have access to their own farmlands and livelihoods, due to insecurity, travel distances, and restrictions by the UPDF to leave the camps (Roberts et al. 2009; Nibbe 2010). The United Nations World Food Programme (WFP) provided general food assistance to IDPs from 1997 to 2008. At that time, it was considered to be one of the largest and longest food aid interventions in the world. The distributions were reported to be insufficient both in quality and quantity (Olwedo et al. 2008; Roberts et al. 2009; Nibbe 2010; WFP Uganda 2012). The rations were shipped from the United States of America (USA) and contained maize or sorghum, beans or pulses, cooking oil (fortified with vitamin A and D), and at times corn soya blend fortified with vitamin A (though only a short period). They were distributed monthly in collaboration with the Norwegian

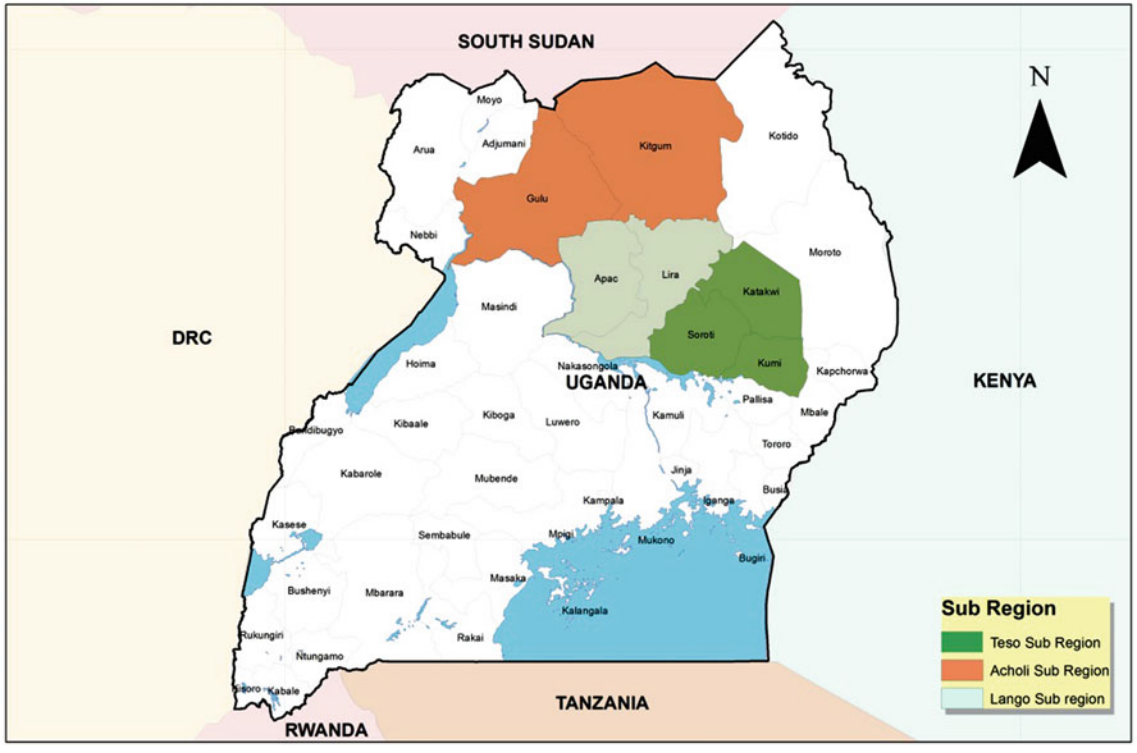

Fig. 1 Map of Uganda. The subregions of Acholi, Lango, and Teso were most affected by the armed conflict in 1986–2006. The map was developed by and used with permission from Ceaser Okumu Law, Gulu HDSS, Faculty of Medicine, Gulu University. Key: *HDSS* Health and Demographic Surveillance Site

Fig. 2 Part of an internally displaced persons' (IDP) camp in northern Uganda. The picture shows a part of an IDP camp in northern Uganda during the war. The IDP camp size range from 5,000 to 65,000 people that lived in closely build mud brick huts with thatched roofs. The picture is taken by Professor Susan Reynolds Whyte, Department of Anthropology at the University of Copenhagen, and is presented with permission from Professor Whyte

Refugee Council, camp leaders, and local leaders. Only vulnerable groups (elderly and disabled) received rations covering 100% the standard daily requirement throughout the relief period, while the general population received between 40 and 100% dependent on the supply from the USA and security situations (Nibbe 2010; WFP Uganda 2012). A standard food ration for general food relief from WFP contains 2,100 kcal per person per day, which represents the nutritional requirements for an average healthy adult (WFP). Not until 2003, supplementary and therapeutic feeding for pregnant women and malnourished children were implemented.

The IDP camps were characterized by environmental, social, and physical dangers including overcrowding, food insecurity, poor housing, collapse of health services, inadequate safe water supply, and poor sanitation, all resulting in high prevalence of acute malnutrition among children, physical illnesses, mental disorders, and high mortality rates (Salama et al. 2004; MoH Uganda 2006; WHO 2007, Spiegel et al. 2010). Accorsi et al. (2005) documented how the conflict "shaped the disease profile" of Gulu district using hospital discharge records between 1992 and 2002 from Lacor Hospital in Gulu. In 1997 and 2002, there was a sharp peak in malnutrition when the conflict escalated. The number of admissions due to measles and pneumonia also peaked in 1996 when there was large migration to IDP camps (Accorsi et al. 2005). A study in Omoro camp in 2006 reported that 6% of the 672 children below 5 years of age suffered from global acute malnutrition (GAM) and 52% were stunted, reflecting the long-standing food shortage and irregular food supply (Olwedo et al. 2008). No studies were conducted on nutritional status among adults. It has long been recognized that both moderate and severe malnutrition have large effects on childhood mortality in low-income countries. Especially, the synergy between malnutrition and infections has an impact on childhood mortality (Pelletier

et al. 1995). Correspondingly, childhood malnutrition measured as low weight-for-age has been shown to predict childhood mortality in Uganda (Vella et al. 1992a, b). In 2005, the Ministry of Health (MoH) of Uganda and the World Health Organization (WHO) conducted a large health and mortality survey among IDPs in the Acholi region (MoH Uganda 2005): The crude mortality rate (CMR), defined as the number of deaths per 10,000 persons per day (see Dictionary of Terms), was 1.54 and above the emergency level of 1 death per 10,000 persons per day. Children below 5 years accounted for 40% of these deaths, with an under-five mortality rate (U5MR) at 3.18 deaths per 10,000 per day (U5MR noncrises, <1.14; emergency threshold, 2.0) (MoH Uganda 2005).

The characteristics of IDP camps were also very similar to the recognized risk factors associated with noncommunicable diseases in developing countries: unplanned rapid urbanization, aging population, increased alcohol and tobacco consumption, decreased physical activity, and diet diversity (Kett 2005; Maher and Sekajugo 2011). Especially, the high level of mental illness contributed to the harmful health behaviors, such as hazardous drinking and increased smoking (Roberts et al. 2011). Roberts et al. (2011) showed that the absence of basic social goods and services was positively associated with mental health disorders, where *lack of food* was the most frequent reported reason for not feeling safe in the camp (93%), and was positively associated with symptoms for depression (Roberts et al. 2008). The forced displacement and loss of livelihood also increased risky behavior for human immunodeficiency virus (HIV) infection (Rujumba and Kwiringira 2010). The coping strategies to meet the basic necessities of life included sex for food, money and other material gifts, marrying off young girls and marital breakdown in favor of those who had money, and sexual violence. Additionally, the Acholi cultural practices like polygamy, widow inheritance, and early marriage (which excited before the war) added to the vulnerability of HIV and other sexual transmitted diseases (STDs) (Westerhaus et al. 2008; Rujumba and Kwiringira 2010). The above-mentioned health and mortality report by WHO found that acquired immunodeficiency syndrome (AIDS) was the second most frequently reported cause of death accounting for 13.5% of all deaths and 71.8% of deaths among 25–50 years old adults in IDP camps in 2005 (MoH Uganda 2005) (Fig. 2).

Adult Undernutrition in Rural Post-conflict Northern Uganda

Northern Uganda has been in a post-conflict transition since signing of the cessation of the hostilities agreement in 2006. In 2008–2010, local government officials put pressure on IDPs to return home, resulting in another population movement from urban camp setups to rural homes of origin. Satellite or transit camps were established to gradually decongest the IDP camps toward their villages. The closing of IDP camps and related challenged have been described in detail by Whyte and colleagues (Whyte et al. 2012; Whyte et al. 2014). The WFP's general food

distribution stopped in 2008 and distributions to vulnerable groups in 2010, and in 2012, all therapeutic feeding programs in health centers closed in the Acholi region. In 2009, the MoH Uganda reported a marked decrease in food security. Main reasons given were poor infrastructure, lack of assets (61% poverty), sudden withdrawal of WFP, and increase in the prevalence of HIV/AIDS (MoH Uganda 2010).

Adult undernutrition in post-conflict areas is a public health concern. Optimal health and nutritional status in post-conflict populations is highly needed for work ability, providing care for families and enhancing independence to rebuild society. Underweight weakens the immune response, reduces physical and cognitive function, and in turn affects morbidity and mortality (Pierce et al. 2010; Roh et al. 2014). Additionally, adult malnutrition has long-term health effects in terms of poor reproductive outcome and poor childhood growth of the next generation (Black et al. 2013). Lastly, poor health status and well-being in a post-conflict vacuum is a risk to human security that can trigger violence and instability.

A population-based study, conducted at the Gulu Health and Demographic Surveillance Site (HDSS) in 2011–2013, found a high prevalence of undernutrition among adults. Undernutrition was classified by body mass index (BMI) (see "Dictionary of Terms" for definition).The prevalence of undernutrition was 22.3% for men and 16.0% for women, whereas the prevalence of overweight was 1.5% for men and 7.6% for women (Schramm et al. 2016). The study included 2,062 men and 2,924 women aged 15 years and above, representing the adult population from a rural subcounty in Gulu district, northern Uganda. This was a cross-sectional community-based study that included anthropometric measurements (weight and height) and survey interviews with information on sociodemographic characteristics, food security, alcohol and smoking consumption, and medical history (Schramm et al. 2016). No other studies have so far been conducted to determine adult nutritional status in northern Uganda. The prevalence of underweight found in the post-conflict area was higher compared to the national prevalence in rural areas reported by the DHS Uganda in 2011, (19.2% and 12.9%, for men and women, respectively), whereas the prevalence of overweight was about half of the national rural prevalence (2.6% and 14.3%) (UBOS and ICF International Inc. 2012). Four community-based studies in the southern regions of Uganda have assessed nutritional status, where the prevalence of underweight ranged from 8.1 to 29.8% among men and 5.9 to 16.5% among women (Maher et al. 2011; Mayega et al. 2012; Kavishe et al. 2015; Kirunda et al. 2015). An overview of the community-based studies examining adult nutritional status in Uganda is presented in Table 1. It should be noted that the studies are not directly comparable; age of study population, underweight classification of young adults, and urban/rural residence should be considered when comparing studies. The highest prevalence of underweight was found by Maher et al. (2011) in southwestern Uganda (Maher et al. 2011). However, the study included participants from 13 years of age and 38.1% of the study population was below 20 years of age. As young adults are at higher risk of being underweight, this may overestimate the prevalence. Additionally, age- and sex-specific BMI cutoffs were not applied for participants below 19 years of age by Maher et al. (2011) and UBOS and ICF

Table 1 Overview of community-based studies examining adult nutritional status in Uganda. Underweight is defined by body mass index (BMI) <18.5 for adults >18 years. Age- and sex-specific BMI cutoff values should be applied to young adults <18 years (see full definition in Dictionary of Terms). Maher et al. (2011) used the BMI <18.5 for all age groups, whereas Schramm et al. 2016 applied age- and sex-specific cutoff values

Author	Study location	Rural/ urban	Year of data collection	N	Age of study participants	Underweight prevalence		Overweight prevalence	
						Men	Women	Men	Women
Maher et al. (2011)	Rakai, southwestern Uganda	Rural	2008–2009	6,678	≥13 years	29.8%	16.5%	4.1%	18.4%
Mayega et al. (2012)[a]	Iganga and Mayuge district, southeast Uganda	Rural and peri-urban	2011	1,656	35–60 years	17.6%	14.6%	9.7%	25.1%
Kavishe et al. (2015)[b]	Rural areas outside of the capital Kampala and Entebbe	Rural	2012–2013	432	≥18 years	16.0%	10.0%	9.2%	41.7%
Kirunda et al. (2015)[a]	Iganga and Mayuge district, southeast Uganda	Rural and peri-urban	2013	1,210	≥18 years	8.1%	5.9%	14.4%	35.7%
Schramm et al. (2016)	Gulu district, northern Uganda	Rural	2011–2013	4,986	≥15 years	22.3%	16.0%	1.5%	7.6%
UBOS and ICF International Inc (2012)[b]	National sample of rural areas	Rural	2011	3,524	Men: 15–54 years Women: 15–49 years	19.2%	12.9%	2.6%	14.3%

Key: *BMI* body mass index, *UBOS* Uganda Bureau of Statistics

[a]Kirunda et al. (2015) included participants both from rural and peri-urban areas ($n = 912$ [75%] from rural areas). Presented estimates are combined rural and peri-urban populations, as data was not stratified by gender in rural areas. The overall (combined gender) prevalence of undernutrition in rural areas was 8.1% vs. 4.0% in peri-urban; the overall prevalence of overweight was 15.8% in rural vs. 23.8% in peri-urban areas. Estimates from Mayaga were not stratified by rural/ peri-urban populations ($n = 1352$ [84%] from rural areas)

[b]Only data from rural populations are included in the table. Kavishe et al. (2015) and UBOS and ICF International Inc (2012) also included participants from urban areas ($n = 484$ and $n = 929$, respectively), not shown in the table

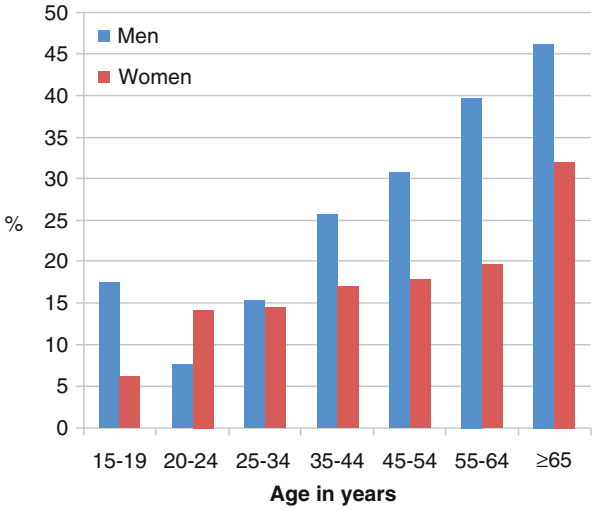

Fig. 3 Prevalence of undernutrition in northern Uganda by gender and age. The prevalence of adult undernutrition is presented by age categories and gender with men in the blue column (*left*) (Figure produced by results from Schramm et al. (2016))

International Inc. (2012) which further can overestimate the prevalence (Maher et al. 2011; UBOS and ICF International Inc 2012). Nevertheless, all studies report the same trend with underweight being more prevalent among men than women and overweight being more prevalent among women than men.

Besides gender differences, Schramm et al. (2016) found that undernutrition varied substantially across age groups, where young men and elderly were most likely to be underweight (Fig. 3) (Schramm et al. 2016). Risk factors for undernutrition were also different between men and women. Among adult men, being divorced/separated compared to being married, smoking daily vs. not smoking, and frequent alcohol consumption vs. not drinking were risk factors for being underweight. However, the association between alcohol consumption and undernutrition was not statistically significant in adjusted analysis. Although 17% of the adult women were widows, being a widow was not associated with being underweight. Smoking was more prevalent among men (32.0%) and virtually nonexisting among women (0.5%). The frequency of alcohol consumption was also higher among men than women. Lastly, among women, but not men, seasonality was associated with undernutrition. Women who were measured during the "hungry-gap rainy season" (May–July) were more likely to be underweight (Schramm et al. 2016). Hence, social and behavioral factors were associated with undernutrition among men but not among women (Table 2). Risk groups or factors associated with underweight were not examined in any of the other studies presented in Table 1 as this was not the main outcome of interest in these studies.

The following section will discuss mechanisms that can contribute to the observed gender difference in the prevalence and risk factors for adult undernutrition (Fig. 3).

Table 2 Individual-level risk factors associated with undernutrition among adults in post-conflict northern Uganda. Summary of findings from a logistic regression analysis using generalized estimation equation from the study by Schramm et al. 2016, examining risk factors for undernutrition among 4,986 adults in post-conflict Uganda (Reproduced and presented with permission from authors (Schramm 2016))

	Male	Female
Age	Young (<20 years) and older (>45 years) age was associated with increased odds of being underweight	Increasing age (from 20 years and above) was associated with increasing odds for being underweight
Marital status	Being divorced/separated was associated with ~2.0 higher odds of being underweight	No association. Note: Being divorced/separated or widowed was *not* associated with underweight
Smoking daily	Smoking daily was associated with 2.5 times higher odds of being underweight	No association
Alcohol consumption frequency	Drinking more than once per week was associated with being underweight (though not statistically significant)	No association
Measured during hungry-gap rainy season	No association	Being measured during hungry-gap rainy season was associated with ~30% higher likelihood of being underweight

Disruption of Traditional Gender Roles and Gender Differences in Undernutrition

When referring to differences between men and women or males and females, the term "gender" is used to describe a social construct, whereas "sex" is used when referring to a biological construct (Krieger 2003). Gender differences can occur from social, cultural, or structural conditions that shape the norms, values, experiences, and behavior of men and women. Poverty and trauma can interact with gender and contribute to excess disease burden in one group. Differences between genders may also be a result of inequality, that is, systematic empowerment of one group over another group (see Dictionary of Terms).

Before the civil war in northern Uganda, the traditional Acholi culture of northern Uganda had clear and defined gender roles and responsibilities between men and women. The man was the income provider, responsible for managing livestock and agricultural activities that require hard physical labor. The man had authority over the women and children and was also responsible for protecting and providing for them. A wife's responsibility was to take care of the children and the household, primarily engaged in the kitchen and subsistence farming activities that are less labor intensive (Adams et al. 2013; Sengupta and Calo 2016).

Disruption of social structures and altered gender roles during the conflict affected men more than women in northern Uganda. During the displacement to

camps, limited access to land and distribution of food relief resulted disempowered and "jobless" men. Women's roles around reproducibility and domestic work did not change to the same extent as men's roles. Men were no longer able to provide and protect their family. Boredom in camp, trauma, disempowerment, and loss of social masculine identity led to deep shame, humiliation, anger, and frustration, which further resulted in high consumption of alcohol and substance use, as well as other unhealthy behaviors among men. Women were producing alcohol and sold it to men. Women also became in power of food within the household as food rations by WFP was by policy given to women of the household at one point (Branch 2008; Kizza et al. 2012; Dolan 2013). Dolan has described this with the concept "The proliferation of small men in Northern Uganda," where women gained power within households and young men could not fulfill social expectations (including finding a wife and providing and protecting the family) and instead they engaged in alcohol abuse, violence, crime, and suicide (Dolan 2002; Dolan 2013). A qualitative study by Schlect et al. (2013) provides in-depth details on the changes and disruptions of marital traditions in northern Uganda (Schlecht et al. 2013).

Structural Mechanisms that Can Lead to Gender Differential Prevalence in Undernutrition

Differential exposure and vulnerability to disease, disability, and injuries are somewhat well known. For example, men are more prone to injury during war, and women are more prone to infectious disease due to closer contact with children. Moreover, the way that men and women are valued in society, including the health-care system, can affect the health behavior of individuals. Policies, health interventions, health systems, and health research are rarely neutral and can contribute to both equity and inequity between population groups. When targeting specific groups for intervention or care, health systems (including international and local health organizations) can be exclusionary and inequitable (Mackintosh 2001; Accorsi et al. 2007). International donors and agencies often see the post-conflict period as an opportunity to undertake reforms of public health institution that include gender policies and women's empowerment interventions (Percival et al. 2014). A study by Percival et al. (2014) suggests that donors in conflict and post-conflict settings, including northern Uganda, have prioritized reproductive and maternal health outcomes to a large extent (Percival et al. 2014). The focus on women (especially pregnant women) and children in health-care development programs and research is not new and reflects a long-term focus of international organizations and donors that are also presented in non-conflict settings.

Taking away "men's 'job'" by prolonged displacement and targeting food aid rations to the women of the household undermines the cultural gender roles and affected men's behavior. A qualitative study by Sengupta and Calo (2016) reported that local leaders perceived the "breakdown of traditions" to be due to non-governmental organizations' (NGOs) focus on gender rights and numerous women's empowerment programs. Sengupta and Calo (2016) further found that NGO

programs were perceived as *women's programs* by the male respondents of the study and that few NGOs target male involvement in women's rights program (Sengupta and Calo 2016). However, the MoH Uganda introduced the policy "male involvement strategy" for antenatal care (ANC) in November 2014 (WHO Africa 2014). The male involvement strategy was intended to encourage men to accompany their spouses during ANC visits. However, the interpretation of the policy was left to health-care providers who interpreted male partner attendance as compulsory and with compulsory HIV testing at the first ANC visit (Rudrum et al. 2015). Rudrum et al. (2015) reported that women are often sent away and miss essential health care if they come without their male partner. The policy of male involvement further contributed to the shift in power between genders; making women responsible for bringing their husbands to the health center shifts the responsibility from the health care system to the women. Leaving women to negotiate with men can also have consequences for the marital relationship and domestic violence (Rudrum et al. 2015).

Gender Differential Exposure to Trauma, Mental Illness, and Substance Use

When reviewing any public health aspect in a post-conflict setting, it is crucial to consider the role of trauma exposure and mental illness. Numerous studies have been conducted on mental health disorders in northern Uganda, and some of them will be presented here. The most commonly reported mental health disorders from northern Uganda are post-traumatic stress disorders (PTSDs), followed by depression and anxiety. Other published domains include suicide ideation or attempts, alcohol abuse, partner violence, child abuse, and feelings of guilt and revenge (Dokkedahl et al. 2015). A review by Dokkedahl et al. (2015) summarized published studies from 2004 to 2014 on mental health disorders in northern Uganda (Dokkedahl et al. 2015), but several studies have been published since. While there are no studies that have investigated the relationship between mental health and nutritional status directly, parallels can be drawn between study results.

Schramm et al. (2016) found that especially young adult men were at higher risk of being underweight (Schramm et al. 2016). Child soldier recruitment was predominantly among 11–16 years, who represent individuals aged 15–30 years at the time of the study. Exposure to abductions and other severe traumatic experiences was more common among boys and men than girls and women (Ovuga et al. 2008; Ertl et al. 2016). This differential exposure itself can put men at higher risk of developing mental illness and poor nutritional status compared to women.

The postwar environment, including community and family contextual factors, can interact with individual-level factors (sex, age, and previous trauma exposure) and either increase or decrease the burden of mental illness in post-conflict populations. For example, Amone-P'Olak et al. (2013) reported an indication that marriage (family context) was a protected factor for poor functioning of formerly

abducted young adults; individuals that were divorced/separated had a higher poor functioning score compared to individuals that were married (Amone-P'Olak et al. 2013). Likewise, Schramm et al. (2016) found that adult men that were divorced/separated had increased odds of being underweight compared to men that were married (Schramm et al. 2016). No gender difference was reported by Amone-P'Olak et al. (2013). On the community level, poor access to mental health-care services plays an enormous role in the burden of mental illness. Only 17% of former abducted youth had seen a mental health-care worker despite ~70% acknowledged that they experienced emotional and behavioral problems and wished to receive help. More women than men had sought help from mental health services. Reported barriers were stigma/discrimination, fear of family breakup, and lack of health-care providers (Amone-P'Olak et al. 2013).

As a consequence of extremely limited mental health care, stigma, and disruption of tradition gender roles, some people cope with psychological stress and symptoms themselves. Alcohol and substance use can be used as a self-medicating coping strategy. Ertl et al. (2016) found a strong association between war-related trauma and alcohol use disorder, as well as emotional abuse in the family and alcohol use disorder (Ertl et al. 2016). Similar findings were found by Roberts et al. (2011) during the insurgency period (Roberts et al. 2011).

Alcohol and substance abuse has been linked to undernutrition in other populations (Falck-Ytter and McCullough 2000). Further, Schramm et al. (2016) found that smoking and alcohol were risk factors for adult undernutrition, but only among men (Schramm et al. 2016). Likewise, Roberts et al. (2011) and Ertl et al. (2016) found alcohol consumption among Acholi women to be rare, which stems from the Acholi cultural tradition where it is not well accepted for girls and women to consume alcohol (Roberts et al. 2011; Ertl et al. 2016).

HIV

It is well known that being HIV-infected can be a cause of undernutrition (Koethe and Heimburger 2010). Additionally, being underweight with HIV further weakens the immune response which can comprise the effects of antiretroviral therapy, increase the risk of opportunistic infections such as tuberculosis (TB) (Holmes et al. 2003), and increase the risk of mortality (Van der Sande et al. 2004; Koethe and Heimburger 2010). The estimated prevalence of HIV infection in northern Uganda in the post-conflict period varies greatly by study, but is consistently higher among women than men. The estimates by the MoH Uganda (2011) were 10.1% among women and 6.3% among men aged 15–49 years, which was higher than the average national estimate of 8.2% and 6.1%, for men and women, respectively (MoH Uganda 2012). In a cohort study with 2,388 people aged 13–49 years from three different districts of northern Uganda, the prevalence of HIV infection was 14.6% among women and 8.5% among men (Malamba et al. 2016). Another study among only young adults in transit camps found the HIV prevalence to be 15.6% and 9.9%, among women and men, respectively (Patel et al. 2014). Data collection methods, selection, and inclusion criteria of participants should be considered when comparing the studies. The prevalence of opportunistic infections has also been found to be

higher among women than men and more prevalent with increasing age (>30 years) in northern Uganda (Rubaihayo et al. 2016).

When the civil war in northern Uganda ended, many of the social, structural, and environmental risk factors to HIV infections persisted. For example, food insecurity is strongly associated with increased risky behavior for HIV transmission (Westerhaus et al. 2008; Rujumba and Kwiringira 2010). A qualitative study by Rumumba and Kwiringira (2010) found that sexual immorality was linked to the perceived severity and relevance of different threats or problems. While participants were aware about the risks and consequences of HIV infection, people were more worried about food, water, and other basic needs than contracting HIV. HIV was described as "something for the future" and not something you die of now like hunger. Hence, unmet basic necessities had overshadowed the concern for HIV/AIDS (Rujumba and Kwiringira 2010).

The nutrition surveys presented in Table 1 were not able to explore if HIV could explain the prevalence of undernutrition. The consistent gender difference in nutritional status (higher prevalence of undernutrition among men than women) does not follow the same pattern with the gender difference in the prevalence of HIV infections. If HIV infection is well treated and managed, the risk of weight loss is lower. Thus, the different patterns may be explained by access to treatment, adherence, and stigma of HIV in northern Uganda. In general, women are more in contact with health care systems due to reproduction, responsibility of caring for children, and factors mentioned above. Increasing evidence suggest that disproportionately less men than women in Africa are accessing HIV treatment, men begin treatment with a more advanced disease stage, and men are more likely to interrupt treatment than women (Cornell et al. 2011). Yet, the rapid scale-up of ART programs has largely focused on women (Cornell et al. 2011). Ethnographic accounts from studies of ANC in northern Uganda give indication that HIV stigma is more present among men than women: "a man's status is greatly reduced by being known to have HIV" (Rudrum et al. 2015, p. 3), [men] fear that they have the virus and would "rather not know" (Rudrum et al. 2015, p. 4), and common cases of women bringing a taxi driver instead of their husband for HIV testing or the husband would show up drunk so he would not be able to have the test taken (Rudrum et al. 2015).

Lastly, associations between HIV and mental illness have also been established in northern Uganda. Mugisha et al. (2015) found HIV to be a risk factor for common mental disorders (Mugisha et al. 2015). Likewise, Malamba et al. (2016) found that participants living with HIV were more likely to report traumatic events, have probable PTSD and depression, and report suicidal ideation (Malamba et al. 2016). Palermo et al. (2013) found that among people living with HIV/AIDS, living in severe food insecure households had a significantly lower mental health score than people living with HIV/AIDS living in food secure households (Palermo et al. 2013).

Elderly

Older age was one of the high-risk groups for undernutrition in the study by Schramm et al. (2016). This is consistent with other studies in sub-Saharan Africa (Kimokoti and Hamer 2008; Cheserek et al. 2012). This is also in line with general

physiologically decline in both weight and height with older age, with a greater decline in weight. Consequences of underweight in elderly include alteration in immune function, decline in functional and cognitive ability, decreased ability to contribute to household and economic activities, poor quality of life, and mortality (Assantachai 2012). In post-conflict areas with migration and withdrawal of food assistance, the ability of older people to meet their basic needs can be challenging (Burton and Breen 2002). Elderly are increasingly being recognized as a vulnerable group in complex emergencies; however, they are still rarely included in nutrition assessments (Young et al. 2004). Elderly are also not a priority in development programs as they are viewed as contributing little to the society (Kimokoti and Hamer 2008). Most health studies and surveys, including the DHS, do not collect data on elderly. As a result, this group is systematically excluded from health research, public health planning, and policy, including fund allocations. In sub-Saharan Africa, the older population (>60 years) are projected to increase fourfold between 2005 and 2050 (UN DESA 2001). Elderly have a higher disease burden and will therefore have large contributions to the cost of health care in the future.

Policies and Protocols

Focusing on conventional target groups in health interventions and not adapting to the local context may have contributed to disruption of existing family and social structures and thereby create other risk groups that are not targeted. These nutritional consequences may be maintained after the conflict. Moreover, issues of gender inequality and social disruption may mirror a more general pattern in low-income countries that only becomes more pronounced in this post-conflict setting (Wyrod 2008). Health policy and interventions must consider gender relations within the historical and traditional aspects when implementing human rights and women empowerment strategies. As described above, post-conflict stressors are experienced and responded to differently between men and women. Health research and health data collected by organizations involved in conflict and post-conflict settings should systematically analyze data disaggregated by gender to be able to adjust health interventions to the local context and avoid unintended consequences.

Moreover, new approaches to better understand the complex interaction between behavioral, social, and structural determinants of health and disease in post-conflict settings are warranted. Social factors such as poverty, stigmatization, and structural violence may have great importance to the nature of morbidity and mortality. The term “syndemic” was first introduced by Merrill Singer in the 1990s and refers to two or more epidemics or diseases that interact with each other and with social and structural conditions which generate excess morbidity and mortality due to a synergetic effect (Singer et al. 2017). Social stigmatization of disease can have great importance for syndemic interactions. For example, stigmatization of HIV can result in the experience of enhanced stress; stress can further lead to adverse coping strategies such as substance abuse and social harmful behaviors which can lead to increased risk of mental illness and malnutrition; psychological distress and

malnutrition can further lead to other diseases. Syndemics may occur more easily in vulnerable groups such as post-conflict populations that are already affected by adverse social conditions. The high prevalence undernutrition among men may be a result of interactions between high levels of mental illness, HIV (or other diseases), substance abuse, and undernutrition itself, which further interacts with the social and structural conditions such as gender inequality, stigma, stress, feelings of disempowerment and shame, poverty, and limited access to health care. Additionally, early life trauma may be a significant social condition that increases the likelihood of syndemics within conflict and post-conflict populations. Recognizing and understanding these clusters and interactions of diseases and conditions are crucial for improving public health in post-conflict settings. This includes investigating the effect of co-occurring conditions and social conditions when assessing specific health outcomes. Because excess disease burden may be the result of social and structural (political) factors, interventions may be within and outside of the official health care system. A detailed description and recommendation for further research and practices have been published in the Lancet Series of Syndemics (Lancet 2017).

Dictionary of Terms

- **Internally displaced persons** – Internally displaced persons (IDPs) are defined as people who have been forced or obliged to flee their home to protected areas, particularly due to armed conflict, situations of general violence, violence of human rights, or natural or human-made disasters. IDPs flee or are forced to move to protected areas within their country and do not cross recognized international borders. They remain under the protection of their own government, not protected by international law or eligible to receive the same type of assistance as refugees (Salama et al. 2001). However, nonbinding legal principles for internal displacement have been developed to address shortfalls in protecting IDPs (Deng 1999). Refugees are people who may leave for the same reason as IDPs but flee to another country and cross international borders. They are protected under the United Nations 1951 Refugee Convention, where the United Nations High Commissioner for Refugees (UNCHR) has an international mandate to protect the rights of refugees and provide basic services (UNHCR 1967).
- **Post-conflict** – There is no universally accepted definition of a post-conflict setting. However, there is consensus that a country or an area is considered "post-conflict" when hostilities and violence have ceased and a peace agreement has been signed (Canavan et al. 2008). The transition can be very complex and context-determined. Often, several conflicts co-exit where some end and others continue. Some conflicts become chronic and displaced persons remain in camps or are without settlement for decades. A formal end to a conflict can also be replaced by high level of violence and instability, sometimes result in renewal of war (Haar and Rubenstein 2012). The post-conflict recovery and reconstruction can be understood as a process that includes efforts to improve restoration of law and order, political governance, economic rehabilitation, and development and

social conditions, including health. Hence, the real and tough battles to sustain peace and rebuilt society begin after the war. International organizations and donors often see the post-conflict period as a window of opportunity to implement a wide range of public sector reforms, including improving health care and ensuring equity and human rights, with the political will to "bring better back" (Percival et al. 2014).

- **Adult undernutrition** – This chapter focuses on undernutrition in terms of underweight, classified by body mass index (BMI [weight (kg)/height (m) ^{2}]). Adult individuals above 19 years of age are classified as underweight when their BMI is below 18.5. For young adults aged 15–19, underweight is classified by age- and sex-specific z-scores compared to the World Health Organization (WHO) reference growth standards (de Onis 2007). The chapter does not cover nutrient deficiencies, such as iron and vitamin A deficiencies.
- **Inequality** – Health inequality refers to differences in health indicators in groups that raise concern about justice (equity) as they may be systematically related to social and structural conditions that are modifiable. Gender inequality in health refers to unequal distribution in health between men and women (as a social construct), whereby one group (men or women) is systematically empowered over the other by actors and institutions in society.
- **Equity and inequity** – Health equity is an ethical concept of distributive justice: implies that everyone has the same opportunities for a healthy life. Working toward health equity means minimizing inequality and that health should not be compromised because of gender, age, income, or other factors. Subgroups in populations may be treated differently to achieve equity in health.
- **Crude mortality rate and under-five mortality rate** – Mortality rates are measures of the number of deaths in a given population in a given time. Crude mortality rate (CMR) is usually defined as number of deaths per 1,000 individuals per year. The under-five mortality rate (U5MR) is usually defined as the number of deaths of children below 5 years of age per 1,000 live birth. During armed conflicts, information on live birth and mortality is often not available. The WHO Health and Mortality survey (MoH Uganda 2005) referred to in this chapter uses an alternative definition, whereby CMR and U5MR are defined as the number of death over a total person-time at risk. Being within the study population defined being at risk. Person-time was defined as the cumulative time spent in the recall period of the study (maximum 6 months) by all persons in the study sample. The CMR and U5MR were therefore expressed as the number of deaths per 10,000 persons per day. See the health and mortality report by WHO for further details (MoH Uganda 2005).
- **Syndemics** – The term syndemics refers to the existence of two of more epidemics, diseases, or other health conditions in a population that interact with each other and with social conditions which result in excess morbidity and mortality due to a synergetic effect. Hence, syndemics is a set of mutually enhanced epidemics with biologic interaction of diseases and is sustained in a population due to adverse social conditions. They involve interactions of all disease types and health conditions such as infections, noncommunicable diseases including

mental illness, malnutrition, toxic exposure, and behavioral conditions. The interaction is often caused or enhanced by health inequalities due to poverty, stigmatization, or structural violence (Lancet 2017; Singer et al. 2017).

Summary Points

- This chapter outlines the prevalence and high-risk groups for adult undernutrition and discusses the social, behavioral, and structural mechanisms that can lead to adult undernutrition in a post-conflict setting like northern Uganda.
- Undernutrition is defined as underweight, classified by body mass index (BMI [weight (kg)/height (m) ^{2}]). Adult individuals above 19 years of age are classified as underweight when their BMI is below 18.5. For young adults aged 15–19, underweight is classified by age- and sex-specific z-scores compared to the WHO reference growth standards (de Onis 2007).
- Northern Uganda experienced two decades of armed conflict (1986–2006), where 90% of the population was forced to live in internally displaced persons' (IDP) camps.
- Disruption of social structures and altered gender roles affected men more than women; trauma and loss of masculinity and identity led to humiliation and shame, which further led to high alcohol consumption, substance use, and mental illness.
- The prevalence of adult undernutrition was higher among men than women, where young men and elderly were most likely to be underweight.
- Risk factors for undernutrition among men included social and behavioral factors: being divorced, smoking, and frequent alcohol intake. Despite 17% of women were widows, social or behavioral factors were not associated with underweight among women.
- Similar factors (marital status, alcohol) have been associated with common mental illnesses in northern Uganda. However, no study has yet examined the direct link between mental health and nutrition in this setting.
- Applied gender policies in food aid distributions and development programs do not match with the high-risk groups of adult undernutrition in northern Uganda.
- Focusing on conventional target groups in health interventions and not adapting to the local context may have contributed to disruption of existing family and social structures.
- The high prevalence of undernutrition among men may be a result of a "syndemic" interaction between mental illness, HIV, substance abuse, and undernutrition itself, which further interacts with the social and structural conditions such as gender inequality, stigma, stress, feelings of disempowerment and shame, poverty, and limited access to health care.
- This emphasizes the need for better approached to consider gender norms and values within the historical and traditional aspect when implementing women empowerment strategies in post-conflict settings. Furthermore, health data should systematically be analyzed gender-disaggregated.

Initial Hunger, a Subjective, Reproducible Limit in Intake Associated with Low Blood Glucose: A Training for Malnourished Infants and Overweight Adults

29

Mario Ciampolini

Contents

Abstract

In this review, we describe the training of the passage from scheduled to demanded meals in infants and adults. Reduction in energy intake was obtained by subjectively abolishing conditioned meals and by administering food only after demand by the infant or after hunger perception by the adult (Initial Hunger Meal Pattern; IHMP). Conditioned meals were those scheduled and/or presented to the infant as well to the adult by sight, smell, mentioning, gesturing, or simply

V. R. Preedy, V. B. Patel (eds.), *Handbook of Famine, Starvation, and Nutrient Deprivation*, https://doi.org/10.1007/978-3-319-55387-0_125

at a fixed mealtime. In contrast IHMP training consisted of meal suspension and of feeding after the first infant's demand or after an adult's self-noticing arousal of hunger. IHMP was checked by measuring blood glucose (MBG) and was associated with significant decreases in diary-reported energy-intake, preprandial blood glucose, glycated hemoglobin, body weight, insulin AUC in glucose tolerance tests and in days with diarrhea as compared to randomized control subjects who maintained conditioned meals. There were metabolic differences between those who received conditioned and demanded (IHMP) meals. Subjects adapted themselves to IHMP training easily. We explain characteristics like hunger equivalents, adjustments of energy intake to energy expenditure, blood glucose measurements, and characteristics that emerge in IHMP in contrast with scheduled meals. We also review previous studies in which the meals upon demand have been used. Other areas mentioned in this review include coverage on portable glucose monitoring, standard measurements of blood glucose, training protocols to remove conditioned meals and implement IHMP, the features of *Initial Hunger*, and other aspects of metabolic control that interlink hunger, meal feeding, blood glucose, and energy balance.

Keywords

Blood glucose · Diabetes · Insulin resistance · Overweight · Fattening · Energy balance · Energy intake · Limit in energy intake · Hunger · Meal onset · Energy availability · Bowel disorders · Malnutrition

List of Abbreviations

AUC	Area under curve of GTT
BG	Blood glucose, an index of energy availability in blood for the whole body
BMI	Body mass index = body weight in kg divided by squared height in meters
GTT	Oral glucose tolerance test
IH	Initial hunger
IHMP	Initial hunger meal pattern
MBG	Mean preprandial blood glucose
RMR	Resting metabolic rate
TEE	Daily total energy expenditure

Introduction

In the following text, we describe our observations and findings on undernourished infants with diarrhea, some basic facts of the intestine, the immune response, and intestinal bacteria.

The alimentary canal is exposed to a large amount of viable bacteria: about 100 trillions per gram of content. Many hundreds of species have no immune effect on the mucosa, but there are 5–15% of species that are capable of eliciting an

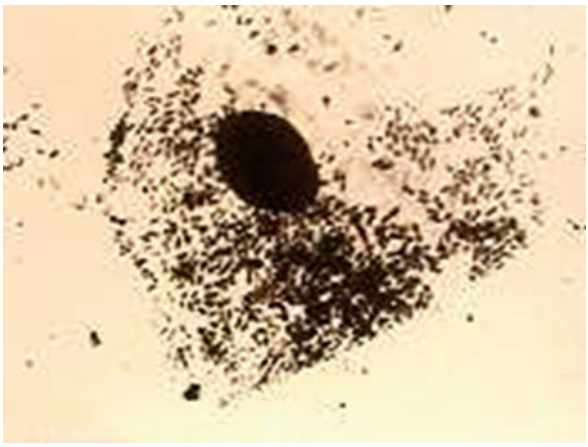

Fig. 1 Epithelial cell shed from intestinal mucosa and covered by bacteria. Magnification is 2000X. (Courtesy of Ciampolini et al. 1996, Copyright Clearance Center's Rights Link® service)

antibody response and inducing inflammation (Van der Waaij et al. 1996; Ciampolini et al. 1996, 2000). These immunogenic species alone do not provoke a general illness, but the antigen-immune elimination process damages underlying tissues (Van der Waaij et al. 1996).

The number of immune cells in the small intestinal mucosa is impressively large. Half of the immune cells of the whole body are in the small intestine (Mowat 1987; Brandtzaeg et al. 1989). The absorption of nutrients from food is thus a competition between mucosa cells and bacteria (Ciampolini et al. 1996, 2000). Figure 1 well represents the bacterial environment in intestinal lumen.

For feeding and preventing bacterial growth, in our clinic, mothers had to provide energy dense food only when necessary, i.e., food was not offered when the child was calm and happy. As soon as the baby changed their mood, the mother gave them a meal. Missing a meal reduced intestinal bacteria concentrations (Ciampolini et al. 1996). The child did not suffer hunger but only signaled it. This was an Initial Hunger Meal Pattern (IHMP). Figure 2 reports that during the associated low mean preprandial blood glucose (BG) in a week (reported as diary average glycaemia in Fig. 2), antibody response to Helicobacter pylori decreased, presumably reflecting lower H pylori growth.

In our clinic, we encountered most infants and adults with diarrhea and malabsorption who did not have Coeliac disease. We randomly assigned them to one of either two groups: (i) intervention (IHMP) or (ii) control. Controls remained on conditioned feeding. There were thus two groups in comparison for infancy and two groups for adulthood. Groups of overweight adults and malnourished infants provided further comparisons.

The intervention (Initial Hunger Meal Pattern, IHMP) consisted of suggesting subjects or mothers to suspend meals and to wait for the arousal of gastric pangs (adults), unexplainable unpleasant moods (infants), fussiness or walking in search for food, or verbal or gestural demand for food before seeing the food or laid table (Ciampolini et al. 1990).

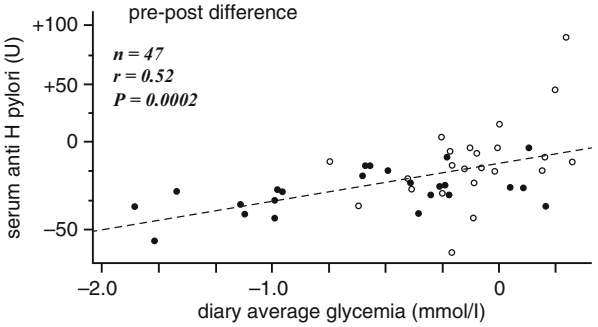

Fig. 2 Positive correlation between serum concentration of anti-*H. pylori* and diary mean preprandial Blood Glucose (MBG). Values represent the pre-/postdifferences. Black and white dots show trained and control subjects, respectively. $n = 47$, $rho = 0.52$, $p < 0.0002$. (Courtesy of Ciampolini et al. 2000; Copyright Clearance Center's Rights Link® service)

The prevalent way of eating is conditioned and sets the limit (arbitrary!) on body weight or fatness (Ciampolini et al. 2010, 2013b; Ciampolini and Bianchi 2006; Ciampolini and Sifone 2011; Fisher and Birch 2002; de Ridder et al. 2014; Herbert 2014; Melanson et al. 1999), whereas IHMP sets the limit in the arousal of subjective hunger sensations. Conditioned meals are those suggested by sight or smell of food, with company, by laid tables or by even mentioning these situations. Removing conditioned meals, i.e., implementing IHMP to achieve normative insulin sensitivity, abolished reflexes that depressed intestinal digestive functions as well as intestinal absorption (Ciampolini 1974, 1976). This was associated with a reduction of insulin resistance (Ciampolini 2013). In children, removing conditioned meals (i.e., implementing IHMP) decreased mean blood glucose (MBG) and in adults decreased the area under glucose curve (AUC) in glucose tolerance tests (GTTs) in association with lowering MBG (Ciampolini and Sifone 2011; Ciampolini 2012).

Investigating the Portable Glucose Monitor

We investigated preprandial events in blood by weekly diaries that reported blood glucose measurements with a portable device before the three main meals. Single blood glucose measurements were performed with a reliable portable potentiometer using the hexokinase method (Glucocard Memory; Menarini diagnostics; Florence, Italy). Measurements were made at 15 min before each meal. This constituted the *glucose diary*. The adults had to personally measure blood glucose in the same blood sample with the portable instrument. The reliability of the data was compared against the autoanalyzer results generated in the laboratory. **The autoanalyzer obtained a mean ± SD of 89.9 ± 11.3 mg/dL, adults measured 89.0 ± 12.5 mg/dL ($N = 85$). The mean difference (0.9 ± 7.1) was not significant. On absolute values, the mean difference was: 5.7 ± 4.3 mg/dL with no bias.** Measurements from the

blood glucose diary had a low confidence interval, 3.8 mg/dL, and after 5 months it was 6.0 mg/dL (no bias).

Measuring preprandial blood glucose is useful for the patient as they can directly notice their changes as a result of unbalanced meals (between intake and expenditure) and so may make appropriate adjustments. Moreover, he/she can learn the effects of physical exercise, changes in the immediate environment, and occasional stressful and untoward events on blood glucose (Ciampolini et al. 1990, 2010, 2013b; Ciampolini and Bianchi 2006; Ciampolini 2012). MBG characterizes the individual's meal pattern better than energy intake and much better than single fasting measurements (Ciampolini and Sifone 2011).

In the preprandial setting, BG and MBG are directly associated with insulin resistance. BG summarizes the metabolic condition that follows the previous meal and indicates energy availability (Ciampolini and Bianchi 2006; Ciampolini et al. 2010; Ciampolini and Sifone 2011). The metabolic conditions created by the previous meal ceases completely with the incoming meal. The *glucose diary* mentioned above has wide applicability and may be accurately performed by the patient under the surveillance of the family physician.

Standard Measurement of Blood Glucose

Sampling BG after an overnight fast is poorly standardized. The liver delivers glucose into blood every 12 min resulting in approximately 10% changes (Campfield and Smith 2003). Ambient temperature, physical activity, food, and stress all significantly increase blood glucose. Half of overweight subjects have high morning BG or do not consume breakfast and also those subjects who consume breakfast have unpredictable fasting BG because of variability in time, the amount of dietary energy, food composition of the previous dinner, physical activity before going to bed, and the degree to which the individual is insulated when in bed.

Sampling blood glucose within 15 min before a meal is a sufficiently reproducible (Confidence interval = 3.8 mg/dL). BG measurement at this sampling summarizes energy availability and balance for the period from last meal to the moment of sampling. This provides information about either the abundance or insufficiency (energy balance) of the last meal in comparison with the expenditure between meals. The measurements of blood glucose when receiving food energy indicate the energy available for a given situation. Being aware of this was considered the best way to adjust meal energy. As a consequence, overweight subjects lost their fear of hypoglycemic events later in the morning.

Meal onset produces a completely new metabolic condition with an increase in energy availability, a change in metabolic rate, and changes in gastric, intestinal, liver, and pancreatic functions (Ciampolini 1974, 1976; Ciampolini et al. 2013b).

The weekly MBG was calculated from 21 preprandial measurements in a week. MBG was consistent in a given subject because of the narrow confidence interval of preprandial BGs within the same person (Ciampolini and Sifone 2011). At recruitment,

the BGs of 120 investigated adults by portable device showed a mean confidence interval of ±3.84 mg/dL. By itself, this small confidence interval suggests reliability.

The normal BG range between 65 and 110 mg/dL was obtained in our studies by measuring BG in different subjects. We could stratify the 120 subjects into ten small strata. Each stratum contained subjects without differences in MBG that instead were significant from all other strata. We might say that each subject maintained a meal pattern directed by the aim of a stable level of energy availability within his/her own MBG stratum even during ad libitum meal feeding. Infants' MBGs showed stratification in less strata.

High energy availability is associated with depressed intestinal activity. To show the existence of this association, we reduced metabolic rate in experimental animals and in humans by elevating environmental temperature and tested xylose absorption in experimental animals and humans in the two conditions of energy availability: high and low (Figs. 3 and 4).

The high environmental temperature decreased the intestinal absorption rate of xylose (Ciampolini 1974, 1976). In this condition, long permanence of nutrients in the small intestine allows bacterial growth and possible diarrhea relapses. The relationship between bacterial growth and diarrhea relapses has been separately studied in children (Ciampolini et al. 1996, 2014; Ciampolini 2012).

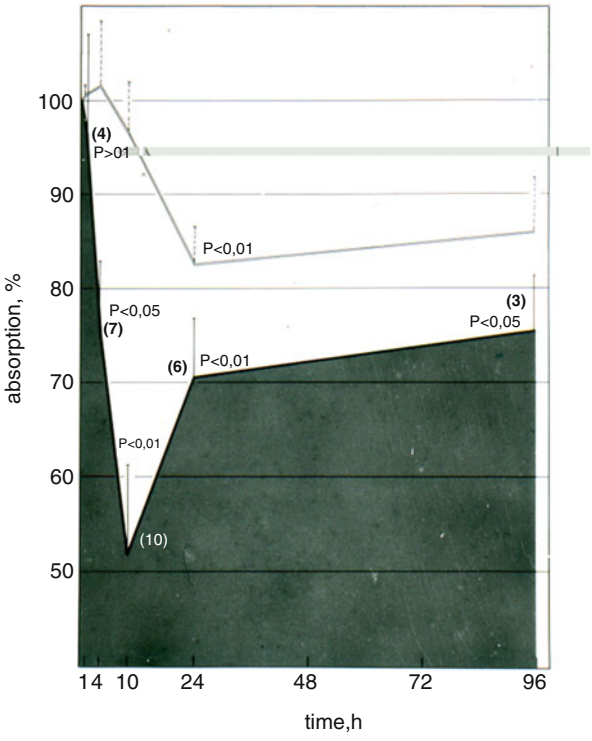

Fig. 3 Percentage of increased absorption in cold environment (6 °C) over absorption in warm environment (31 °C) of intragastric xylose in rats. (Courtesy of Ciampolini, IRSC 1974 Copyright Clearance Center's Rights Link® service)

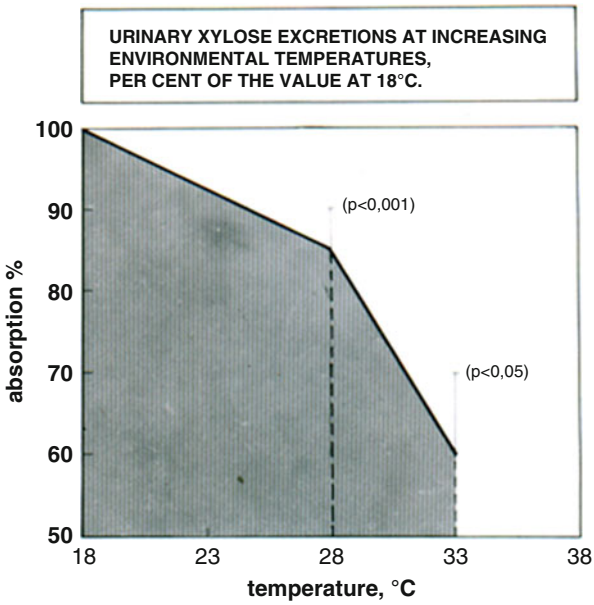

Fig. 4 Significant, negative correlation between environmental temperature and xylose absorption in man. (Courtesy of Ciampolini, Min Ped 1976 Copyright Clearance Center's Rights Link® service)

High total cholesterol, high triglycerides, low HDL cholesterol, high uric acid, high basal insulin, and high insulin responses during Glucose Tolerance Tests (GTTs) are correlated with high MBG (Ciampolini and Bianchi 2006; Reaven 2006) and contribute to the metabolic syndrome. BG assessments protect the overweight subjects against hypoglycemia and against fear of becoming hypoglycemic.

Training Protocol to Remove Conditioned Meals and Implement IHMP (Ciampolini and Bianchi 2006)

Below are the practical details of the training protocol for implementing IHMP:

1. Suspend meals for up to 48 h
2. Locate physical sensations of hunger
3. Measure blood glucose concentrations
4. Mentally associate the physical sensation with the blood glucose concentrations
5. Begin with a meal of about 300 kcal
6. Repeat 1–5 increasing the meal size in proportion to the desired inter-meal interval
7. Repeat the above procedure for 2 weeks. At each appearance of physical hunger, compare the sensations and the measured blood glucose with the previous sensations and measurement

Initial Hunger (IH)

Hunger arousal was associated with low BG, arousal of gastric activity, and a decrease in bacterial counts in the duodenum (Ciampolini et al. 1996). This suggests arousal of hunger might be the best moment for the intake of food. Initial Hunger (IH) appeared after meal withdrawal as a biophysical, subjective sensation that coincided with a recognizable (constant) physiological state of diminishing energy availability. This physiological state recurred more than once per day and suggested spontaneous energy intake in the absence of visual, olfactory, or word food cues (Ciampolini et al. 1990, 2010; Ciampolini and Bianchi 2006; Ciampolini and Sifone 2011; Ciampolini 2012; Fisher and Birch 2002). Blood glucose marked the metabolic condition at which IH could be recognized. In one study on hunger training, individualized fasting blood glucose was used to indicate when a meal could begin; hunger training was a feasible technique and was successful in over 80% of preprandial instances over 2 weeks (Jospe et al. 2015).

In home diaries, lean adults and mothers of toddlers reported IH associated with a blood glucose that was low in 90% of occasions. This percentage decreased to 60% of meals in overweight adults and to 50% in overweight children. We encountered two obese diabetic subjects who never developed hunger after meal suspension. Moreover, hunger sensations became weak and irregular in those who were years over the age of 60.

Training in Implementing IHMP

Regarding those with diarrhea (mentioned above), after the first short period of treatment, the infants and adults were trained for 7 weeks under the researchers' supervision. The first step was suspending meals until the child gave signs of hunger (Ciampolini et al. 1990, 2012). The desire for food consisted in a change of mood from tedious or restless behavior to crying. Mothers assessed the children's IH before them showing food or a laid table. On the first demand, before serving the meal, mothers were asked both to memorize the manifestations of restlessness and to measure blood glucose. On other occasions, the same child moved around in search of food or showed what he/she wanted. The first meal was postponed from 0 to 48 h, but on average 2 h after the usual schedule. At the meals that followed the mothers repeated the learned strategies. In the interval, mothers encouraged children to expend energy by physical activities rather than offering food (dietary energy). Energy-dense food with more than 60 kcal/100 g was allowed initially in a limited amount but in a growing quantity after the demand for food and after eating fruit or vegetables.

The recommended portion of fruit or vegetables was 150 g of vegetables before lunch and dinner and 200 g of fruit before breakfast. The energy-dense food was calculated in such a way as to evoke a new demand before the time fixed for the subsequent meal. Nonstarchy vegetables were recommended in large amounts (in adults, 300 g per meal or half/one kg per day). This amount prevented fainting

in overweight subjects (Ciampolini and Lovell Smith 2014). After 3–14 days training, mothers had learned how to evaluate both the energy left in blood (from blood glucose) from the preceding meal and the food energy needed to cover the gap up to the time for the following meal.

The amount of food, its content, and the timing of the meal were adjusted for each meal and situation. Mothers administered food energy which correlated with physical activity. They also found a way to make their children manifest IH (demand for food) 3–4 times a day (Ciampolini et al. 1990, 2012, 2013b). Provision of nonstarchy vegetables attenuated feeding and hunger-related behavior when food administration ceased and when energy intake was sufficient to cover the interval of time between the last and before the next planned meal.

After some days of trials and errors, and occasionally, of irregular mealtimes, mothers succeeded in obtaining the children's demand/meal 3 or 4 times per day with an average error of less than 30 min in 90% of cases. Such alimentary rhythms are called Recognizing Hunger or Initial Hunger Meal Patterns (Ciampolini et al. 1990, 2012). No food category was prohibited, except for saturated and trans fats. Nonstarchy vegetables intake was positively correlated with the intensity of hunger arousal in the same meal and intended to produce a negative hunger intensity in the subsequent meal.

The Feeding Relationship with the Mother

In the Pediatric Gastroenterology Unit, mothers of diarrheic and malnourished infants were educated to improve the health of their children and to avoid adverse health effects in their adulthood. They were also encouraged to ensure that their children avoided meals with positive energy balance (Ciampolini 2012). This requires a continuous physical monitoring of the child by the mother and for the mother to be very consciously and subconsciously mindful of the child. It requires skill and attention and the mother has to be prepared for an unremitting fight against conditioned intake of food. Mothers were the main carers in these recovering children. Some nurses were very mindful of the clinical studies and collaborated accordingly. Only one father was of help among thousands of families. Husbands however helped in the creation of a calm and serene environment.

The Timing of Blood Glucose Measurements

Subjects avoided blood glucose measurements taken less than 1 h after consuming even a few grams of food, after changes in ambient temperature, after physical activity such as walking or cycling, under behavioral stress or fever. This is because blood glucose in these circumstances is higher than 1 h after cessation of the transient metabolic condition (Ciampolini and Bianchi 2006).

The Home Diary and Blood Glucose Measurements

Seven-day home diaries were used to document and record blood glucose measurements before the three main meals, the intake of dietary energy and vegetable intake, hours in bed and hours spent during physical and outdoor activities, and the presence or absence of preprandial sensations of epigastric hunger. Infants' mothers compiled the diaries before training, after 7 weeks and at the end of investigations.

In one study, 24 similar diarrheic infant-mother pairs of the same age were trained to IHMP and the resting metabolic rate (RMR) was measured by indirect calorimetry in 14 and total energy expenditure (TEE) by doubly labeled water in 10 infants. RMR decreased by 15.4%; TEE decreased by 15.5%, from 80.1 ± 6.9 to 67.8 ± 10.0 kcal/kg/d. In the synchronous 10 day food diaries, energy intake decreased by 17.9%, from 85.7 ± 15.3 to 70.3 ± 15.8 kcal/kg/d (pre/post $P < 0.001$) after intervention. No difference was found between TEE and energy intake at recruitment, at final assessments, and in the pre-/post-decreases. The height Z-score increased significantly, while increments in body weight were normal.

We always required an objective assessment, and after the first training days, we asked adults to write the presumed blood glucose before measurement. Adults in training were often surprised in being able to predict the measured blood glucose (Fig. 5).

Fourteen out of 46 trained subjects who were not hungry had BGs below 87 mg/dL, the maximum limit of blood glucose of those who were hungry (Fig. 6). These 14 subjects showed an average estimation error of 4.5 ± 3.1% of the measured blood

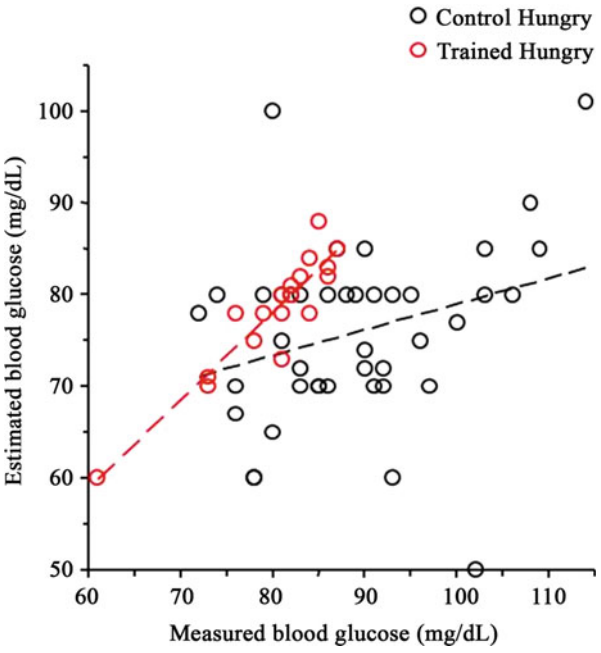

Fig. 5 Estimated versus measured blood glucose of subjects reporting to be hungry at the final laboratory investigative session. Notes: Hollow red circles, trained hungry subjects ($n = 18$); hollow black circles, control (untrained) hungry subjects ($n = 42$). Linear correlation was significant for the trained data (dashed red line; $r = 0.92$; $p = 0.0001$) but not for the control data (dashed black line; $r = 0.29$, $p = 0.06$). glucose, which did not significantly differ from the estimation error of the 18 trained subjects who were hungry (Ciampolini and Bianchi 2006).

Distinguishing Conditioned Hunger from Hunger After Meal Suspension

One question that needs to be addressed is whether adults learn to recognize children' hunger manifestations that arise after meal suspension from conditioned hunger sensations. Another question relates to the difference between the subjective blood glucose estimations and the biochemical measurements (Ciampolini and Bianchi 2006). To address this, we measured blood glucose by autoanalyzer (which has a 1% error). In our studies, adolescents have the lowest BG estimation error and people over 60 the highest. Given these observations, we later studied diarrheic infants and in adults who were less than 60 years old in the full confidence of the data derived from glucose measurements (Figs. 5 and 6).

Twenty-four diarrheic infants in their second year of life were trained to IHMP, and the resting metabolic rate (RMR) was measured by indirect calorimetry in

Table 1 Estimation of blood glucose by mothers on food demand from their infants in hospital just before blood sampling and autoanalyzer measurement: 54 infants demanded food before sampling, 16 infants did not demand food

Demanding food ($n = 54$)		With no food demand ($n = 16$)	
Estimation[a]	Measurement	Estimation	Measurement
77.4 ± 3.6[b]	74.6 ± 7.7	88.7 ± 5.9	96.3 ± 10.5[c]

14 and total energy expenditure (TEE) by doubly labeled water in 10 infants. The training consisted of blood glucose measurements at hunger arousal to validate the subjective hunger sensations and lasted 2 weeks. RMR decreased by 15.4%; TEE decreased by 15.5%, from 80.1 ± 6.9 to 67.8 ± 10.0 kcal/kg/d. In the synchronous 10 day food diaries, energy intake decreased by 17.9%, from 85.7 ± 15.3 to 70.3 ± 15.8 kcal/kg/d (pre/post $P < 0.001$) after intervention. No difference was found between TEE and energy intake at recruitment, at final assessments, and in the pre-/postdecreases.

In another study, 64 trained and 72 control subjects came to the hospital laboratory before breakfast following an overnight fast (Ciampolini and Bianchi 2006; Ciampolini et al. 2010; Ciampolini and Sifone 2011). All subjects declared current presence or absence of hunger and estimated blood glucose. A glucose autoanalyzer measured the actual blood glucose (Fig. 5 for adults, Table 1 for infants). The number of control adults (42 out of 72) stating hunger was significantly higher than the number of hungry trained subjects (18 out of 64) (Ciampolini and Bianchi 2006). All hungry adults described hunger sensations as gastric emptiness or gastric pangs. In the hungry trained group, the mean estimated blood glucose was 78.1 ± 6.7 and the mean measured value was 80.1 ± 6.3 mg/dL. This measured blood glucose was significantly lower than the measurements in hungry control subjects (89.2 ± 10.2 mg/dL) and in not-hungry subjects of both trained (90.0 ± 6.6 mg/dL) and control (90.6 ± 10.9 mg/dL) groups.

The absolute value of the difference between estimated and measured glucose (estimation error) in the hungry trained group (3.2 ± 2.4% of the measured value) was significantly lower than the one in the hungry control group (16.7 ± 11.0%). Linear regressions of the values in the hungry groups show that there was a significant correlation between estimated and measured blood glucose in the trained group ($r = 0.92$; $P = 0.0001$) but not in the control group ($r = 0.29$; $P = 0.06$). All these findings prove that control (untrained) adults do not reflect their biochemical condition when stating hunger and when estimating blood glucose.

In the hospital laboratory, control adults assessed their blood glucose and hunger state some minutes before having breakfast. Right after responding to questions about hunger, control adults focused on food and developed gastroduodenal Pavlovian reflexes. They described hunger as a tenuous, continuous state of hollow

stomach rather than intermittent sensations of wave bursts as physiological studies suggest. Their statements reflected a lack of experience in self-observations or did not have the ability to compare current sensations with past experiences. Humans tend to maintain constant blood glucose before meals (confidence interval ± 3.8 mg/dL around MBG in a week). Control adults, who asserted to be hungry, did not display blood glucose levels that were lower than their personal, habitual high BG levels (Ciampolini and Bianchi 2006; Ciampolini et al. 2010; Ciampolini and Sifone 2011). Only 8 out of 42 controls stating to be hungry had low blood glucose estimation errors (Ciampolini and Bianchi 2006, Fig. 5). Except for this minority, control adults reported conditioned hunger. All these differences were modest. The main difference consisted in the onset of hunger sensations: either before focusing on food (after meal suspension) or after focusing on food (conditioned). Low blood glucose values can confirm this distinction.

Not-Hungry Adults (Hunger Equivalents)

At the final investigative session, the trained and control adults that were not hungry significantly underestimated their glucose levels. Their estimation errors were, respectively, 4.8 ± 3.2 mg/dL and 16.1 ± 11.3 mg/dL in trained and control groups. The linear correlation between estimated and measured blood glucose was highly significant in the trained group but not significant in controls.

The difference between trained and control groups did not depend on gender, age, number of years at school, weight, or body mass index. Under 87 mg/dL, the estimation error was low in both trained and control groups apart the adult's statement on hunger (Fig. 6). In adults with values above 87 mg/dL of BG, the estimation error increased significantly. Despite them not being hungry, 12 out of 14 trained adults under 87 mg/dL and 3 out of 32 above 87 mg/dL described the slight sensations they used to estimate blood glucose concentrations. Thus, compared to controls, who did not report equivalents of hunger ($n = 30$), a significantly higher proportion out of the 46 not-hungry trained adults was able to report sensations different from gastric hunger. This was useful in estimating their blood glucoses, and this ability to report these sensations prevailed when their blood glucose was below 87 mg/dL. In their reports, 15 adults described either physical ($n = 3$) or mental weakness ($n = 10$) or abdominal changes in tension or movement ($n = 2$). Six out of 46 not-hungry trained adults, but none of the control adults, felt gastric IH before entering the hospital for the final session. However, the sensations faded while waiting for blood sampling. In the not-hungry adults' reports, the sensations of mental weakness consisted of difficulty in sustained mental concentration, impatience, irritability, drowsiness, gnawing sensation, loss of enthusiasm and effectiveness at mental work, or poor mood at their jobs.

The aforementioned mental sensations emerged alone or in addition to gastric or other sensations and ceased with the meal. Sensing impairment during physical activity was associated with heavy physical exercise outdoors and often signaled a change from a former sedentary life style. This sensation was used regularly to

indicate a meal signal with an increased requirement of high-energy-dense food for the following meal(s). The prevalence of these "hunger equivalents" ranged from an occasional occurrence to less than 15% of meals in phone reports. Two adults reported that they never sensed (gastric) hunger, but estimated blood glucose within 6% estimation error always by assessing mental or muscular weakness during training or during the final investigative session. In their reports, these adults consumed meals at blood glucose estimation between 78 and 85 mg/dL. Also Caudwell et al. (2013) found weakness and low RMR as signals for starting meals.

We recently encountered two obese adults who denied any hunger arousal after 48 h fasting. The two adults were diabetic type 2. They decreased their body weight by more than 15% and before dinner BG decreased to 75.3 mg/dL. This value is inside Low BGs in the Fig. 5. During hunger weakness, blood glucose, blood glucose estimation error, and RMR have low values (Ciampolini and Bianchi 2006; Ciampolini et al. 2010; Ciampolini and Sifone 2011; Caudwell et al. 2013). These characteristics suggest that hunger weakness is a reliable signal for intake just like hunger pangs.

One out of 89 trained adults (Ciampolini and Sifone 2011) reported not having gastric sensations at all, even long after consuming a meal. We suggested to the subject that meal should start after the estimation of blood glucose decrease to lower than 81.8 mg/dL. The adult endured physical weakness for 2 h before meal consumption, blood glucose fell from 92.5 ± 5.1 mg/dL to 80.7 ± 5.7 mg/dL, and body weight from 74.5 to 67.4 kg after 36 days. The adult coped with an open air heavy job during a cold winter. At recruitment, he was 189.5 cm tall with a BMI = 20.75. His energy intake showed a decrease from 3613 ± 615 kcal/day to 1817 ± 394 kcal/day. We suggested to this adult to use the sensation of physical weakness as IH and as an appropriate signal for meal onset. In the following 40 days, the adult increased dietary energy intake to 2380 ± 459 kcal/day, blood glucose to 85.6 ± 4.7, and weight to 70.95 kg. In the meantime, complaints reported at recruitment (abdominal pain and dermatitis) were ameliorated. This "case" suggests the need for higher blood glucose than 76.6 ± 3.7 mg/dL for subjects engaged in intense, daylong physical exercise (Ciampolini and Sifone 2011).

Overall it seems, trained subjects are able to recognize hunger by gastric sensations or by body or mental weakness. The first signal is a threshold and is quite definite. The second is gradual and unspecific.

Adapting Energy Intake to Energy Expenditure

In Table 2, we report final values in 27 adults who had a high MBG out of 89 who practiced IHMP for 5 months (Ciampolini and Sifone 2011). Six out of 27 were engaged in heavy manual work in a cold, open air climate. They asserted to comply accurately with IHMP and their high insulin sensitivity at GTT supported their assertions. Heavy physical activity in a cold climate may require high blood glucose and impose IH arousal when blood glucose is high for sedentary people. In our investigations (Figs. 5 and 6), intestinal functions and xylose absorption increased

Table 2 Heavy outdoor manual work (6 High BG) versus a sedentary lifestyle in 21 High BG of 27 (out of 89) adults who failed to reach Low BG (76.6 ± 3.7 mg/dL) at study end

	6 High BG	21 High BG ab
Final mean blood glucose (mg/dL)	86.4 ± 4.0	87.1 ± 5.3
Final insulin AUC (mU/L/3 h)	124 ± 26	207 ± 99 c
Final blood glucose AUC (mg/dL/3 h)	536 ± 56	601 ± 82 d
Insulin sensitivity index	11.4 ± 2.9	6.68 ± 4.0 e
Beta cell function index	1.29 ± 0.66	1.43 ± 1.22

[a]Six High BG subjects reported doing heavy work all day in outdoor environment during cold weather and reported accurate compliance with IHMP. No significant differences in the five parameters from recruitment. At recruitment, MBG was 86.9 ± 5.3 mg/dL in 27 High BG subjects
[b]The 21 High BG subjects included 15 that were Low BG after 7 weeks training (diary assessment) and six who had higher MBG than 100 mg/dL at recruitment

their rate during cold exposure in association with an increase in resting metabolic rate (Ciampolini 1974, 1976).

Adjusting energy intake according to hunger delay or anticipation is useful to maintain a steady, optimal blood glucose level. IHMP consists of a meal by meal exhaustion of nutrients in the blood with the last meal. This prevents absorption slowdowns and avoids slow intestinal absorption, bacterial growth, immune stimulation, and relapses in diarrhea.

In the first decade of our studies in a pediatric ward, we did not measure blood glucose before meals and we limited children's intake by administering food only on demand (See also: Fisher and Birch 2002). The limit in intake was not biochemical (Ciampolini et al. 1990, 2010; Ciampolini and Sifone 2011; Ciampolini et al. 2013a; Ciampolini and Bianchi 2006; Ciampolini 2012). In the occurrence of a discrepancy between hunger arousal and high blood glucose, we previously suggested mothers (and adults for themselves) to let the hunger manifestations prevail (IH arousal and IHMP). The infants did not suffer endured hunger as a consequence.

Conditioned and Demanded Meals and Validation of Diary Energy Intake

In overweight people, the only imposition they had was to approximate meal energy intake to prevent hunger arousal before the planned subsequent intake of food. We measured body weight at the beginning and the end of the 7 day diary. A decrease in body weight suggested an underreporting in overweight people who wanted to lose weight (Ciampolini et al. 2010). When subjects wanted a treatment for bowel disorders, we found no weight loss during the weekly diary, i.e., diaries of these subjects showed no underreporting (Ciampolini et al. 2010).

We also studied 24 infants with functional disorders of the bowel with regard to: (a) energy intake by a 10-day food diary; (b) RMR (indirect calorimetry) in 14 toddlers, and (c) TEE by doubly labeled water in 10 toddlers (Ciampolini et al. 2013a). Their blood parameters, anthropometry, and number of days with diarrhea were assessed before training and 50 days after training. Energy intake decreased from 85.7 ± 15.3 to 70.3 ± 15.8 kcal/kg/d (−17.9%). and TEE decreased from 80.1 ± 6.9 to 67.8 ± 10.0 kcal/kg/d (−15.5%). We found no statistical difference between intake and expenditure at recruitment, after training and in the decrease that occurred during IHMP. Dietary energy intake decreased more than expenditure (although the difference was not significant). Also fecal energy loss decreased during IHMP. This decrease in fecal energy compensated the modest difference between intake and expenditure (Ciampolini et al. 2001). RMR decreased from 58.6 ± 7.8 to 49.0 ± 9.1 kcal/kg/d (−15.4%). The height Z-score increased significantly, while weight growth was normal.

IHMP and Malnutrition

MBG is positively associated with insulin resistance, depressing intestinal functions, perturbing the microbiome, and developing an overall subclinical state of inflammation. In turn, this state produces functional diseases like asthma, arthritis, bowel disorders, and a long-term evolution to metabolic, vascular, and malignant risks. Meals with excessive energy intake are signaled by high BG before the following meal. The consequent energy availability becomes lower during IHMP than during a conditioned meal pattern. A meal pattern dictated by IH arousals lowers energy intake, BG, and insulin resistance; it maintains body weight in lean subjects and prevents risks.

A controlled study was carried out in 9 undernourished infants. Demanded meals were associated with low preprandial BG, significantly lower energy intake, prompt recovery from diarrhea, and slow recovery of lean body mass in 2 years.

Another study documented the recovery of a 12 years old boy from severe malnutrition by implementing IHMP. The MBG decreased from 98.9 ± 15.1 mg/dL to 78. 6 ± 2.9 mg/dL. This boy grew from a Gomez index of 56% (BMI 10.7) at recruitment to an index of 80% (BMI 19.6) at the age of 20. Undernourished people often have insulin resistance that impairs the passage of nutrients absorbed from blood into lean body tissues. These facts and observations suggest together that IHMP may prevent alterations of the microbiome and to avoid a deficiency in immune function from birth onwards.

Dictionary of Terms

- High Blood Glucose. This is a blood glucose of over 82 mg/dL.
- Initial Hunger: This consists of gastric pangs or physical weakness **that arise after meal suspension** and that are associated with low blood glucose.

- Initial Hunger Meal Pattern (IHMP): Energy intake is adjusted to three arousals of initial hunger per day.
- Low Blood Glucose is a blood glucose below 82 mg/dL.
- MBG = mean blood glucose: mean of BG measurements **before meals** in a week.
- Normal body weight, BMI under 25.
- Overweight = BMI > 25.
- BMI = Body weight in kg divided by the height square in meters.

Summary Points

- Initial hunger before meals protects both undernourished and overweight subjects. This may be related to the fact that more than half immune cells of the body reside in the small intestinal mucosa.
- In infancy or sedentary adulthood, humans can learn to recognize initial hunger arousal at the same blood glucose, 76.6 ± 3.7 mg/dL.
- This means that initial hunger corresponds to a reproducible metabolic condition that can be identified and recognized by humans.
- Initial hunger arises between 0 and 48 h after meals in healthy children and healthy adults but not in obese diabetics.
- An initial hunger meal pattern (IHMP) consists of initial hunger arousal three times a day. Practicing IHMP is associated with increased insulin sensitivity, lower energy intake (−18%), lower mean blood glucose (MBG) (−15 to −20%), lower resting metabolic rate (RMR)(−15%), and lower total energy expenditure (TEE)(−16%).
- The individual regression toward an even energy balance under IHMP is proportionate to the value at recruitment.
- About a third of healthy people show at recruitment (before any training) the same low MBG, low RMR, and associated insulin sensitivity that are gained by people after training IHMP.

Abstract

The observation that the demand for a commodity decreases as its unit price increases is called demand elasticity. Applied to food, and to rodents in an operant behavior situation, we call this cost-based anorexia. We review evidence that rats and mice show cost-based anorexia when food is available in either 23-h (continuous access) protocols or as discrete food opportunities. The decrease in food intake of rats at higher unit food price is associated with sustained high operant response rates that, in the food opportunity protocol, occupy the entire time available. In contrast, mice do not show sustained high response rates and, in the food opportunity protocol, show rapid decline of food intake within a meal even when intake is very low and weight loss rapid. Differential price experiments, either for the same food at different times or for different foods, show that

Introduction

Famine, starvation, and/or malnutrition have been commonplace throughout evolution of most species, and it is only in the last ~10,000 years that organized agriculture has made spectacular strides in alleviating food insecurity. But these measures do not completely insulate humans from fluctuating food availability, such as those due to environmental extremes and climate change, or increased food demand by a burgeoning global population. A mismatch of supply and demand has been used historically as an agent of subjugation, and today's global market or economic forces represent centralized control of power and wealth. Less wealthy nations, or individuals of lower socioeconomic status within wealthy nations, are differentially vulnerable to economic exploitation of food resources in amount and quality (Gendron and Audet 2012). This chapter will focus on the investigation of the way in which economic or cost variables (effectively, commoditization) affect food consumption in highly controlled laboratory studies using rats and mice. Understanding these processes at a fundamental level may prove to be useful in interpreting and ameliorating food-related problems in humans, ranging from food insecurity to disorders such as anorexia nervosa (AN). Before addressing these issues, which appear to represent a breakdown of physiological regulation, it is appropriate to give a synopsis of such physiological approaches.

Homeostasis and Feeding Behavior

Homeostatic theories posit that in a system with a constantly fluctuating variable, such as energy balance (the difference between intakes and expenditures), the fluctuations will be tightly regulated in order to maintain a nearly constant

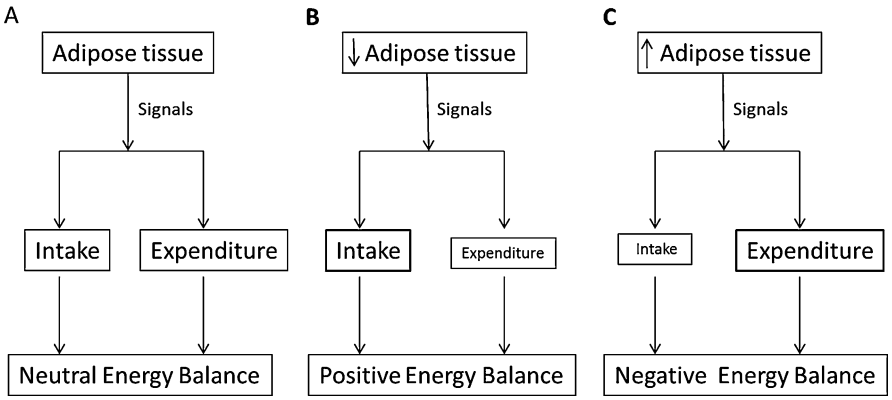

Fig. 1 Simplified diagram of homeostatic theory for energy balance of an organism. Each panel represents the sequence of events that theoretically result in (**a**) stable body weight, (**b**) body weight loss, (**c**) body weight gain

equilibrium. This model requires the existence of sensor(s) that monitor the fluctuations and activate appropriate mechanisms when suprathreshold deviations occur. Cannon's (1929) concept of homeostasis was extended to the field of feeding behavior to explain maintenance of a stable body weight. Imbalances in energy intake and expenditure result in changes in body weight. One instantiation of homeostasis uses a set point concept, a reference against which the current state of the organism is compared (Bolles 1980; Carpenter 2004). In this model, deviations from a set point (in the hypothetical case of body weight this might be mediated via a marker of body fat mass) would trigger an error which activates the system to correct the deviation (Fig. 1).

The increase in the incidence of obesity in humans over the last several decades provides evidence that any set point mechanism for body mass, or a derivative, is weak: internal signaling mechanisms are not strong enough to control feeding behavior in the face of an abundance of relatively palatable food. In addition to palatability, it is evident that environmental factors, in particular availability and cost, have to be incorporated in order to truly understand how the brain organizes food acquisition and maintenance of adequate energy balance. Consistent with this view, a multifactorial analysis of human feeding (De Castro 2010) posited both compensated and uncompensated factors, each of which could be ascribed weighting factors in terms of their actual effect on food intake. The compensated factors act in a way predicted by homeostasis, and uncompensated factors do not.

Foraging, Cost, and Convenience

In the natural environment, animals including humans forage for food. Optimal foraging theory posits that, for a given food environment, animals will maximize their gross energy gain which is the difference between the metabolic energy yield of

the food and the cost of obtaining it (Schoener 1971). Much evidence supports this general proposition, although there will be exceptions such as when a particular constituent (e.g., protein) may be more important than actual energy yield per se (DiBattista 1991). In animals, cost is measured in terms of physical exertion and time. For humans, we must add token currency (money). The primordial neurobiological algebra that maximizes gross energy gain is exploited by businesses in the form of convenience foods and large packages or portions, which are equivalent to the ecologically improbable condition of abundant food or "constant-glut" (McNamara et al. 2015).

In the animal laboratory setting, most of these variables can be controlled. Food availability and/or demand can be experimentally regulated in quality (e.g., nutritional value, energy density, or palatability), quantity (e.g., ration amount, duration of access), or both. Food may either be delivered at no cost to the animal (by far the most common procedure, although of questionable ecological significance) or the animal is required to forage in a controlled fashion. Foraging cost may be imposed by requiring repeated behavioral (operant) responses or overcoming an obstacle. Further, cost may be imposed either at the level of access in which performing the required task results in free access to a relatively large amount of food, or consumption in which each unit or morsel of food has a task requirement, or both. To simplify foraging studies in the laboratory, most have used a homogeneous nutritionally complete food (e.g., grain-based chow pellets), and this will be assumed in the following sections unless explicitly noted.

Collier and his colleagues were the first to show, in rats, that access (or procurement) cost has a markedly different effect on food demand than consummatory (or unit) cost (Collier 2005; Collier et al. 1972). In particular, they found that access cost altered the episodic organization of food intake but not the amount eaten per day. As access cost increased, rats initiated fewer sustained eating episodes or meals but with a compensatory increase in meal size. In contrast, consummatory cost altered amount eaten per day but not the pattern. As unit cost increased, rats ate less per day. This result generates an economic demand curve, in which consumption of a commodity decreases as its unit price increases. The curvature of the function is called elasticity. Essential commodities like food are expected to have relatively flat or inelastic functions compared with nonessential items (Hursh 1984; Hursh and Silberberg 2008).

Cost-Based Anorexia (CBA): Continuous Access

A result from our laboratory using young adult Sprague-Dawley rats pressing a lever for 45-mg pellets and C57BL/6 mice nose poking for 20-mg pellets in 23-h daily sessions is shown in Fig. 2 (compiled from Rowland et al. 2015). Each fixed unit price (FUP, in behavioral responses per pellet) was enforced for four consecutive days after which the price was increased. The left panel of Fig. 2 shows mean daily food intakes, expressed as % of intake at the lowest cost (actual intakes: 530 pellets or 23.8 g in rats and 200 pellets or 4.0 g in mice). The right panel of Fig. 2 shows the

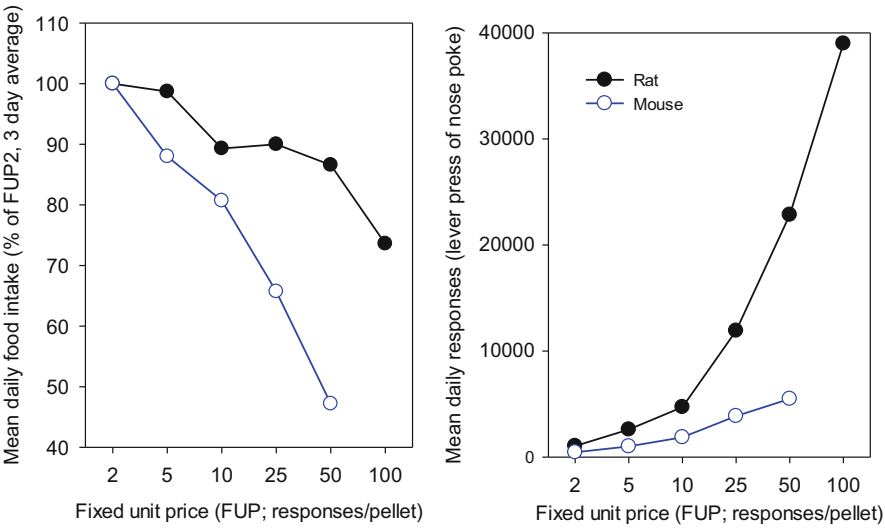

Fig. 2 Relative daily food intake or demand, and associated behavioral responses, in rats and mice as a function of the price of each pellet of food. *Left panel* shows demand curves as a function of unit price (*FUP*; categorical scale) for food pellets in groups of 6–8 male Sprague-Dawley rats (*circles*) and C57BL/6 mice (*triangles*) with 23 h per day availability to earn food. Daily intakes of 45-mg pellets (rats) or 20-mg pellets (mice) are 3-day averages shown as % of the intake at FUP2 for that group. *Right panel* shows the corresponding mean number of lever presses (rats) or nose pokes (mice) per 23-h session

corresponding mean numbers of responses emitted per day. Rats and mice generated classic demand curves, but it is evident that the elasticity in mice was higher than in rats. In fact, almost half the mice did not complete FUP 50 due to weight loss >15% (our criterion for removal from study) whereas all rats completed FUP 50 and the next highest price step (FUP 100). Under these conditions, the number of food pellets earned per day by rats is about twice the number in mice and this led us to predict that mice should show less elasticity than rats. The observed result thus was contrary to our prediction. The associated number of responses (not shown) further illustrated this unexpected species difference: the maximum daily response output by mice was only ~30% of that in rats. In another study (Atalayer and Rowland 2009), we found that lever pressing and nose poking produced identical demand curves in mice, so the difference in response type cannot explain the large species difference in Fig. 2.

Other data (Bauman 1991) show that the maximum lever press rates of rats are of the order of two per second and, at that rate, they would have taken >5 h to emit the ~40,000 daily responses at FUP 100. Given that most of the eating occurred during the artificial 12-h night, and that actual sustained rates will likely be below the maximum, rats at FUP 100 may have spent most of the night responding. To address this question, the time of food delivery was recorded throughout the 23-h sessions. At low FUP, rats acquired food in relatively discrete episodes or meals,

most of which were nocturnal, and comparable to rat meal patterns previously described without cost imposed (Le Magnen and Tallon 1966). As FUP increased, the rate of eating slowed because of the interpellet response requirement, so meals took longer and much of the night. However, meals were still evident although the number taken per day decreased as FUP increased while their average size remained constant (Rowland et al. 2015).

The corresponding calculation in mice (~6,000 responses) would predict ~2-h per day spent in responding, a relatively small fraction of the nychthemeron. Examination of response and pellet distributions throughout the 23-h session revealed a pattern completely different from rats. In particular, the first 6–8 h of the night was characterized by low rates of eating but without apparent segmentation into meals – the mice appeared to be grazing. This is consistent with findings by others (Goulding et al. 2008) that C57BL/6 mice show almost continuous locomotor activity interrupted by occasional eating during this time, a result we have subsequently corroborated in our test protocol using photobeams to measure locomotor activity. During the latter half of the night, activity was more episodic (probably with sleep episodes) and eating was correspondingly more episodic. During the daytime, both activity and amount eaten were low and episodic. There was relatively little change in this basic pattern as FUP increased. Thus, the reason that mice emit fewer responses than rats seems to be due, in part, to high levels of locomotor activity that may preclude sustained, multipellet bouts of eating. Consistent with this reasoning of a direct relationship between level of spontaneous locomotion and meal structure, Goulding et al. (2008) showed that an obese strain of mice with low spontaneous locomotor activity was observed to engage in meal-like episodes throughout the night. We (Rowland et al. 2015) have identified a somewhat more episodic pattern of feeding in an outbred strain (CD-1) of mice compared with C57BL/6, but have not compared spontaneous locomotion in these two or other strains (Kelly et al. 2011; Loos et al. 2014).

In part to amplify the time limitation on responding, as well as to emulate typical human eating patterns, we have conducted (see next section) parallel studies in which food can only be earned at discrete times or food opportunities (FOs). These are functionally equivalent to meals.

Cost-Based Anorexia (CBA): Feeding Opportunity Protocol

In our initial report of feeding opportunity (FO) protocols (Atalayer and Rowland 2012), mice were given either 4, 8, or 16 FOs per 23-h session, mostly at night, and with reciprocal duration of each FO (i.e., 40, 20, or 10 min) so that the total availability of food was always 160 min. In the 16 and 8 FO protocols, we found that mice did not eat at several FOs. All of our subsequent work in both rats and mice thus has used 4 FOs, each of 40 min duration. In both rats (unpublished data) and mice (Atalayer and Rowland 2012; Rowland et al. 2016), daily food intakes were 80–90% of those in the 23-h protocols at each corresponding FUP, so the shapes of

the daily food demand curves in 4 FO protocols are similar to those for continuous access shown in Fig. 2.

In one study, using Sprague-Dawley rats, the FOs started at 1800, 2200, 0200, and 0600 (which we will refer to ordinally as FO 1, 2, 3, and 4), with lights off 1800–0600-h. At each FUP, intake at FO 2 (midnight) was slightly greater than at FOs 1 (start night) or 3 (late night). Intake at FO 4 (dawn) was much lower even at FUP 100 when total daily intake was only ~50% of ad lib levels. Thus, at these higher FUPs, even if responses during FOs 1–3 were limited by time or fatigue (see below) the animals still had the opportunity of making up at least some of the food deficit and so obtund their rapid weight loss by eating more during FO 4, but they did not.

Assuming a ceiling response rate of ~two responses per second, then compressing the responses into 40-min episodes has the potential to limit intake at high FUP. Thus, mean numbers of pellets earned in successive 10-min segments of each FO were examined. Those for the largest meal (FO 2) are shown in Fig. 3 (left panel) for low and high FUPs (5 and 50); data for FOs 1 and 3 (not shown) were essentially identical. At low FUP, intake was high for the first ~10 min of the 40 min FO and declined monotonically thereafter, with some individuals stopping completely. At higher FUP, a high rate of responding (average 2.3 responses/sec at FUP 50) was maintained throughout the 40 min (Fig. 3). Thus, neither fatigue nor satiation from

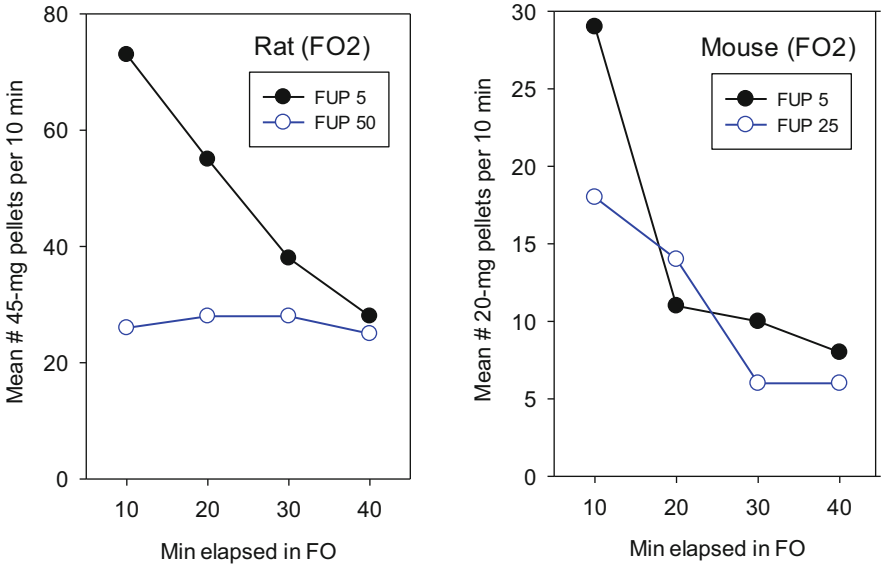

Fig. 3 Pellets earned in successive 10-min segments of a 40-min feeding opportunity (*FO*). By rats and mice. Left panel shows the mean number of 45-mg pellets earned by male rats (n=6) in successive 10-min segments of 40-min feeding opportunity #2 (FO 2) in the 4 FO protocol for the last 3 days at FUP 5 and FUP 50. Right panel shows mean number of 20-mg pellets earned by male mice (n=6) in successive 10-min segments during FO 2 of a similar protocol at FUP 5 and FUP 25

food ingested at the start of the FO were evident within the 40 min. A similarly flat function was observed in these animals at twice the FUP (100) when the ceiling response rate allowed only about half the intake in each 10-min segment. Even at these high FUPs at which intakes at FOs 1–3 were clearly limited by ceiling response rates, FO 4 (dawn) remained relatively small despite body weight loss approaching 10%.

In the 4 FO protocol, as with continuous food access, some aspects of mouse behavior differed from rats (Fig. 3, right panel). In general, as in rats, the highest intakes in mice were at FOs 1–3, and much smaller at FO 4, although modulating factors to this pattern will be discussed later. At low FUP (5), the temporal evolution of responding and intake at FO 2 (usually the largest) were similar to those in rats, with a marked reduction in pellets earned in successive 10-min segments (Fig. 3, right panel; full analysis in Rowland et al. 2016). In contrast, the maximum number of pellets obtained in the first 10 min by mice was only ~35% of the corresponding number in rats at corresponding FUPs, and the response rate was correspondingly lower. At FUP 25 (the highest ratio analyzed because, as noted before, almost half the mice did not complete higher FUPs due to excessive body weight loss) the temporal evolution of responding and intake was similar to that at lower FUP (Fig. 3, right panel). Unlike rats at higher FUP (Fig. 3, left panel), mice did not maintain their higher initial rate of responding throughout the 40-min FO, exhibiting apparent satiation even when intake early in the FO was relatively low due to the cost or response requirement. Had the mice maintained their initial rate throughout most of the 40 min then intake at FUP 25 would have been at least as high as at FUP 5 and instead showed a decline which, if the study had been continued longer, would have resulted in a self-destructive level of inanition.

Compared with rats, mice have a smaller body mass and higher surface-to-volume ratio. Thus, a given % change in food intake has a much larger effect on body weight (as % of initial) of mice than rats. By the end of the FUP 100 segment in the 4 FO protocol, rats had lost an average of 22 g body weight (~7% of initial weights) with most of that loss during FUP 50 and 100 segments. In mice, weight loss was ~8% of initial at the end of FUP 25, but 50% of animals did not complete FUP 50 due to weight loss >15% (Rowland et al. 2016). Importantly, during rapid weight loss at FUP 25 or 50, intake did not change across successive days. Individuals that ate the least day after day were the first to be removed due to weight loss. For completeness, we should note that while sex differences are sometimes evident (Minervini et al. 2015; Rowland et al. 2016), they have been omitted to simplify the foregoing section since they do not alter the main conclusions.

These data leave us with two unexpected observations in mice. First, they show satiation within a FO even when total intake is insufficient to maintain body weight. Second, within higher FUP segments, food intake does not increase while body weight decreases across days in either 23-h or 4 FO protocols. It is as if the combination of small initial amounts of food intake with the prospect of working moderately hard to obtain more food triggered satiation-like behavior even in the face of weight loss that would have proven terminal had it been allowed to go that far. We believe that this phenomenon of CBA has several of the characteristics of the

restrictive form of AN, namely, low or slow intake and premature but unforced satiation in the face of continued weight loss (Bergh et al. 2013). This is substantially different from the cause of CBA in rats which is due mainly to ceiling response rates. However, in both rats and mice, the lower intake at FO 4 cannot be so easily understood. One possibility is that of a strong circadian modulation of eating.

Effect of Zeitgeber and Differential Cost on Food Demand in Mice

In the foregoing section using the 4 FO protocol, we described how intake at FO 4, which occurred at or near the time of lights on ("dawn"), was less than half the intake at the first three (nocturnal) FOs (Atalayer and Rowland 2012; Rowland et al. 2016). It is possible that light and/or an endogenous circadian oscillator has an important inhibitory effect at FO 4.

We first tested this hypothesis by examining the effect of different timing of the FOs relative to the Zeitgeber (Minaya et al. 2016). This design used 4-h phase advanced and phase delayed groups and confirmed that light and/or an endogenous oscillator did appear to have an inhibitory effect. The most robust finding was that the characteristic variation in FO size, with intake at the smallest FO only ~30% of that at the largest FO, remained in all groups and at each of FUPs 5, 10, and 25.

It is thus possible that light and/or phase of an endogenous oscillator effectively increases the cost of food acquisition, and this is reflected in one or more small FOs; in a natural environment, such a strategy may improve inclusive fitness by foraging mainly at time(s) of low predation risk. We reasoned that by altering the price of food at different times, it may be possible to gain a better understanding of the factors causing variation in FO size and, indirectly, in satiation mechanism. We devised an economic choice protocol where animals were given access to constant costly (CC) and intermittent inexpensive (II) food to investigate whether the timing of cheap food relative to the Zeitgeber affects this decision (Minaya et al. 2016). Access to II 45-mg food pellets (FUP 5) was restricted to four 15 min opportunities that paralleled the timing of 4 FOs described above. In subsequent segments of the study using the same mice, the timing of access to II food was either advanced or delayed by 4 h such that the first FO started either 4 h prior to or 4 h after lights out. CC 45-mg food pellets (FUP 100) were available at all other times in the 23-h session, similar to the continuous access protocols discussed previously (note the larger pellet size and higher FUP).

In spite of the 20-fold difference in FUP between CC and II food, mice consumed substantial amounts from each source on a daily basis (Table 1). In the first segment, when the first 3 FOs were during the night and FO 4 was early in the day, as described before, the intake at the first 3 FOs was high and the 4th FO was very small (<20% the size). In the second segment, the first FO (in the late day) was completely omitted by all the mice, and the three nocturnal FOs were relatively large. In the third segment, the last two FOs (in the first half of the day) were very small, while the first two (at night) were large. In this latter condition, with two small II FOs, the relative amount of food taken from the CC lever was some 30% higher than in the other two

Table 1 Daily food intakes of mice from continuous costly (*CC*) and intermittent inexpensive (*II*) sources as the timing of episodes changed relative to Zeitgeber

	Total intake from CC	Total intake from II	Intake during 15 min II episodes starting at					
			D9	N1	N5	N9	D1	D5
Part 1	1.6	1.8	x	0.5	0.6	0.6	0.1	x
Part 2	1.8	1.7	0	0.4	0.6	0.6	x	x
Part 3	2.3	1.3	x	x	0.6	0.6	0.1	0

CC was fixed unit price (*FUP*) 100; II was FUP 5. Mean intakes have been rounded to the nearest 0.1 g and are for IIs starting in the ninth hour of daylight (*D9*), the first hour of the night (*N1*), the fifth hour of the night (*N5*), etc. x indicates the absence of a programmed II at that time. 0 indicates that none of the 10 mice ate in that interval (Data compiled from Table 2 and Fig. 4 of Minaya et al. (2016))

segments. Mice thus chose to expend significantly more effort to obtain expensive food and thereby maintain total intake, as more of the cheap food opportunities shifted to daytime. Further, almost all of the CC food obtained was nocturnal, and particularly during the first half of the night (Minaya et al. 2016). These data suggest that light exerts a more potent suppressive effect than price on food intake in mice. In a similar study in rats (unpublished data) we again found a difference from mice: rats ate almost all of their daily food during II opportunities.

The above study in mice did not examine the effect of changes in either the ratio of CC to II pricing (20:1) or sequential increases in both (e.g., to FUP 10 and 200). Instead, we examined the effect of diet palatability that would be expected to affect its intrinsic reward value relative to cost.

Effect of Differential Pricing on Food Demand for a Preferred Diet

This experiment in C57BL/6 mice used continuous 23-h access and a two lever arrangement. Presses on one lever delivered a highly palatable, preferred diet (either 55% dextrose or 35% fat in the form of 45-mg pellets) while presses on the other lever delivered a less preferred, grain-based diet, both delivered to a common, centrally located trough. Initially, both diets were available at the same FUP. Subsequently, FUP for the preferred diet was doubled every 4 days while the FUP of the grain-based diet was maintained constant and low.

As expected, when both foods were offered at the same low cost, intake of the more palatable diet was much greater than that of the bland grain-based food (Fig. 4). As the relative cost of the more palatable diet increased, animals took progressively less while intake of the cheaper grain-based alternative increased. The indifference point at which 50% of daily intake was from each diet was when the relative cost was, on average, five-to tenfold higher for these particular palatable diets. Both initial preference for and the indifference ratio were slightly higher for the dextrose compared with the fat diet. There was considerable individual variability in the indifference point, with some animals reaching it with only a doubling of relative price while

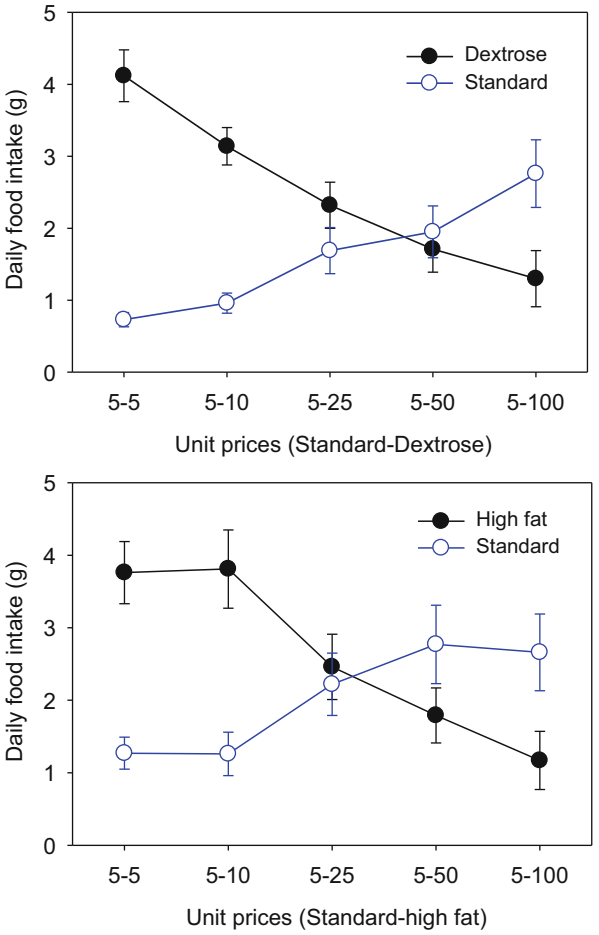

Fig. 4 Daily food intakes of mice earning a palatable diet available concurrently with standard grain-based pellets at various relative prices. Shown are M+SE for 12 C57Bl/6 mice. The *top panel* shows a choice between 55% dextrose pellets and standard diet, while the *bottom panel* shows a choice between 35% fat pellets and standard diet (Minaya and Rowland unpublished data)

others maintained preference for the palatable diet even at the highest cost. This might reflect individual differences in relative palatability, in cost sensitivity, or a combination. Although not emphasized previously, we routinely observe individual differences in demand elasticity in both 23-h and 4 FO protocols in mice using a single standard food (Rowland et al. 2015). These individual differences, as well as strain differences, remain an aspect in need of systematic investigation especially as they may relate to vulnerability of humans to AN and other eating disorders.

CBA Compared with ABA

It is relevant to compare, briefly, the current CBA protocol with the much-used model of activity-based anorexia (ABA). ABA combines severely restricted time of access to food (typically, a single 2-h access per day but without cost) with access to

running wheels which uniquely are reinforcing and increase energy expenditure (Klenotich and Dulawa 2012; Koh et al. 2000). Rats or mice without wheels eat sufficient food on this schedule to survive, albeit at reduced body weight. Restricted animals with additional wheel access do not increase their intake above this level, and are constantly in negative energy balance to the point of death, or a more humane end-point criterion of weight loss (Gutierrez 2013; Méquinion et al. 2015). The protocol has been criticized because fatal levels of anorexia and weight loss occur only in a narrow range of conditions (Boakes and Dwyer 1997; Koh et al. 2000; Wu et al. 2014), and it certainly does not emulate human AN in which food is easily available but is refused. Further, compared with our 4 FO protocol, the restriction of food to a single 2-h epoch is physiologically more challenging. If we suppose that a daily intake of 50% ad lib is a minimum compatible with survival, mice in the 4 FO protocol would need to eat ~0.5 g at each meal, which is clearly feasible (Fig 2, Table 1). In contrast, in the ABA protocol even no-wheel mice would need to eat 2 g within 2 h, which may be close to the stomach capacity (~1 cc) and/or emptying rate (half-life for a resin-based gavage = 74 min; Schwarz et al. 2002). CBA protocols thus have some degree of apparent and ultimately maladaptive choice by mice that is not obviously constrained by gastric capacity. Instead, hormonal changes that occur during the earliest stages of the FO are a candidate mechanism by which this early satiation occurs in consummatory cost protocols in mice. Identification of these or other (e.g., genetic) factors that exaggerate CBA may lead to new insights in the treatment of AN.

Policies and Protocols

Use of animals described in this Chapter was approved by the University of Florida Animal Care and Use Committee and is consistent with guidelines of the National Research Council. Animals were singly housed in standard operant behavior test chambers in daily sessions lasting 23 h at ambient temperature 23 °C and a 12:12 light cycle. They were removed to holding cages for 1 h per day while the test chambers were cleaned and serviced. The animals earned all of their food during sessions (closed economy) using the specific cost protocols mentioned in the text.

Dictionary of Terms

- **Anorexia nervosa** – A psychiatric disorder of eating in which patients excessively restrict food intake and lose excessive body weight, yet believe themselves to be heavier (distorted body image)
- **C57Bl/6** – A widely used pigmented (black coat) strain of mice; particularly susceptible to obesity when fed high fat diet and is also a background strain for most transgenic manipulations.

- **Consummatory cost** – A cost (money, time, effort) that applies to each unit of a commodity acquired; in the case of food this may refer to small units that are fractions of a meal or serving.
- **Cost-based anorexia** – Decrease in daily food intake (of animals) as consummatory cost increases, with concomitant body weight loss to dangerously low levels.
- **Demand** – In economic terms, as used herein, demand refers to the quantity of a commodity consumed in a discrete unit of time – such as number of food pellets per day.
- **Homeostasis** – For a given physiological variable, the ensemble of mechanisms within the body of a living organism which actively regulate that variable such that it remains relatively constant.
- **Nose poke response** – Rodents move their snout a small distance (<1 cm) into and out of a recess containing a photobeam or other movement sensor, so generating a (computer-acquired) record of a behavioral response.
- **Operant behavior** – Behavioral responses (either nose pokes or lever presses) on a device that cause the delivery of a reinforcer (food pellet) according to a programmed requirement.
- **Palatability** – The pleasure or hedonic reward experienced when consuming food (or fluid); unlike taste or flavor, palatability changes with the physiological state of an organism and in particular decreases during the course of a meal of that particular commodity.
- **Satiation** – The process(es) that cause interaction with a commodity to spontaneously wane or cease, for example, cessation of eating after a certain amount has been consumed.
- **Sprague-Dawley** – A widely used albino outbred strain of rat.
- **Zeitgeber** – Regular environmental cue(s), most usually the change in illumination which occurs every 24 h, that cause the internal circadian clock(s) to reset or entrain to the external world.

Summary Points

- We introduce cost-based anorexia (CBA), a new animal model of anorexia nervosa.
- Rats and mice decrease daily food intake as the cost (number of behavioral responses) per food unit increases.
- Food intake decreases despite ongoing and significant body weight loss.
- This phenomenon is exaggerated when food is available intermittently, in food opportunities (FOs) which are functionally similar to meals, compared with 23-h (continuous) availability.
- In rats, the decrease of intake occurs when responding occurs at maximum rates and occupies a substantial fraction (23-h) or almost all (FOs) of the time available.
- In mice, the decrease of food intake is not associated with sustained high rates of responding.

- In the FO protocol, mice slow eating after the first few minutes. This phenomenon appears similar to the disinterest in food shown by anorexia nervosa patients.
- Food intake across FOs show some dependence on circadian oscillators.
- In a choice situation, palatable foods are preferred by mice until their average cost is five-to tenfold higher than that of bland food, but there is substantial individual variability in this ratio.
- Future experiments might fruitfully examine genetic vulnerability to CBA and/or effects of hormones secreted during the early part of a FO as potential mechanisms by which ambient cost exerts such a profound inhibitory effect on food intake.

Quality of Life in Adult Anorexia Nervosa

31

Enrica Marzola and Giovanni Abbate-Daga

Contents

Abstract

Anorexia nervosa (AN) is a severe mental disorder characterized by high mortality with typical onset in female adolescents. Quality of life (QoL) is strongly impaired in AN and potentially underestimated because of the ego-syntonicity of this illness which makes sufferers not fully aware of their symptoms. Taken together, eating disorders (including also bulimia nervosa and binge eating disorder) are characterized by poor QoL when compared to the general population. However, data are mixed as to whether QoL is most impaired in AN or in other eating disorders. With respect to QoL in AN subtypes, the binge-purging one resulted to have poorer QoL levels than the restricting one. Those with AN reported levels of QoL comparable to those of schizophrenic and severely

depressed patients. It is of importance that QoL is taken into account in treatments since outpatient and inpatient interventions were shown to be able to improve it effectively.

Introduction

This chapter will describe the role of quality of life in anorexia nervosa, a serious mental illness characterized by high mortality. At the beginning of the chapter, anorexia nervosa will be in-depth described, then the methodological issues related to assessing quality of life will be pointed out and finally clinical and research implications of quality of life in anorexia nervosa will be discussed. The main findings from the field will be outlined comparing anorexia nervosa with other both psychiatric and physical disorders.

Anorexia Nervosa

According to the Diagnostic and Statistical manual of Mental disorders (DSM-5; APA 2013), Eating Disorders (EDs) are severe mental illnesses characterized by aberrant eating behaviors ranging from extreme dieting to overeating coupled with weight and body shape concerns. Additionally, harmful compensatory behaviors can occur. The official position of the Academy for Eating Disorders, a global and renowned association of researchers and clinicians with ED expertise, highlights how these disorders are as severe as other major psychiatric disorders (Klump et al. 2009). EDs include three major diagnostic categories: anorexia nervosa (AN), bulimia nervosa (BN), and binge eating disorder (BED). This chapter will focus on AN, an ED characterized by an ego-syntonic resistance to eating coupled with marked weight loss due to a relentless pursuit of thinness. Women are mostly

Table 1 Diagnostic criteria of anorexia nervosa

Diagnostic criteria of anorexia nervosa:
1. Restrictive eating and low weight (Body Mass Index <19)
2. Fear of weight gain
3. Body image distortion
Diagnostic subtypes:
• Restricting-AN: affected individuals lose weight only dieting and over-exercising
• Binge purging-AN: affected individuals periodically engage in binge eating and purging behaviors like vomiting or using diuretics and laxatives, although maintaining restrictive eating and low weight

affected and the onset of AN typically occurs in adolescence; however, age at onset has been reported to be decreasing (Favaro et al. 2009) and onsets before puberty may occur as well.

AN sufferers tend to be obsessed about food and becoming "fat" in spite of severe caloric reductions (see Table 1). Even if strongly underweight those with AN perceive themselves as overweight because of body image distortions. The body image disturbance is the key psychopathological factor and it can be present with different severity levels. In fact, some patients are aware of their emaciation, but refuse to lose weight because their self-esteem is strongly related to their body appearance while some other individuals perceive themselves as overweight or flabby to the point of resembling full-blown delusions (Konstantakopoulos et al. 2012). Two main subtypes of AN have been described: restricting-type AN (R-AN) and binge/purging-type AN (BP-AN). The first group of patients lose weight only by dieting and over-exercising. The second group periodically engage in binge eating and purging behaviors like vomiting or using diuretics and laxatives, although maintaining restrictive eating and low weight (APA 2013). Different degrees of clinical severity can be described (APA 2013) according to individuals' Body Mass Index (BMI, kg/m^2), ranging from mild (BMI > 17) to extreme (BMI < 15). Although often present, amenorrhea is no longer a criterion needed to make AN diagnosis since the lack of menstrual cycle does not correlate with psychopathological conditions (Abbate-Daga et al. 2011a).

Pathogenesis of AN is multifactorial and largely unknown, involving biological and psychosocial underpinnings. In this regard, it has been called into question the cultural pressure to be thin (Hoek et al. 2005); nevertheless, only a minority of individuals who diet end up developing AN. Therefore, other causative factors should be considered and a relevant twin study (Bulik et al. 2006) demonstrated the role of genetic vulnerability. Also psychological factors like temperament traits, perfectionism, and marked sensitivity to criticism have been identified as relevant in AN pathogenesis (Jacobi et al. 2004). Finally, as for other mental disorders, neurodevelopmental trajectories have a role in AN as well; in particular perinatal traumas (Favaro et al. 2006), neuropsychological inefficiencies (Abbate-Daga et al. 2015), and some peculiarities in brain functioning (Kaye et al. 2013). As showed by animal models, malnutrition plays a key role in maintaining and exacerbating eating symptomatology thus generating a vicious cycle of restricting and over-exercising (Gutierrez 2013).

Hence, AN is a complex illness which is difficult to fully understand; it often requires a continuum of therapeutic interventions including outpatient, day patient, and inpatient services (NICE 2004; Klump et al. 2009). Treatments imply a strong involvement of parents and families, in particular with adolescents (Murray and Le Grange 2014). Mid- and long-term sequelae are common with sufferers being impaired with respect to physical problems and social functioning. As stated at the beginning of this chapter, AN is an ego-syntonic disorder so patients' motivation is frequently poor (Abbate-Daga et al. 2013). As a consequence, lengthy and costly hospitalizations for medical care and weight restoration are often necessary to minimize the risk of complications and death (Marzola et al. 2013). Less than half of affected individuals recover and in approximately 20% of cases a chronic course takes place (Steinhausen 2002). Currently, no "gold standard" treatments exist for AN (NICE, 2004); as a result, relapse is quite common (30–50%; Guarda 2008) and mortality is high also because of heightened suicidality (Arcelus et al. 2011). In fact, the standardized mortality ratio of AN is 5.9 which is the highest mortality of any psychosomatic disorder (Erdur et al. 2012).

Why to Assess Quality of Life in Anorexia Nervosa

The World Health Organization defines quality of life (QoL) as "individuals' perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns. It is a broad ranging concept affected in a complex way by the person's physical health, psychological state, level of independence, social relationships, personal beliefs, and their relationship to salient features of their environment" (The WHOQOL Group 1993). QoL describes a broad multidimensional construct and sometimes in medical literature it is preferred to refer to a discrete component of it, namely the health-related QoL (HRQoL). The latter is mostly subjective, multifactorial, and variable in time and represents "the functional effect of an illness and its consequent therapy upon a patient, as perceived by the patient" (Miller 2002).

QoL is key in both physical and mental health fields and it has been highlighted the need to address this issue in treatment (Jenkins et al. 2011; Sy et al. 2013). In fact, over the last two decades, the assessment of QoL has become increasingly relevant for EDs in general and AN in particular. It is noteworthy that the DSM-5 diagnostic system (APA 2013) requires individuals' functional impairment to make the diagnosis of a mental disorder. Furthermore, policy-makers became interested in this parameter when evaluating cost-effectiveness (Stuhldreher et al. 2012) and novel therapeutic interventions for those disorders that tend to have a protracted course like AN (Wonderlich et al. 2012). QoL is also an important measure of treatment effectiveness (Sy et al. 2013).

The assessment of QoL in AN is of particular interest for those patients showing malnutrition-related sequelae that affect patients not only when acutely losing weight but also during recovery; this is particularly true for those with extreme AN (i.e., BMI < 15). Consequences of malnutrition often have as a result social isolation and emotional and social avoidance (Wildes et al. 2010), thus in turn

Table 2 Usefulness of assessing quality of life in anorexia nervosa

QoL in AN is useful to evaluate:
1. Organic malnutrition-related sequelae
2. Psychological consequences of both malnutrition and illness
3. Social consequences of both malnutrition and illness
4. Clinical outcome
5. Cost-effectiveness
6. The comparison of AN with other physical and mental illnesses

impacting on QoL. Sufferers with a long duration of illness (e.g., 15–20 years) could report several sequelae like fractures, movement impairments, loss of autonomy, inability to go to work, and loneliness.

Moreover, assessing QoL allows to compare data across different diagnoses in both psychiatric and organic/medical conditions. Still, the assessment of QoL in EDs can help predict clinical outcomes in treated individuals and their risk of relapse and recurrence (Spitzer et al. 1995). Finally, from a research standpoint, QoL assessments have been increasingly considered as patient-oriented outcome measures in addition to the traditional ones (e.g., weight restoration, absence of binge-purging episodes; Bamford et al. 2015). See Table 2 for a summary of the relevance of assessing QoL in AN.

How to Assess Quality of Life in Anorexia Nervosa

The debate is currently open on how to precisely measure QoL in AN. A number of tools have been used over the past years with research studies using either generic or ED-specific instruments.

Generic instruments are represented by tools such as the EuroQoL 5D (EQ-5D VAS; EuroQoL Group 1990) or the Medical Outcome Short Form Health Survey (SF-36; Ware and Sherbourne 1992) which have been largely used in biomedical research in order to measure QoL. Such instruments have been used across different medical settings ranging from surgery (Carradice et al. 2012) to psychiatry (Maratos et al. 2012). These instruments are useful for several reasons: they are well known and broadly used, can be used by non-ED trained people, are common in literature, and most importantly make data on AN comparable with other medical and psychiatric fields. The latter aspect is of importance because it allows to compare QoL with other invalidating disorders of both psychiatric (e.g., schizophrenia and bipolar disorders) and medical pertinence (e.g., diabetes and coronary disease). However, some cons in using such assessments should be acknowledged as well. For example, anxiety and affective disorders are particularly common in AN (Swinbourne et al. 2012; Abbate-Daga et al. 2011b); since generic measures of QoL usually include questions evaluating general psychiatric symptoms, it is sometimes difficult to disentangle to what extent poor quality of life is due to the ED symptomatology or to the broader psychopathological condition.

Table 3 Main instruments used to assess quality of life in anorexia nervosa.

(a) **Generic**
• EuroQoL 5D (EQ-5D VAS; EuroQoL Group 1990)
• Medical Outcome Short Form Health Survey (SF-36; Ware and Sherbourne 1992)
(b) **Eating disorder specific**
• Eating Disorders Quality of Life instrument (Engel et al. 2006)
• Health-related Quality of Life for eating disorders questionnaire (Las Hayas et al. 2006)
• Eating Disorders Quality of Life Scale (Adair et al. 2007)
• Quality of Life for Eating Disorders measure (Abraham et al. 2006)
• Clinical Impairment Assessment questionnaire (Bohn and Fairburn 2008)

Since research interest about QoL in the ED field increased over the past years, disorder-specific measures have been developed as well. Such instruments have been pioneered in order to capture more appropriately AN-specific characteristics such as partial awareness of illness and poor motivation to change (Ackard et al. 2014; Mond et al. 2005; Muñoz et al. 2009). ED-specific instruments to assess QoL include: the Eating Disorders Quality of Life instrument (Engel et al. 2006), a 25-item scale with four subscales (psychological, physical/cognitive, work/school, and financial) and a total score, the Health-related Quality of Life for Eating Disorders questionnaire (Las Hayas et al. 2006), a 50-item instrument with 8 subscales (symptoms, restrict behaviors, body image, mental health, emotional role, physical role, personality traits, social relations), the Eating Disorders Quality of Life Scale (Adair et al. 2007), a 40-item scale with 12 subscales (cognitive, education/vocation, family and close relationships, relationships with others, future outlook, appearance, leisure, psychological, emotional, values and beliefs, physical, and eating), the Quality of Life for Eating Disorders measure (Abraham et al. 2006), a 21-item measure assessing behavior, eating disorder feelings, psychological feelings, effects on daily life, effects on acute medical status and body weight, and the Clinical Impairment Assessment questionnaire (Bohn and Fairburn 2008), a 16-item questionnaire generating a total score and three subscale scores (personal impairment, cognitive impairment, and social impairment).

Albeit precise, the disadvantage is that such instruments make it difficult to compare QoL results across physic or mental conditions (Ackard et al. 2014). The main instruments to assess quality of life in anorexia nervosa are summarized in Table 3.

Quality of Life in Anorexia Nervosa

Scientific literature has shed light on the fact that individuals affected by EDs show poorer QoL than healthy controls and other psychiatric patients (de la Rie et al. 2005; Keilen et al. 1994; Mond et al. 2005; Tirico et al. 2010) as summarized by a recent meta-analysis (Winkler et al. 2014). The impairment in QoL has been found to be comparable with that of various other serious illnesses like angina and anxiety disorders (Keilen et al. 1994; Spitzer et al. 1995). QoL has been found as even

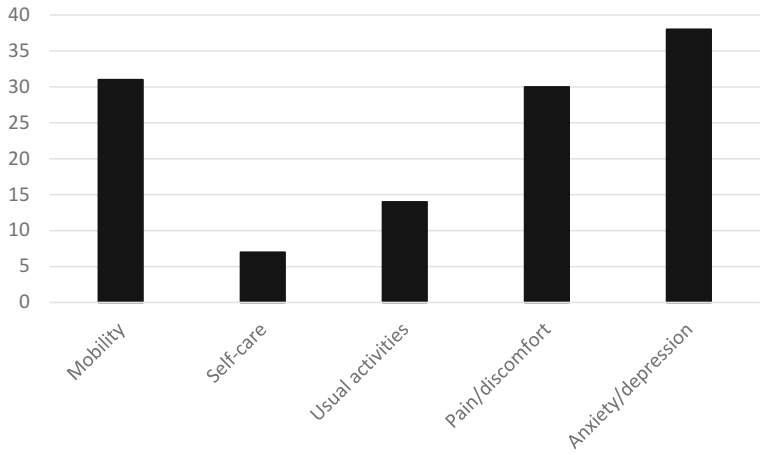

Fig. 1 Proportions of patients with anorexia nervosa reporting extreme problems in the five areas of QoL as measured by the EuroQoL 5D (Abbate-Daga et al. 2014)

more impaired in case of AN patients requiring hospitalization through the emergency department: in fact, research from our group reported scores comparable to those of patients affected by coronary disease (Goldsmith et al. 2010) but lower than that shown by psychotic and bipolar individuals (McCrone et al. 2009). In particular, patients who require an emergency hospital admission report high subjective sufferance and strong movement impairment (Abbate-Daga et al. 2014; Fig. 1). The latter finding is striking in the light of the fact that patients are usually young and starvation can be so extreme to lead to cachexia-death.

When comparing QoL across ED diagnostic subtypes, data are mixed but in spite of diagnostic differences, QoL has been consistently found to be poor mostly in case of extreme dieting (Mitchison et al. 2012) and when hospitalizations are needed (Ackard et al. 2014). Acute and chronic starvation emerges as one of the strongest factors determining poor QoL. Given such results, Hay (2003) proposed that such an impairment could be due to over−/underweight, with worse QoL for those with extremes of BMI (i.e., <20 and >30) (Hay 2003) and thus higher in those with normal weight. Several studies found no relevant differences across different ED subtypes in overall QoL (de la Rie et al. 2005; Latner et al. 2008; Winkler et al. 2014). In keeping with these findings, a recent meta-analysis confirmed the impairment of QoL across EDs, but failed to detect any differences between diagnostic groups (Winkler et al. 2014). However, other works found lower QoL in AN patients when compared to those with BN (Bamford and Sly 2010), and other reports showed higher QoL in AN (Doll et al. 2005; Mond et al. 2005; Padierna et al. 2000). Nevertheless, the latter studies used more often generic measures of QoL, thus potentially underestimating the impact of the illness on sufferers' lives (Tirico et al. 2010); additionally, increased likelihood of self-harm in this group seems to contradict such results (Doll et al. 2005) and different levels of severity of AN could have been put together in these studies further explaining such variable results. Still,

BED patients have been described as having the lowest QoL when compared to the other EDs (Baiano et al. 2014).

Physical functioning seems to be the only exception since it appeared not to be influenced by the EDs (Padierna et al. 2000; Winkler et al. 2014) although in case of emergency hospital admissions it was found to be affected as well (Abbate-Daga et al. 2014). Given the severe organic sequelae of EDs (NICE 2004) and the frequent presence of over-exercise as a compensatory behavior (Peñas-Lledó et al. 2002), this may seem a discordant result. In particular, when each component of QoL is analyzed, little impairment in physical domains is usually reported by AN patients when compared to other ED individuals (Latner et al. 2008; Tirico et al. 2010). In fact, ED patients do not report physical QoL as strongly affected (Latner et al. 2008). However, a relevant caveat should be borne in mind when analyzing research results on QoL in EDs: AN is an ego-syntonic disorder so affected individuals tend to be unaware of the burden of their symptoms and some aspects of the illness may be underestimated by sufferers. This is even more true when comparing those with AN with BN and BED sufferers since BN and BED are characterized by strongly ego-dystonic behaviors like binge eating.

Furthermore, when compared to individuals with BN, those with AN showed lower psychological and physical/cognitive QoL (Bamford and Sly 2010). In line with these findings, AN people have been also described as having poorer social skills and higher functional impairment when compared to BN individuals (Turner et al. 2010). Interestingly, recovered ED patients had a higher QoL than ill ED patients, but they still reported poorer QoL than healthy controls did (de la Rie et al. 2005).

With respect to differences in QoL between diagnostic subtypes of AN, data suggest that those with BP-AN are more impaired than R-AN (Padierna et al. 2000; De Jong et al. 2013) and this seems to correlate with clinical severity (De Jong et al. 2013). Relatedly, QoL of those with R-AN tend to improve at follow-up differently from those with BP-AN (Carter et al. 2008). However, these results may be biased by the aforementioned ego-syntonicity that characterizes mostly R-AN (Mond et al. 2005); in fact, assessing QoL in R-AN patients may pose a relevant problem because weight loss occurs without the more ego-dystonic episodes of binge eating and purging which occur in both BP-AN, BN, and BED.

Interesting data emerge also by comparing AN people with other groups of patients. For example, Carter et al. (2008) showed that AN patients scored higher on illness intrusiveness than other groups affected by either physical or psychiatric disorders. This datum highlights how AN impacts on sufferers' lives in a various and contradictory way. In fact, on one hand patients do not realize malnutrition- and illness-related consequences; on the other hand they feel overwhelmed by the disorder. Sometimes patients' thoughts about body and food are strongly time consuming and obsess affected individuals to the point of hindering food- and eating-related activities. As a result, patients maintain their suffering but at the same time would like to be free again. This ambivalence can make patients feel stuck in their illness thus heightening their demoralization (Abbate-Daga et al. 2013) and potentially induce suicidal behaviors as a way to avoid such a poor QoL. Still, ED individuals showed higher emotional reaction and social isolation than groups with physical illnesses. When AN individuals

are compared with schizophrenic and depressed patients, those with a longstanding AN scored similarly to schizophrenic patients for self-care and social contact (González et al. 2001). Also, other psychiatric patients resulted to perceive more reliably their QoL than AN people (González et al. 2001). As a result, the AN group seemed to be impaired in QoL like other severe and potentially chronic mental illnesses like schizophrenia and depressive disorder (Arkell and Robinson 2008).

Scientific literature has recently started to shed light on those factors that determine an additional impairment of QoL in AN highlighting that bingeing (Hay 2003; Latner et al. 2008; De Jong et al. 2013) and purging (Mond et al. 2005; Tirico et al. 2010; De Jong et al. 2013) behaviors influence negatively patients' QoL in both clinical and community samples. However, it remains unclear to what extent the frequency of such behaviors influences QoL (Jenkins et al. 2011). Also subjective bulimic episodes and compensatory behaviors (e.g., fasting, abuse of laxatives or diuretics, and self-induced vomiting) negatively impacted prognosis (Latner et al. 2008). Little evidence exists on the role of BMI, mostly in severely underweight samples (Jenkins et al. 2011) with data from our group showing that no correlations can be found between BMI and QoL in severe AN patients undergoing hospitalization (Abbate-Daga et al. 2014). Notwithstanding, this factor has been found to affect QoL in some reports (Bamford and Sly 2010). As aforementioned, malnutrition more than BMI impacts on QoL: in fact, patients with low QoL can have fair BMI levels and vice versa. It is well known that rapid weight loss rather than BMI per se can represent a risk factor for individuals' health and tend to impact both QoL and brain functioning (Jeejeebhoy 1998).

Also ED severity has been found to be a predictor of poor QoL (Tirico et al. 2010; Bamford and Sly 2010). Data are more mixed with regard to chronicity although reports showed its relevance in QoL (Tirico et al. 2010) with poorer QoL in individuals with illness duration greater than 5 years. It has also been found a relationship between improvement of eating symptoms and QoL, mostly with respect to family support, leisure activities, economic resources, and perceived mental health dimensions (Sy et al. 2013). Psychiatric comorbidity is endemic to AN sufferers (Swinbourne et al. 2012; Abbate-Daga et al. 2011b) and particularly major depression can influence QoL. In fact, AN people reported similar scores to those of depressed patients, with a strong correlation between depressed mood and QoL due to relational avoidance and social isolation (Arkell and Robinson 2008). After all, EDs and depressive symptomatology are strongly entrenched: recent research showed that such symptoms are correlated with persistence of body image disturbances (Junne et al. 2016). Therefore, more specific assessments of QoL should evaluate this fundamental and specific area. In this light, Stanghellini and collaborators developed an assessment (Identity and Eating disorders, IDEA; Stanghellini et al. 2012) that assesses patients' perspectives about their body and that should be compared to instruments assessing QoL.

Readiness for change is another factor which can be involved in the improvement of QoL. In fact, it has been found to be negatively correlated with the length of stay needed to achieve a positive outcome during hospitalization (McHugh 2007). Treatment motivation can be crucial concerning subjective QoL: in fact, those who are motivated to be treated hope to improve their condition and in turn have a more active and positive attitude towards their disorder. It is necessary to be strong to fight

Table 4 Main factors related to quality of life in eating disorders

Somatic area:
1. Malnutrition effects
2. Low weight
3. Somatic sequelae of the disorders
4. Limitations to movement
Clinical area:
1. Severity of eating psychopathology
2. Purgning behaviors
3. Over-exercise
4. Duration of illness
5. Body image disturbances
6. Diagnosis and diagnostic subtypes
7. Intrusiveness of symptoms
8. Depressive and anxious comorbidity
Psychosocial area:
1. Social isolation
2. Work impairment
3. Family burden
Sufferers' attitude towards their disorder:
1. Ego-syntonicity
2. Denial of illness
3. Motivation to treatments

EDs and a good therapeutic alliance is recommended (Abbate-Daga et al. 2013). Motivation is key also with long-standing patients since it can lead to a tipping point promoting patients' long journey towards recovery and QoL improvement (Dawson et al. 2014). Table 4 summarizes main factors QoL-related in EDs.

Clinical and Research Implications of Quality of Life When Treating Anorexia Nervosa

Over the past years QoL has increasingly been considered as an outcome measure, although many times as a secondary one. As a result, QoL has been studied also in a therapeutic framework with earlier data showing no differences in QoL between treated and untreated patients (Latner et al. 2008). Such findings have been partially confuted by some studies conducted with inpatients demonstrating improved QoL upon hospital discharge (Carter et al. 2008; Abbate-Daga et al. 2014). For example, data from our group (Abbate-Daga et al. 2014) showed that emergency hospitalizations in AN can be effective at improving QoL over the short run. In fact, upon discharge patients reported to be improved in mobility, pain/discomfort, and anxiety/

Table 5 Treatment for those affected by severe and enduring anorexia nervosa

• Multidisciplinary team with eating disorders-trained therapists
• Detailed anamnesis of previous treatments
• Agree upon small objectives, including medical stability
• Empathic relationship and clarity about treatment goals
• Main focus on quality of life: less attention paid to eating psychopathology and more to psychosocial functioning and to the feelings of loneliness

depression scales. Furthermore, the extent of the perceived impairment was milder after hospitalization with the latter resulting a useful intervention to improve both somatic and motor difficulties and to motivate discouraged and psychologically distressed patients. As recommended by international guidelines (NICE 2004) such QoL changes should represent only a first-step goal in treatment.

Very few data exist on the long-term effectiveness of treatments on QoL; Pohjolainen and collaborators (2016) reported that after 8 years QoL was still severely impaired, although gradually improved, in both AN and BN compared to general population.

Treating QoL can be particularly meaningful for AN patients with a severe and enduring disorder. In fact, treatments for AN focus on the resolution of medical symptoms, first of all weight gain, and this is a strong need for the vast majority of affected individuals. However, it has been proposed that those who struggled with AN for several years may need a shift in such a treatment focus (Wonderlich et al. 2012; Table 5) because the ordinary definition of recovery may be no longer adequate. A shared definition of recovery does not exist for AN, but all proposed definitions do include weight restoration. Notwithstanding, this might not be the case for those with a severe and enduring disorder, since recovery should take into account the impact of AN on QoL rather than full weight restoration. Psychotherapy was found to be effective in improving QoL of patients with a severe and long-standing disorder (Touyz et al. 2013), but research also showed that improvements in QoL can be predicted and driven by the improvement of both BMI and eating psychopathology (Bamford et al. 2015); thus, a balance between weight restoration and QoL should be achieved in treatment.

Conclusions

QoL in EDs appears overall poor because of both physical and psychosocial factors. In case of a severe ED, illness duration is usually protracted with treatment resistance and eventually generating a vicious cycle that over time impacts objective and subjective well-being with increased social isolation and poor functioning. QoL over time tends to become poorer and poorer, particularly for AN sufferers as well as that of other family members (Santonastaso et al. 1997).

Malnutrition is a core-element in deteriorating QoL for both physical sequelae and negative effects on brain functioning (Seitz et al. 2014). Furthermore, it should be also mentioned the effect of the specific psychopathology of EDs: sufferers can spend a relevant amount of time struggling with eating symptoms and eating-related thoughts and engage complex rituals checking food and body, often perceived as intrusive and oppressive. Over time, a feeling of failure can further impair QoL.

Treatments should address QoL more precisely and carefully. In this light, it is of importance to focus on patients' perspectives about better treatment and future (Malson et al. 2011) and to help sufferers understand how the improvement of eating symptoms and that of QoL can be intertwined. Finally, treating those with an enduring disorder can require a specific therapeutic effort on QoL in order to achieve the stabilization of psychiatric and eating symptoms and the improvement of social skills alike (Wonderlich et al. 2012). Although research on the effectiveness of such models is only in its infancy, consensus has been reached on the need to pay closer attention to QoL when treating EDs.

Policies and Protocols

Protocols

Protocols may include "how to" techniques such as assessing deficiency or malnutrition, measures of social factors (quality of life, food security), physical or biochemical measurements (blood, anthropometry, etc.).

In order to assess quality of life (QoL) in anorexia nervosa (AN), different approaches can be used. In fact, how to precisely measure QoL in AN is a currently debated topic. Several self-report either generic or eating disorder (ED)-specific measures have been used over the past years. Generic instruments are represented by tools such as the EuroQoL 5D (EQ-5D VAS; EuroQoL Group 1990) or the Medical Outcome Short Form Health Survey (SF-36; Ware and Sherbourne 1992) which have been largely used in biomedical research in order to measure QoL. Such instruments have been used across a variety of different medical settings and can be of help because they are well known and broadly used, can be used by non-ED trained people, and are common in literature and finally, make data on AN comparable with other medical and psychiatric fields. Nevertheless, eating disorder-specific measures have been developed as well. Such instruments have been pioneered in order to capture more appropriately AN-specific characteristics such as partial awareness of illness and poor motivation to change (Ackard et al. 2014; Mond et al. 2005; Muñoz et al. 2009). ED-specific instruments to assess QoL include: the Eating Disorders Quality of Life instrument (Engel et al. 2006), a 25-item scale with four subscales (psychological,

physical/cognitive, work/school, and financial) and a total score, the Health-related Quality of Life for Eating Disorders questionnaire (Las Hayas et al. 2006), a 50-item instrument with 8 subscales (symptoms, restrict behaviors, body image, mental health, emotional role, physical role, personality traits, social relations), the Eating Disorders Quality of Life Scale (Adair et al. 2007), a 40-item scale with 12 subscales (cognitive, education/vocation, family and close relationships, relationships with others, future outlook, appearance, leisure, psychological, emotional, values and beliefs, physical, and eating), the Quality of Life for Eating Disorders measure (Abraham et al. 2006), a 21-item measure assessing behavior, eating disorder feelings, psychological feelings, effects on daily life, effects on acute medical status and body weight, and the Clinical Impairment Assessment questionnaire (Bohn and Fairburn 2008), a 16-item questionnaire generating a total score and three subscale scores (personal impairment, cognitive impairment, and social impairment). However, these tools make it difficult to compare QoL results across physic or mental conditions (Ackard et al. 2014).

Policies

Policies can include exiting or more forward thinking guidelines and can include recommendation for workers in the field, groups, institutions, or governments. It can also include guidelines such as precautionary measures or interventions such as education.

In the ED field guidelines are lacking in several respects; for example, a formal staging of the EDs is currently not available. Nevertheless, according to the available body of evidence, it is important to provide ED patients with the assessment of quality of life (QoL). In fact, QoL is key in both physical and mental health fields and it has been highlighted the need to address this issue in treatment (Jenkins et al. 2011; Sy et al. 2013). With more detail, the DSM-5 diagnostic system (APA 2013) requires individuals' functional impairment to make the diagnosis of a mental disorder. Relatedly, policy-makers became interested in this parameter when evaluating cost-effectiveness (Stuhldreher et al. 2012) and QoL has become an important measure of treatment effectiveness (Sy et al. 2013). Assessing QoL in AN is of particular interest for those patients showing malnutrition-related sequelae, mostly in case of extreme AN (i.e., BMI < 15). Consequences of malnutrition often have as a result social isolation and emotional and social avoidance (Wildes et al. 2010), thus in turn impacting on QoL. Sufferers with a long duration of illness (e.g., 15–20 years) could report several sequelae like fractures, movement impairments, loss of autonomy, inability to go to work, and loneliness. Moreover, assessing QoL allows to compare data across different diagnoses in both psychiatric and organic/medical conditions. Still, the assessment of QoL in EDs can help predict clinical outcomes in treated individuals and their risk of relapse and recurrence (Spitzer et al. 1995). Finally, from a research standpoint, QoL assessments have been

increasingly considered as patient-oriented outcome measures in addition to the traditional ones (e.g., weight restoration, absence of binge-purging episodes; Bamford et al. 2015).

Dictionary of Terms

- **Anorexia nervosa** – Severe mental illness characterized by weight loss, obsessions about food and body shape, and body image distortions.
- **Body Mass Index** – Is a measure of body fat that applies to adult people. It is calculated as follows: kg/m^2. Commonly accepted BMI ranges are: underweight: under 18.5 kg/m2, normal weight: 18.5 to 25, overweight: 25 to 30, obese: over 30.
- **Ego-syntonicity** – It refers to behaviors and feelings considered as acceptable according to each individual's psychological needs. It is the opposite of ego-dystonicity which can be defined as the aspects of one's behavior viewed as inconsistent with one's fundamental beliefs.
- **Quality of life** – Multidimensional construct describing subjective perceptions about physical, psychological, relational, and emotional areas of individual's life.
- **Schizophrenia** – Severe mental illness that affects individuals' thoughts, feelings, and behaviors. Affected individuals tend to lose their contacts with reality. Although a rare disorders, schizophrenia is a chronic and disabling disorder.

Summary Points

- Anorexia nervosa is a severe mental disorder characterized by high mortality.
- Quality of life is strongly impaired in anorexia nervosa and potentially underestimated because of the ego-syntonicity of this illness.
- Data are mixed as to whether quality of life is most impaired in anorexia nervosa or in other eating disorders.
- Severity of malnutrition, eating psychopathology, body image distortions, psychiatric comorbidity, and social isolation seem to be mostly related to quality of life rather than Body Mass Index.
- Those with anorexia nervosa reported levels of quality of life comparable to those of schizophrenic and severely depressed patients.
- It is of importance that quality of life is taken into account in treatments.
- Preliminary data highlight that the treatment of eating disorders can improve patients' quality of life.
- The debate is open as to whether those with a chronic disorder can improve their quality of life without substantially improving their eating disorder.

Abstract

A significant minority of individuals with eating disorders suffers with symptoms for more than 5 years (American Psychiatric Association, Diagnostic and statistical manual of mental disorders (DSM-5), American Psychiatric Pub, 2013). While most of those diagnosed with anorexia nervosa (AN) recover within 5 years of onset, others are more long-standing and have difficulty responding to established interventions (Wonderlich et al., Int J Eat Disord 45(4):467–475, 2012). Severe and enduring AN (SE-AN) is a term that refers to chronic AN, typically 7 years or longer in duration. Outcome data have shown that 7 years marks a plateau in course of illness trajectories, where recovering becomes less likely (Robinson, Severe and enduring eating disorders: a need for some new ideas, paper presented at the eating disorders international conference, London, 2010). SE-AN is by definition severe in nature, and treatment is imperative. However, research guiding the selection of targeted intervention for this population is scant. Consequently, clinicians often view individuals with SE-AN with little optimism and few positive expectations. This chapter will review the available literature to date about SE-AN. The aims of the current chapter are to: (1) empirically define SE-AN, (2) discuss the functional outcomes of those with a chronic history of AN, (3) describe various intervention strategies that show promise, and (4) summarize a randomized controlled trial (RCT) comparing two types of treatment for SE-AN (Touyz et al., Psychol Med 43 (12):2501–2511, 2013). Our review and conclusions highlight the challenges with the current literature, the importance of continuing research on this topic, and the need to set more realistic treatment goals with this population.

Introduction

A significant minority of individuals with eating disorders (ED) suffers with symptoms for years. The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), describes anorexia nervosa (AN) as a serious psychiatric and medical disorder characterized by (1) a significantly low body weight, where the individual restricts food intake to weigh less than minimally normal; (2) an intense fear of gaining weight, usually with concurrent behaviors, such as excessive exercise, that inhibit weight gain; and (3) disturbance in body experience, which often includes a preoccupation with one's weight and an inability to acknowledge or recognize one's severe thinness (American Psychological Association 2013). The criteria and specifiers are presented in Table 1. While most individuals diagnosed with AN recover within 5 years of onset, others experience a more long-standing illness and have difficulty responding to established psychological interventions (American Psychological Association 2013; Wonderlich et al. 2012).

Table 1 The DSM-5 diagnostic criteria for anorexia nervosa (American Psychological Association 2013) is shown. Additionally, the DSM-5 specifies between two subtypes, the restricting type and the binge eating/purging type, as well as by level of severity based on BMI (body mass index)

Diagnostic criteria			
A	A significantly low body weight, where the individual restricts food intake to weigh less than minimally normal		
B	An intense fear of gaining weight, usually with concurrent behaviors, such as excessive exercise, that inhibit weight gain		
C	Disturbance in body experience, which often includes a preoccupation with one's weight and an inability to acknowledge or recognize one's severe thinness		
Subtype			
Restricting type: criteria A is mainly achieved through dieting, fasting, and/or excessive exercise		**Binge eating/purging type:** criteria A is mainly achieved through self-induced vomiting or misusing laxatives, diuretics, or enemas	
Level of severity			
Mild: BMI $\geq$17 kg/m^2	**Moderate:** BMI 16–16.99 kg/m^2	**Severe:** BMI 15–15.99 kg/m^2	**Extreme:** BMI $<$15 kg/m^2

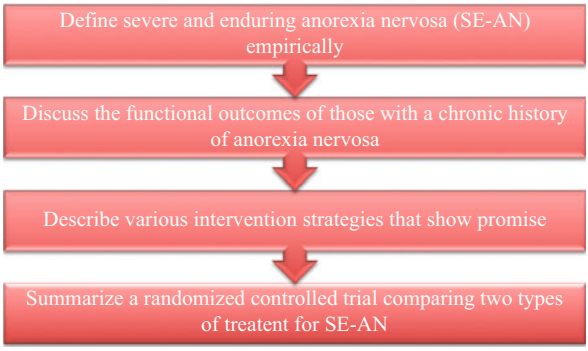

Fig. 1 Chapter goals. In discussing the SE-AN literature to date, the progression of the current chapter is shown

Severe and enduring AN (SE-AN) is a term that refers to chronic AN, typically 7 years or longer in duration. Outcome data have shown that 7 years marks a plateau in course of illness trajectories, where recovering becomes less likely (Robinson 2010). The debilitating nature of SE-AN confers an increase in disability, resulting in a higher likelihood of these patients receiving financial support and health benefits from the government and becoming a burden to their families (Touyz and Hay 2015). According to prior research analyzing chronic AN, there is a poor prognosis for those with SE-AN, as the mortality rates rise in relation to duration of illness (Steinhausen 2002).

SE-AN is by definition severe in nature, and treatment is imperative. However, research guiding the selection of targeted intervention for this population is scant. Consequently, clinicians often view individuals with SE-AN with little optimism and few positive expectations. This chapter will review the available literature on this topic. First, we will empirically define SE-AN. Second, we will describe the functional outcomes of those with a chronic history of AN. Third, we will summarize various intervention strategies that show promise. Lastly, we will describe a randomized controlled trial (RCT) that has compared two types of treatment for those with SE-AN (Touyz et al. 2013). Our review may serve as a basis for highlighting more realistic treatment goals (i.e., away from expectations of full recovery and toward improvement in quality of life (QOL) factors along with modest weight gain), which might increase patient engagement and foster treatment progression (Fig. 1).

Defining SE-AN

Prior research has indirectly studied the longitudinal outcomes of those with chronic AN. For instance, results from a 21-year follow-up study revealed that a longer duration of illness prior to first treatment, and insufficient weight gain during initial hospitalization for the illness, predicts poorer outcomes (Zipfel et al. 2000). Notably, RCTs conducted for patients with AN exhibit an extremely high attrition rate, hovering around 40%. Results suggest that only a minority of patients is willing to

stay in treatment trials; therefore, identifying those with chronic histories as early as possible is necessary for treatment engagement (Halmi 2008). The findings of prior RCTs that include chronic AN are listed in Table 2 as a reference.

More recently, as studies have evolved, the field has come to label this chronic history as SE-AN. Even though the literature has begun to focus on these more severe cases, there is considerable variability in how clinicians define chronic ED due to the lack of empirical data to support this distinction (Wonderlich et al. 2012). Researchers and clinicians often have difficulty agreeing on a common definition because chronicity and severity can relate to a variety of factors. While most use a combination of illness duration, functional impairment, and/or number of hospitalizations as indicators for differentiating those with ED from those with severe and enduring ED (SEED; Wonderlich et al. 2012), each of these individual indices also requires consensus of definition to inform the broader category.

Wildes et al. (2016) have developed an empirically derived operational definition of SE-AN. Specifically, they present a mixed categorical-dimensional model to group those with AN into two categories of severity (low versus high severity) and along three continuous dimensions: ED behaviors, life satisfaction, and indicators of chronicity (i.e., length of illness, number of hospitalizations, and severely low BMI). Results highlight that more than illness duration and number of hospitalizations should be considered when distinguishing between AN and SE-AN (Fig. 2). Specifically, understanding the patient's QOL from a holistic approach may be warranted, but further research is required to replicate and validate this model.

Functional Outcomes and QOL Factors in SE-AN

Arkell and Robinson (2008) conducted a study comparing those with SE-AN to other severe psychiatric diagnoses. The researchers collected original data for 11 participants with SE-AN to compare with preexisting data collected on 106 primary care patients with moderate-severe depression and a standardized community sample of 128 patients with schizophrenia (Parker et al. 1991; Skevington and Wright 2001). The researchers have found that those with SE-AN and severely depressed individuals are similar on measures of QOL, while those with SE-AN are similar to patients with schizophrenia on measures of life skills. These studies illustrate the severity of SE-AN in terms of QOL and functional outcomes.

In another study, Robinson et al. (2015) interviewed eight participants with an illness duration of over 20 years using thematic analysis for a qualitative description of functional impairments. They found that SE-AN appears to affect functioning across multiple domains, with particular difficulty in psychological and social realms and evidence of occupational and physical problems as well. Results suggest that these individuals often feel depressed and hopeless, as well as socially isolated and avoidant. They also tend to experience difficulties maintaining employment and have medical complications secondary to malnutrition (Robinson et al. 2015). These findings further speak to the need for a treatment model for SE-AN that focuses on

Table 2 Randomized controlled therapy trials of adults including chronic AN

Author, year	Publication title	Publication	Participants	Intervention	Findings
Dare et al. (2001)	Psychological therapies for adults with anorexia nervosa. Randomized controlled trial of outpatient treatments	Br J Psychiatry	84 (2 men) with AN (DSM-IV), mean age 26.3 years and all >18	Focal psychoanalytic psychotherapy (1 year), cognitive analytic therapy (7 months), family therapy (1 year), or routine treatment (1 year)	At 1 year, there was modest symptomatic improvement with several patients remaining significantly underweight. Focal psychoanalytic and family therapies were superior to routine treatment (control)
McIntosh et al. (2005)	Three psychotherapies for anorexia nervosa: A randomized controlled trial	Am J Psychiatry	56 females with AN (DSM-IV) or EDNOS AN (BMI 17.5–19) without consideration of amenorrhea criteria. Age range 17–40	CBT, IP, or nonspecific clinical management	Nonspecific clinical management was superior to specific therapies; 70% or participants did not complete treatment or made minimal treatment gains
Pike et al. (2003)	Cognitive behavior therapy in the post-hospitalization treatment of anorexia nervosa	Am J Psychiatry	33 females with AN (DSM-IV). Mean BMI for both groups, 16 and 15.2, age range 18–45	50 sessions of CBT or nutritional counseling over 1 year following discharge from hospitalization	CBT was found superior to nutritional counseling for preventing relapse post-hospitalization
Touyz et al. (2013)	Treating severe and enduring anorexia nervosa: A randomized controlled trial	Psychol Med	63 females with AN. Mean age 33.4 (20–62), mean BMI 16.2, mean duration of illness 16.4 years	30 sessions CBT-AN or SSCM over 8 months	85% of participants completed treatment. There were no significant differences between treatment groups; at follow-up the CBT-AN group had a better outcome

(*continued*)

Table 2 (continued)

Author, year	Publication title	Publication	Participants	Intervention	Findings
Zipfel et al. (2014)	Focal psychodynamic therapy, cognitive behaviour therapy, and optimized treatment as usual in outpatients with anorexia nervosa (ANTOP): Randomized controlled trial	Lancet	242 females with AN (DSM-IV) or AN minus one criterion, BMI 15–18.5, age ≥18	10 months of focal psychodynamic therapy, enhanced CBT, or optimized treatment as usual	At the end of treatment, all groups had increases in BMI with no significant differences between groups
Byrne et al. (2017)	A randomized controlled trial of three psychological treatments for anorexia nervosa	Psychol Med	120 (3 men) with AN. Mean age 26.2, mean BMI 16.7, median duration of illness 4 years	25–40 sessions (over a 10-month period) of SSCM, Maudsley model AN treatment for adults, or enhanced CBT	60% of participants completed treatment. All groups resulted in improvements in BMI, ED symptoms, and psychological/psychosocial well-being with no significant differences between groups at EOT and 12-month follow-up

The findings of prior randomized controlled trials that include chronic anorexia nervosa are shown. These studies illustrate the outcomes of various treatments for those with anorexia nervosa. The data exhibits extremely high attrition rates and suggests the continued limitation of losing many participants from treatment trials

patient resiliency and improvements in QOL and social functioning. That said, research on SE-AN examining the predictive association between core symptom improvement (i.e., in BMI and ED severity) and QOL shows a significant temporal relationship between the two (Bamford et al. 2015). However, even if positive changes in QOL are predicated on weight gain and behavioral symptom reduction, the imposition of full recovery as a treatment goal for those with SE-AN may compromise engagement and retention. Thus, it is important to develop interventions that directly target the psychosocial consequences of chronic AN.

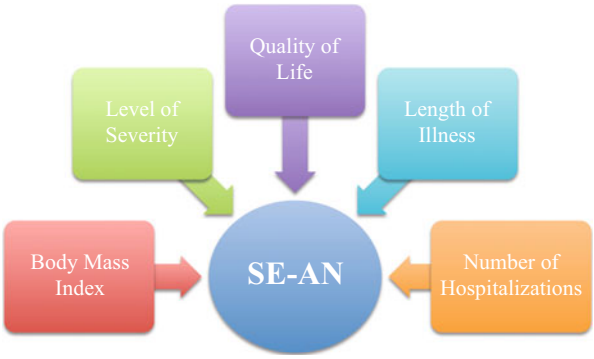

Fig. 2 Additional factors to consider for SE-AN. Wildes et al. (2016) highlight that more than illness duration and number of hospitalizations should be considered when distinguishing between AN and SE-AN, such as the factors shown here

Therapeutic Interventions for SE-AN

Psychological Interventions

To address the unique needs and differential outcome data of individuals with persistent AN (Hay et al. 2015; Zipfel et al. 2000, 2014), several in the field have proposed a clinical staging model (Touyz and Hay 2015; Treasure et al. 2015b), which acknowledges a progression of illness across the lifespan, with the necessary type and level of intervention varying as a function of degree of chronicity. Specifically, they argue that more severe neurobiological changes occur with longer illness duration, leading to an entrenched belief system that requires modification of traditional treatment goals to focus on QOL factors and habitual cognitive biases (Treasure et al. 2015a). Others suggest using supportive humanistic techniques, with a particular focus on promoting autonomy and identifying both effective and ineffective elements of past treatments (Wonderlich et al. 2012).

As described in detail below and presented in Fig. 3, in one RCT focusing on the SE-AN population, modified cognitive behavioral therapy for AN (CBT-AN) and specialist supportive clinical management (SSCM) both show promise in treating those with SE-AN. The CBT-AN manual used in the RCT, developed by Pike et al. (2003), modifies cognitive behavioral therapy (CBT) to address cognitive and behavioral distortions directly affecting AN. The authors stress a schema-focused approach to determine how the patient's internal representations of the self and others relate to their ED symptomatology. When comparing 1 year of CBT-AN to nutritional counseling for 33 weight-restored adult patients with AN, researchers found that those randomized to CBT-AN are less likely to relapse and have better outcomes as assessed by weight status, the Eating Disorder Examination (EDE; Fairburn and Cooper 1993), and the Structured Clinical Interview for DSM-IV Axis I Disorders to assess current comorbidity (Pike et al. 2003).

SSCM for AN is structured around clinical management and supportive therapy (McIntosh et al. 2010). This treatment promotes healthier eating behaviors to restore weight gain by providing clinical monitoring, nutritional information, and

CBT-AN	SSCM
Builds rapport and initiates treatment	Includes clinical monitoring, nutritional information, and psychoeducation regarding AN and healthier eating habits
Addresses cognitive and behavioral distortions directly affecting AN	Identifies and targets issues directly affecting the maintenance of the eating disorder
Utilizes a schema-focused approach to determine the patient's internal representation of self and others in relation to eating disorder symptomatology	Builds upon the patient's strengths
Plans for relapse prevention	Plans for relapse prevention
Touyz et al (2013) altered the goal for both treatments to increase quality of life factors	

Fig. 3 Comparison of CBT-AN and SSCM. A comparison of the two treatments analyzed in the Touyz et al. (2013) randomized controlled trial is shown here. In addition to the elements of the treatments described in the original protocols, Touyz et al. (2013) altered the treatment goal to focus on improving quality of life factors as opposed to full weight restoration

psychoeducation regarding AN. Simultaneously, the patient and therapist address any other relevant issues that are affecting the development and maintenance of the ED, build upon patient strengths, and ultimately plan for relapse prevention (McIntosh et al. 2010). This intervention was compared to CBT and interpersonal psychotherapy over 20 weeks of treatment for 56 women with AN and SSCM and was found to have better outcomes compared to interpersonal psychotherapy as assessed by the EDE (Fairburn and Cooper 1993) and better outcomes compared to both CBT and interpersonal psychotherapy on the Global Assessment of Functioning (McIntosh et al. 2005).

Neuropsychological Interventions

Park et al. (2014) discuss the possibility of implementing cognitive remediation therapy (CRT) for these individuals in an effort to target the severe negative habitual behavior and to improve cognitive flexibility. In a preliminary experiment with four patients with AN, implementing CRT for ten sessions improved cognitive flexibility on neuropsychological tests of set shifting and as described qualitatively by the patients after the intervention (Tchanturia et al. 2007). Abbate-Daga et al. (2012) presented a case series of 20 participants with AN that further demonstrates that CRT can increase set-shifting abilities and cognitive flexibility. Although research in this area has mostly been conducted with AN, this intervention shows promise and should be further investigated for its potential in altering severe cognitive biases that are more prominent in those with SE-AN (Treasure et al. 2015a).

Additionally, altering the attentional capacity that those with AN put on food-related stimuli has been suggested as a novel treatment and an alternative to traditional CBT (Treasure et al. 2015a). This intervention shifts attention at a nonconscious level by using a computer program (Renwick et al. 2013; Schmidt

and Campbell 2013) to redirect attention away from intrinsically rewarding illness-compatible stimuli and toward more positive health-related stimuli. In a review of the literature, Renwick et al. (2013) indicated that this process can involve simultaneously presenting neutral words with food or body-related words on a computer screen and measuring the participant's reaction time for selecting the neutral word. It is suggested that reducing attention on disorder-relevant stimuli will become more automatic as this process is repeated throughout treatment.

Conversely, in order to address the behavioral biases that maintain the rigid eating behaviors, Treasure et al. (2015a) proposed using additional implementation intentions. Specifically, an IF-THEN format might promote goal-directed behavior, such as increasing food consumption or developing healthier eating habits. Additionally, in vivo exposures might be a helpful adjunct to treatment to reduce anxiety associated with seeing and eating food (Treasure et al. 2015a).

While having intuitive appeal for their compatibility with SE-AN, most of these treatment approaches have not been specifically studied with this population, and those that have require replication (Treasure et al. 2015a; Hay et al. 2012). In an effort to establish evidence-based treatments, Hay et al. (2015) submitted a PROSPERO protocol to conduct a meta-analysis that plans to examine RCTs that include individuals with AN for at least 3 years, as well as those who are considered resistant to treatment with at least two failed attempts at treatment. They will compare outcomes across intervention groups to determine the effectiveness of various treatments for those with their determined definition of SE-AN.

Neurotechnological Interventions

Because of the severity and long-lasting changes that result from a diagnosis, new avenues for treatment are being considered (Touyz and Hay 2015). As the behaviors associated with the disorder become cognitively habituated, neuroprogressive changes occur from prolonged AN (Treasure et al. 2015a). In considering the neuroplasticity of the brain, treatments that target this mechanism include deep brain stimulation (DBS), transcranial magnetic stimulation (TMS), and pharmacological interventions (Touyz and Hay 2015; Treasure et al. 2015a); however, it is important to note that the studies analyzing these treatment interventions include small sample sizes.

Preliminary data from a small trial of six participants suggests that DBS to the subcallosal cingulate, which has been previously shown successful in treating those with resistant depression, improves weight status and QOL in half of the patients with SE-AN (Lipsman et al. 2013). Targeting the nucleus accumbens and anterior cingulate cortex with DBS should be studied more extensively as a possible intervention strategy due to the newer understanding of the role of the reward-related neurocircuitries in the etiology and maintenance of AN (Oudijn et al. 2013).

TMS, a noninvasive neuromodulatory technique that increases neural activity in a localized area of the brain through a stimulation machine held close to the head, shows potential promise in the treatment of AN (Park et al. 2014). There is some

evidence supporting that one session of this technique to the left dorsolateral prefrontal cortex reduces anxiety in those with AN due to an increase in neuroplasticity. However, the data is limited to a small pilot study, and it is still unknown whether this method leads to an increase in food consumption (Van den Eynde et al. 2013).

As for pharmacological interventions, more research with intranasal oxytocin, a hormone released naturally during social bonding, should be considered (Treasure et al. 2015a). It appears that one dose of it has been shown to reduce fixations on body image (Kim et al. 2014). While this hormone may reduce avoidance behaviors associated with AN, such as the avoidance of threatening foods and social situations, more research is necessary to determine its role in treatment of SE-AN (Treasure et al. 2015a).

Randomized Controlled Trial for SE-AN

The severity and chronicity of SE-AN make it especially difficult to treat. Few research studies have been conducted to examine targeted treatment options for those with SE-AN. Specifically, most hospital programs are ill-equipped to track patients based on severity, and, thus, individuals with SE-AN are often grouped together and treated with the same clinical goals as those with AN (Touyz et al. 2013). Only one RCT to date has examined an intervention specifically designed for patients with SE-AN. The aims of the RCT were to determine the outcomes of adapting established AN psychotherapy protocols to address the distinctive features of this subgroup (Touyz et al. 2013).

The participants of the study included females meeting criteria for AN, excluding amenorrhea, for at least 7 years. Exclusion criteria included currently experiencing a manic or psychotic episode, substance or alcohol abuse/dependence, significant medical problems unrelated to malnutrition, were in psychotherapy and unwilling to postpone treatment for the study duration, or anticipated moving too far to travel to the study site within the next 12 months. Sixty-three eligible participants (86%) were willing to participate. Participants were randomized to either 30 sessions of modified CBT-AN or modified SSCM over an 8-month period. In order to fit this population, the participants in both conditions were informed that the goal of treatment was to improve QOL across domains, instead of focusing solely on fully achieving expected body weight as described in the original manuals.

The four phases of CBT-AN included (1) building rapport and initiating treatment, (2) altering maladaptive cognitions and behaviors associated with eating, (3) analyzing overarching schemas beyond those associated with eating, and (4) promoting use of CBT-AN strategies posttreatment. For the SSCM condition, participants received more general psychoeducation and supportive psychotherapy. The sample of 63 females ranged in age from 20 to 62 ($M = 33.4$, SD = 9.6), ranged in illness duration from 7 to 49 years ($M = 16.6$, SD = 8.5), and ranged in BMI from 11.8 to 18.5 kg/m^2 ($M = 16.2$, SD = 1.3). Participants were assessed at baseline, at the end of treatment (EOT), and at 6- and 12-month follow-ups. Twenty-six of 31

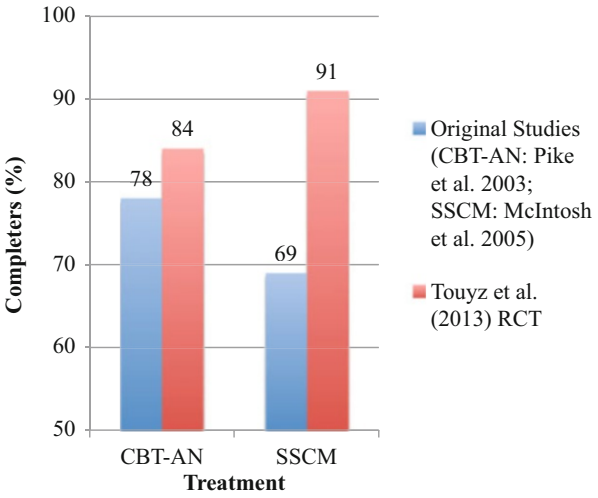

Fig. 4 Comparing percentage of completers for studies by treatment. The percentage of completers for Touyz et al. (2013) compared to Pike et al. (2003) and McIntosh et al. (2005) by treatment type is illustrated. The difference between the (Touyz et al. 2013) RCT and the original AN trials is the explicit treatment goal moving away from full weight restoration to improving quality of life factors. This appears to have a direct impact on rates of participation and completion among participants

CBT-AN (84%) and 29 of 32 SSCM (91%) participants completed treatment. Overall, 71.4% of those completed 6-month follow-up data (22 CBT-AN, 23 SSCM) and 79.4% completed 12-month follow-up data (24 CBT-AN, 26 SSCM) with no significant differences for completion rates between intervention groups.

The existing RCT and AN phenomenology literature have not specifically included, excluded, or distinguished between those with SE-AN and AN. SE-AN is considered a subset of AN samples in research to date. In comparing these modified treatments for this RCT to prior research with these protocols, more SE-AN participants completed the modified CBT-AN treatment (84%; Touyz et al. 2013) compared to all of the AN participants in the original CBT-AN trial (78%; Pike et al. 2003). Additionally, 72% of eligible participants agreed to participate in the original SSCM trial and 69% of those randomized to SSCM completed the treatment (McIntosh et al. 2005), compared to 86% that agreed to participate and 91% that completed the modified SSCM in the RCT (Touyz et al. 2013). This is shown in Fig. 4. This explicit altered treatment goal away from full weight restoration improves rates of participation and completion relative to the standard AN trials.

Participants in both treatment conditions showed significant improvements across all of the assessment time points on measures of QOL, physical and psychological well-being, BMI, ED symptomatology, and readiness to recover as assessed by the Eating Disorder Quality of Life Instrument (EDQOL; Engel et al. 2006), the Short Form-12 Health Status Questionnaire (SF-12; Ware et al. 1996), the Beck Depression Inventory (BDI; Beck et al. 1996), the Weissman Social Adjustment Scale

(WSAS; Weissman and Bothwell 1976), the EDE (Fairburn and Cooper 1993), and the Anorexia Nervosa Stages of Change Questionnaire (ANSOCQ; Rieger et al. 2002; Touyz et al. 2013). Although not statistically significant, CBT-AN produced greater social adjustment and readiness for change, as well as reduced ED symptomatology, at follow-up when compared to SSCM. Therefore, the results suggest that expanding treatment goals to focus on QOL keeps those with SE-AN involved in the treatment process and indirectly affects weight restoration.

In addition to outcome data, few RCTs for AN have examined moderators and predictors to address for whom treatment is most effective for and the mechanisms in which the treatment produces results. Consequently, researchers were interested in conducting an exploratory analysis of predictors and moderators associated with the outcomes of treatment using data collected from the RCT (Touyz et al. 2013; Le Grange et al. 2014). Of the 13 variables collected at baseline, including age, BMI, relationship status, duration of illness, subtype of illness (AN restricting type versus AN binge-purging type), employment status, education, medical concerns, psychotropic medication, EDE Global, ANSOCQ, BDI, and WSAS, four emerged as moderators at EOT. Specifically, those with higher levels of ED psychopathology, depression, older age, and the binge-purging subtype of AN were more successful in CBT-AN compared to SSCM. As for predictors, younger age, shorter duration of illness, and better interpersonal functioning predicted better outcomes at EOT for both conditions on measures of QOL, psychological well-being, and depressive symptoms, while unemployment and being on psychotropic medication predicted worse outcomes on these measures. When comparing baseline to 6- and 12-month follow-up, AN subtype also emerged as a significant predictor, such that those with the restricting subtype predicted better outcomes on measures of QOL, psychological well-being, and depressive symptoms and the use of psychotropic medication predicted worse outcomes on those measures at 12-month follow-up (Le Grange et al. 2014).

Further secondary analyses of the RCT looked at attrition and therapeutic alliance. Elbaky et al. (2014) found that dropout rates were higher among those with the binge-purging subtype and those with poorer QOL. In addition, therapeutic alliance has consistently been demonstrated to be a significant predictor of outcome for psychological interventions, including the treatment of AN (Antoniou and Cooper 2013). Stiles-Shields et al. (2013) examined therapeutic alliance in the two study treatments with the Helping Relationship Questionnaire (HRQ; Luborsky et al. 1985), finding no difference in alliance between CBT-AN and SSCM. In addition, therapeutic alliance significantly improved from treatment at week 2 compared to week 15 and EOT. While earlier development of alliance predicted lower levels on the Restraint and Shape Concern subscales of the EDE (Fairburn and Cooper 1993) at 12-month follow-up, therapeutic alliance assessed at a later time point in treatment predicted improvements on all outcome measures of ED symptomatology and depression except on the Shape Concern subscale of the EDE (Fairburn and Cooper 1993) at EOT and follow-up (Stiles-Shields et al. 2013). These results suggest that it takes time to develop the therapeutic alliance for those with SE-AN; however, the development of that relationship is important to promote and sustain positive change.

Summary and Conclusions

The goal of this chapter was to summarize the empirical evidence surrounding SE-AN. It was previously understood that treating those with chronic AN would lead to few positive outcomes. Although there is still little known about this population, the research that has been conducted shows promise with this clinical population. Specifically, setting more realistic goals away from significant weight gain to QOL factors and modest weight gain might make treatment progression and successful outcomes more feasible. A greater focus on QOL has the potential to decrease medical instabilities with the objective of spending less time in inpatient hospital care. As clinicians will continue to encounter those with chronic histories of ED, we propose that additional research with this population will contribute to clarifying the definition of SE-AN and provide more sufficient empirical evidence to support efficacious treatment intervention strategies for SE-AN.

Policies and Protocols

In this chapter we have described the available literature to date about severe and enduring anorexia nervosa. Below we describe recommendations for professionals in the field to have more success with this clinical population. We suggest the importance of:

- Early identification and intervention of eating disorders for treatment engagement and progression.
- Taking into consideration more than illness duration and number of hospitalizations when distinguishing between anorexia nervosa and severe and enduring anorexia nervosa.
- Considering the relevant treatment goals for this subgroup (i.e., away from expectations of full weight restoration and toward improvement in quality of life factors along with modest weight gain).
- Identifying strengths and weaknesses in their psychological, social, occupational, and physical functioning in order to enhance life domains.
- Remaining optimistic when working with this population as these individuals have likely experienced ineffective treatments in the past and the presented research shows promise for those with severe and enduring anorexia nervosa.
- Additional randomized controlled trials to further examine the efficacy of current treatments, including cognitive behavioral therapy for anorexia nervosa and specialist supportive clinical management, and how they can be improved for this population.
- Further investigation of the neuropsychological and neurotechnological interventions to draw empirical conclusions about their role in the treatment of severe and enduring anorexia nervosa.

Dictionary of Terms

- **Anorexia nervosa** – An eating disorder characterized by low body weight, fear of gaining weight, and body image disturbances in how the person perceives their weight.
- **Cognitive behavioral therapy for anorexia nervosa** – A therapeutic intervention designed to address cognitive distortions and behavioral disturbances associated with eating disorder symptomatology.
- **Eating disorders** – Psychological disorders characterized by disturbances in eating behaviors, such as anorexia nervosa, bulimia nervosa, binge eating disorder, and avoidant/restrictive food intake disorder.
- **Modest weight gain** – Gradual increments of weight restoration, including smaller goals of gaining 1–5 lb at a time rather than an initial goal of obtaining a weight that is considered normal for that individual.
- **Quality of life factors** – A focus on social, emotional, occupational, and physical well-being for those with severe and enduring anorexia nervosa should be considered over weight restoration.
- **Severe and enduring anorexia nervosa** – Those individuals suffering with anorexia nervosa for at least 7 years, who are unable to sustain improvement and tend to experience multiple hospitalizations due to the severity of the illness.
- **Specialist supportive clinical management** – An intervention strategy aimed at providing psychoeducation, nutritional counseling, and support to those with eating disorders as a way to gain knowledge and autonomy for addressing the illness after treatment.

Summary Points

- While most individuals with eating disorders recover within 5 years of onset, others are more long-standing and have difficulty responding to established psychosocial interventions (American Psychological Association 2013; Wonderlich et al. 2012).
- Severe and enduring anorexia nervosa (SE-AN) often refers to those who have a history of anorexia nervosa (AN) for at least 7 years because research has found that those with eating disorders reach a plateau around 7 years, where recovering becomes less likely (Robinson 2010).
- Research guiding the selection of targeted intervention for this population is scant; consequently, clinicians often view individuals with SE-AN with little optimism and few positive expectations.
- Researchers and clinicians often have difficulty agreeing on a common definition of SE-AN because chronicity and severity can relate to a variety of factors. While most use a combination of illness duration, functional impairment, and/or number of hospitalizations as indicators for differentiating those with eating disorders from those with severe and enduring eating disorders (SEED; Wonderlich et al.

2012), each of these individual indices also requires consensus of definition to inform the broader category.

- Considering that no clear cutoffs or operational definitions of SE-AN have been determined, more research that examines those with SE-AN in general, in addition to comparing this population to other eating disorders or SEED, will potentially clarify an appropriate definition.
- Robinson (2010) illustrated the severity of SEED with a study that found that those with SEED and severely depressed individuals were similar on measures of quality of life (QOL), while this group was similar to those with schizophrenia on measures of life skills.
- By interviewing eight participants with a history of AN for over 20 years, Robinson et al. (2015) found that the disorder appears to negatively impact functioning across domains, with particular difficulty in psychological and social realms.
- Although there is some inconsistency regarding the goals of treatment, the literature suggests that using humanistic techniques can be helpful for those with SE-AN, with a particular focus on promoting autonomy, as well as identifying both effective and ineffective elements of past treatments (Wonderlich et al. 2012).
- Potential psychosocial treatment avenues for those with SE-AN include cognitive behavioral therapy for anorexia nervosa (CBT-AN), specialist supportive clinical management (SSCM), cognitive remediation therapy, altering attentional capacity, and implementation interventions.
- As the behaviors associated with prolonged AN become cognitively habituated, treatments that target these neuroprogressive changes include deep brain stimulation (DBS), transcranial magnetic stimulation (TMS), and pharmacological interventions (Touyz and Hay 2015; Treasure et al. 2015a); however, it is important to note that the studies analyzing these treatment interventions include small sample sizes.
- A randomized controlled trial that analyzed treatments for those with SE-AN determined significant improvements for participants in both CBT-AN and SSCM across all of the assessment time points on measures of QOL, physical and psychological well-being, body mass index, eating disorder symptomatology, and readiness to recover. Results suggest that expanding treatment goals to focus on QOL keeps those with SE-AN involved in the treatment process and indirectly affects weight restoration (Touyz et al. 2013).
- Setting more realistic goals away from significant weight gain to QOL factors and modest weight gain might make treatment and successful outcomes more feasible.
- As clinicians will continue to encounter those with chronic histories of eating disorders, we propose that additional research with this population will contribute to clarifying the definition of SE-AN and provide more sufficient empirical evidence to support efficacious treatment intervention strategies for SE-AN.

Endocrine Aspects of Anorexia Nervosa

33

Madhusmita Misra

Contents

Abstract

Anorexia nervosa (AN) is a common condition in adolescents and young adults associated with hypogonadotropic hypogonadism (manifesting as functional hypothalamic amenorrhea), relative hypercortisolemia, a nutritionally acquired growth hormone resistance with low insulin-like growth factor-1 levels, low levels of leptin and oxytocin, and high levels of ghrelin and peptide YY. Low body mass index, reduced lean mass, and hormonal alterations contribute to low bone mineral density in adults and reduced bone accrual in adolescents with

anorexia nervosa leading to an increased risk of fracture. A multidisciplinary treatment team is necessary to manage anorexia nervosa, with close monitoring of eating behaviors and weight changes. Weight gain and menses recovery result in improved bone mineral density, but residual deficits may persist. Calcium and vitamin D intake should be optimized in all. Transdermal 17β-estradiol in replacement doses with cyclic progesterone may be considered in mature adolescent girls with low and decreasing bone mineral density Z-scores, or evidence of skeletal fragility. Combined oral contraceptives are not effective in increasing bone mineral density and may mask spontaneous menstrual resumption. Bisphosphonates increase spine bone mineral density in adults with anorexia nervosa, but not adolescents. Their long half-life limits their use in this age group. Teriparatide increased spine bone mineral density in one study of older women with anorexia nervosa, but these data need to be confirmed with additional studies.

Anorexia nervosa · Growth hormone · Cortisol · Hypothalamic amenorrhea · Appetite regulating hormones · Ghrelin · Leptin · Peptide YY · Low bone density · Fracture risk

List of Abbreviations

AN	Anorexia nervosa
BMD	Bone mineral density
DSM	Diagnostic and statistical manual of mental disorders
DXA	Dual energy x-ray absorptiometry
FHA	Functional hypothalamic amenorrhea
GH	Growth hormone
GnRH	Gonadotropin releasing hormone
IGF-1	Insulin like growth factor-1
IUD	intrauterine device
LH	Luteinizing hormone
Pref-1	Preadipocyte factor-1
PYY	Peptide YY
RANK-L	Receptor activator of nuclear receptor kappa-ligand
T3	Triiodothyronine
T4	Thyroxine
TSH	Thyroid stimulating hormone
vBMD	Volumetric bone mineral density

Introduction

Anorexia nervosa (AN) is a condition of very low weight resulting from restriction of energy intake associated with an intense fear of gaining weight and altered body image (Robinson et al. 2017). DSM-5 does not define a set cut off for what

constitutes low weight and, unlike DSM-IV, does not include amenorrhea as a diagnostic criterion. However, delayed menarche in adolescents and functional hypothalamic amenorrhea are commonly associated with AN (Misra et al. 2004a; Peterson et al. 2016). Other endocrine findings in this condition of self-imposed starvation include an acquired growth hormone (GH) resistance with low insulin like growth factor-1 (IGF-1) levels, relative hypercortisolemia, altered levels of appetite regulating peptides, a state similar to the sick euthyroid syndrome, and impaired bone metabolism. Most endocrine changes are adaptive to the state of undernutrition to preserve energy for essential body functions, increase food intake, increase substrate availability for gluconeogenesis, and reduce resting energy expenditure. However, many of these changes have a deleterious effect on bone, as we will discuss.

Hypothalamic-Pituitary-Gonadal Axis

Functional hypothalamic amenorrhea (FHA) is common and in one study was reported in 38–73% of women who met AN criteria per DSM-5 (Peterson et al. 2016), which no longer requires amenorrhea as a diagnostic criterion for the disorder. The highest prevalence was noted in those with the binge-purge variant of AN and the lowest with the purge only variant. Changes in LH pulsatility (a reflection of changes in gonadotropin releasing hormone (GnRH) pulsatility) result in FHA and low estrogen levels. Women with AN also have lower levels of testosterone than controls (Miller et al. 2007). Altered GnRH secretion is a consequence of endocrine signals that reflect low energy availability. These include low levels of leptin and high levels of ghelin and cortisol (as subsequently described). Fat mass is a reflection of energy stores, and amenorrheic adolescents and women with AN have lower fat mass than those who are eumenorrheic (Misra et al. 2006b; El Ghoch et al. 2016) (Fig. 1). Further, an increase in fat mass (Misra et al. 2006b) and percent calories derived for fat (Baskaran et al. 2017a) predicts menstrual recovery. Suppression of the hypothalamic-pituitary-gonadal axis (and reproductive potential) is an appropriate adaptive response to conserve energy for vital body functions.

The hypothalamic-pituitary-gonadal axis may also be suppressed in males with AN, resulting in lower testosterone (and estradiol) levels than in controls (Misra et al. 2008a). Lower testosterone levels are associated with greater truncal adiposity (Misra et al. 2008b).

Hypogonadism and Bone

Hypogonadism is an important determinant of low bone mineral density (BMD) (Miller et al. 2006; Misra et al. 2004a, 2008a; Kandemir et al. 2017). Estrogen is primarily antiresorptive through suppression of receptor activator of nuclear receptor kappa-ligand (RANK-L) and increased production of osteoprotegerin, resulting in

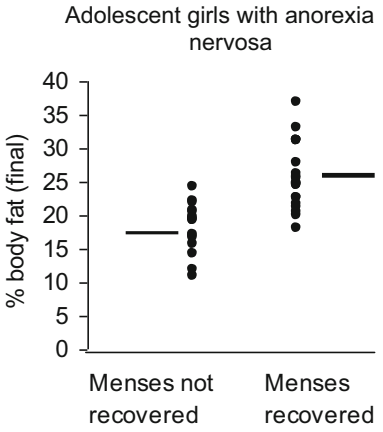

Fig. 1 Percent body fat in adolescent girls with anorexia nervosa who did or did not recover menses over 12-months follow-up. In a 12-month prospective observational study of amenorrheic adolescent girls with anorexia nervosa 12–18 years old, girls who recovered menstrual function during the follow-up period had greater percent body fat at 12-months than those who did not. inhibition of osteoclast differentiation and activation and increased apoptosis. It may also have bone anabolic effects through suppression of sclerostin, a product of osteocytes that otherwise inhibits bone formation. In women, older menarchal age and a longer duration of amenorrhea (reflecting chronicity of estrogen deficiency) are associated with lower BMD (Misra et al. 2004a). Despite low estrogen levels, osteoprotegerin levels are higher in AN than controls, indicating a compensatory mechanism to reduce bone resorption (Misra et al. 2003b). However, RANK-L is elevated, and the ratio of osteoprotegerin to RANK-L is lower than in controls, consistent with a milieu favoring resorption (Golabek et al. 2015).

Interestingly, administration of the combined estrogen-progesterone oral contraceptive pill is not effective in increasing BMD in adults or adolescents with AN (Strokosch et al. 2006; Klibanski et al. 1995), likely because oral ethinyl estradiol decreases IGF-1, an important bone trophic hormone. In contrast, a replacement dose of estrogen given as transdermal 17β-estradiol (100 mcg), a physiologic form of estrogen, with cyclic progesterone does not suppress IGF-1 in adolescents with AN and is effective in increasing bone accrual to rates observed in healthy controls (Misra et al. 2011) (Fig. 2). However, "catch-up" did not occur in this 12-month study, and girls with AN continued to lag behind controls for BMD, likely because many other endocrine changes (in addition to hypogonadism) contribute to low BMD. Transdermal 17β-estradiol did not impact sclerostin levels (Faje et al. 2012), but did decrease preadipocyte factor 1 (Pref-1) (Faje et al. 2013a). Pref-1 is an inhibitor of adipocyte and osteoblast differentiation that is increased in hypogonadal states. A reduction in Pref-1 was associated with a reduction in bone resorption markers and an increase in lumbar BMD.

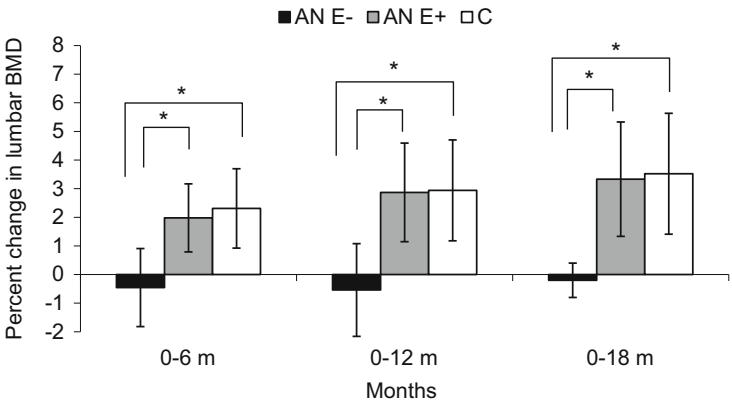

Fig. 2 Impact of physiologic estrogen replacement versus placebo on lumbar spine bone mineral density in adolescent girls with anorexia nervosa, compared to controls followed without intervention over an 18-month period. Adolescent girls with anorexia nervosa 12–18 years old randomized to physiologic estrogen administration as the 100 mcg 17β-estradiol patch and cyclic oral progesterone (AN-E+) had increases in bone density at the lumbar spine at 6, 12, and 18 months compared with those randomized to placebo patches and pills (AN-E-), to approximate bone accrual rates in healthy normal-weight controls (C) of the same age range followed without intervention. (Reprinted with permission from Misra et al. (2011). Copyright © The American Society for Bone and Mineral Research, 2011)

Testosterone is bone anabolic and antiresorptive, and in both males and females with AN, lower testosterone levels are associated with lower BMD (Misra et al. 2008a, Soyka et al. 2002). Data are lacking regarding the impact of testosterone replacement on BMD in males with AN. However, in adult women, transdermal testosterone replacement to approximate levels in the upper half of the normal range for women did not increase BMD, despite an early increase in bone formation markers (Miller et al. 2011). One group has demonstrated a maintenance of BMD Z-scores in adolescent and young adult women with AN given 50 mg of dehydroepiandrosterone daily with a combined oral contraceptive pill (Divasta et al. 2012).

Hypogonadism and Neurocognitive and Mood Outcomes

Hypogonadism is associated with impaired cognitive function, with reduced scores on verbal memory and executive function (Baskaran et al. 2017c), which improve with physiologic estrogen replacement (Baskaran et al. 2017b). Also, physiologic estrogen replacement using the transdermal 17β-estradiol patch improves trait anxiety in girls with AN and prevents the increase in state anxiety and body dissatisfaction with weight gain observed in girls randomized to placebo (Misra et al. 2013). In adult women with AN, lower testosterone levels are associated with higher anxiety and depression scores (Miller et al. 2007).

Hypothalamic-Pituitary-Adrenal Axis

The hypothalamic-pituitary-adrenal axis is in a state of overdrive in AN. Increased cortisol secretion is a consequence of increased pulse frequency and reduced clearance (Boyar et al. 1977; Misra et al. 2004b) (Fig. 3). There is also less suppression of cortisol following administration of oral glucose load in adolescents with AN (Misra et al. 2004b) and with the dexamethasone suppression test in adults with AN compared with controls (Duclos et al. 1999; Estour et al. 1990). Higher cortisol levels are associated with lower BMI and body fat, and weight gain is associated with a reduction in cortisol pulse frequency (Misra et al. 2004b). Cortisol levels are typically not elevated to any more than twice the upper limit of normal.

High cortisol levels are an appropriate adaptive response to undernutrition as cortisol is gluconeogenic, and higher cortisol levels would increase availability of gluconeogenic substrate by increasing proteolysis and help maintain euglycemia. Consistent with this, higher cortisol levels in AN are associated with lower extremity lean mass (Misra et al. 2005a).

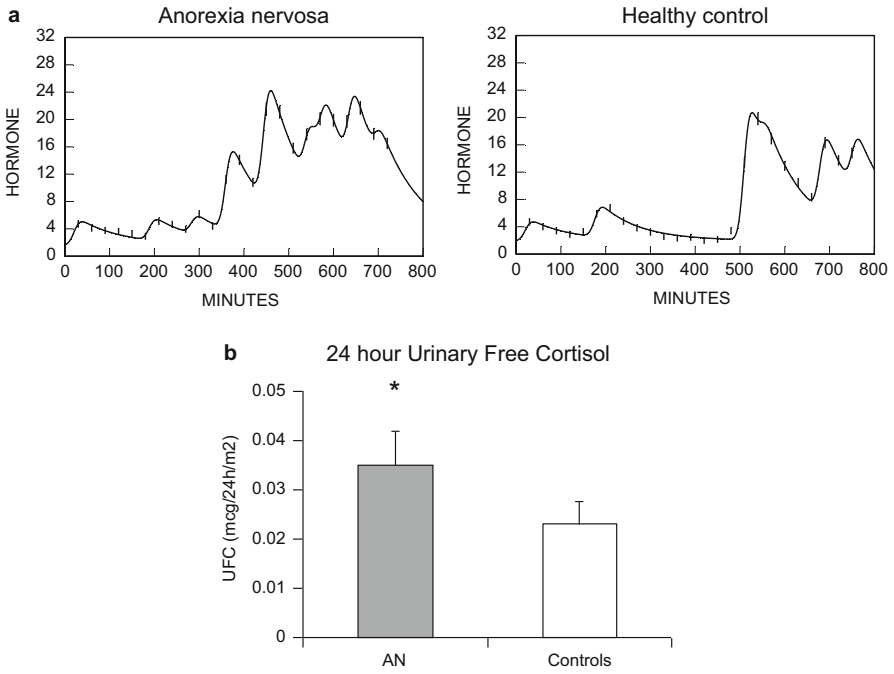

Fig. 3 Cortisol concentrations in adolescent girls with anorexia nervosa compared with healthy normal-weight controls. (**a**) Overnight serum cortisol concentrations (assessed every 30 minutes) in a teenage girl with anorexia nervosa (AN) and a healthy normal-weight control, indicating greater cortisol secretion in the girl with AN. (**b**) 24-h urinary free cortisol levels in adolescents with AN and controls 12–18 years old, showing higher mean urinary free cortisol excretion in AN. (Adapted with permission from Misra et al. (2004b). Copyright © The Endocrine Society 2004)

Hypercortisolemia is deleterious to gonadotropin releasing hormone (GnRH) pulsatility and contributes to suppression of the hypothalamic-pituitary-gonadal axis (Misra and Klibanski 2014). It also has a deleterious effect on bone by increasing bone resorption, suppressing bone formation, reducing gut calcium absorption, and impairing renal handling of calcium. In a study of adolescent girls with AN, higher cortisol levels were associated with lower levels of bone turnover markers and lower BMD (Misra et al. 2004b; Lawson et al. 2009). Normalization of cortisol following recovery should result in improved bone outcomes. In one study, cortisol levels were inversely correlated with anxiety and depression scores (Lawson et al. 2009).

Growth Hormone (GH)- Insulin-like Growth Factor-1 (IGF-1) Axis

AN is characterized by a nutritionally acquired GH resistance, associated with low IGF-1 levels despite high GH concentrations (Misra et al. 2003a, 2004c; Stoving et al. 1999) (Fig. 4). GH secretion is increased in adolescents and adult women with AN, consequent to increased GH pulse mass and frequency (Misra et al. 2003a, 2004c; Stoving et al. 1999). Lower IGF-1 (through reduced negative feedback) and glucose levels and higher ghrelin predict higher GH concentrations (Misra et al. 2003a, 2005b). An increase in GH in those with lower glucose levels is an appropriate adaptive response to increase gluconeogenesis to help maintain euglycemia. This gluconeogenic effect stems from the lipolytic effect of GH, which increases availability of gluconeogenic substrate. In girls with AN, higher GH concentrations are associated with lower trunk fat, consistent with this lipolytic effect (Misra et al. 2005a). Ghrelin is a GH secretagogue; thus, higher ghrelin levels also contribute to increased GH secretion in AN (Misra et al. 2005b). In girls with AN, there is reduced suppression of GH following an oral glucose load, compared to controls (Misra et al. 2004c).

Hepatic resistance to GH results in lower systemic IGF-1, a bone trophic hormone. This hepatic resistance may be mediated via increased fibroblast growth factor-21 (FGF-21), which is induced in the liver during fasting and inhibits IGF-1 secretion by inhibiting signal transducer and activator of transcription-5 (Fazeli et al. 2010b). GH resistance also results from downregulation of GH receptor expression in the liver, as suggested by lower levels of the GH binding protein (the cleaved extracellular component of the GH receptor).

Low IGF- 1 levels are deleterious to the hypothalamic-pituitary-gonadal axis and bone. In addition to hepatic GH resistance, AN is characterized by skeletal GH resistance. Typically, GH should increase surrogate markers of bone formation and resorption. Consistent with this, in normal-weight healthy girls, higher GH concentrations are associated with higher levels of bone turnover markers. This is not seen in girls with AN despite higher GH levels (Misra et al. 2003a). Further, administration of supraphysiologic doses of recombinant human (rh) GH to adult women with AN over a 3-month period (up to 5–6 times physiologic dosing) was not associated with a significant increase in IGF-1 or bone turnover markers, despite a reduction in

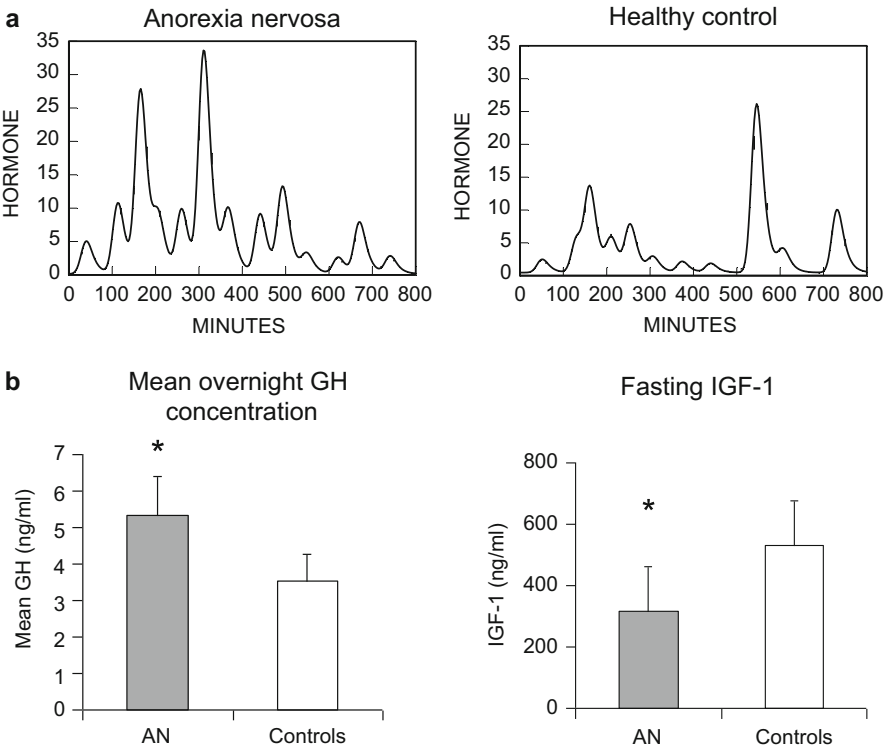

Fig. 4 Impact of anorexia nervosa on growth hormone (GH) and insulin-like growth factor-1 (IGF-1) concentrations. (**a**) Overnight growth hormone (GH) concentrations in a teenage girl with anorexia nervosa (AN) and a normal-weight healthy control indicating increased GH secretion in the girl with AN. (**b**) Mean overnight GH and fasting IGF-1 levels in adolescents with AN and controls 12–18 years old. IGF-1 levels were lower in girls with AN despite higher GH concentrations, indicative of a nutritionally acquired GH resistance. (Adapted with permission from Misra et al. (2003a). Copyright © The Endocrine Society 2003)

body fat (Fazeli et al. 2010a). In contrast, rhIGF-1 administration in replacement doses increased bone formation markers in adult and adolescent females with AN (Grinspoon et al. 1996a, 2002; Misra et al. 2009), and when administered with estrogen over a 9-month period increased BMD in adult women with AN (Grinspoon et al. 2002).

Hypothalamic-Pituitary-Thyroid Axis

Very low weight individuals with AN demonstrate a thyroid profile that resembles the sick euthyroid syndrome. Levels of total triiodothyronine (T3) and free thyroxine (T4) are low normal or low, and thyroid stimulating hormone is

typically normal or low normal (Estour et al. 2010; Misra and Klibanski 2014). Lower thyroid hormone levels should help reduce brown fat thermogenesis and resting energy expenditure, thus preserving energy for vital functions (Singhal et al. 2016). Low or low normal levels of total T3 and free T4 in AN do not require levothyroxine replacement.

Hormones Regulating Food Intake

Leptin is an anorexigenic hormone secreted peripherally by adipocytes. Levels are very low in AN and correlate with fat mass (Grinspoon et al. 1996b; Misra et al. 2005c). Leptin stimulates GnRH secretion, and low leptin levels contribute to hypogonadotropic hypogonadism in AN. In fact, administration of rh leptin (metreleptin) in replacement doses to adult women with FHA resulted in resumption of menstrual cycles in up to 70% of the women and normal ovulation in about 40% (Welt et al. 2004; Sienkiewicz et al. 2011). Leptin is also bone anabolic, and replacement doses of metreleptin increased bone formation markers (Welt et al. 2004). However, consistent with its anorexigenic effects, women receiving metreleptin had a decrease in appetite and body weight over 3 months in one study (Welt et al. 2004) and a decrease in body fat despite careful dose titration to prevent weight loss in a 9-month study (Sienkiewicz et al. 2011). This anorexigenic effect argues against its use in AN.

Ghrelin is a GH secretagogue with orexigenic effects, secreted primarily from the gastric fundus (Nakazato et al. 2001). Adolescent and adult females with AN have high levels of ghrelin compared with controls (Misra et al. 2004c, 2005b; Sedlackova et al. 2012; Stock et al. 2005), with lesser reductions following an oral glucose load (Misra et al. 2004c). Ghrelin administration inhibits gonadotropin secretion in rodents and humans (Kluge et al. 2012), and high ghrelin levels in AN likely contribute to hypogonadotropic hypogonadism. Ghrelin has stimulatory effects on osteoblasts, and in healthy controls, higher ghrelin levels are associated with higher levels of bone formation markers. This association is not evident in AN, suggesting a state of ghrelin resistance (Misra et al. 2005b).

Low levels of leptin and high levels of ghrelin are consistent with an adaptive mechanism to stimulate food intake and increase energy availability in AN. In contrast, peptide YY (PYY), an anorexigenic hormone secreted by the L-cells of the gut, fails to demonstrate this adaptive response and its levels are unexpectedly high in AN (Misra et al. 2006a). PYY is deleterious to osteoblastic activity, and consistent with this, higher PYY levels in AN are associated with lower levels of bone formation markers and lower BMD (Misra et al. 2006a; Utz et al. 2008). A PYY antagonist may thus be beneficial to bone; however, such an agent has not been studied at this time. Oxytocin is another hormone that is anorexigenic and bone anabolic. Levels are appropriately low in AN, and lower levels are associated with lower BMD (Lawson et al. 2011).

Bone Metabolism

A major consequence of the endocrine changes in AN is impaired bone metabolism. Bone metabolism is deleteriously affected because of the associated hypogonadism, hypercortisolemia, GH and ghrelin resistance, low IGF-1 and leptin, and high PYY levels (Misra and Klibanski 2014). Additional factors contributing to impaired bone metabolism are low BMI and reduced lean mass (Misra et al. 2004a). AN is also associated with reduced marrow fat at the spine and femur, which in turn is associated with lower BMD (Bredella et al. 2009). This is consistent with the bone-fat hypothesis of a common progenitor cell giving rise to both adipocytes and osteoblasts; certain conditions may induce transcription factors that stimulate one pathway at the expense of the other. Thus, an increase in marrow adipogenesis may be associated with reduced osteoblastogenesis and lower bone formation. Also, certain medications are deleterious to bone. In particular, use of selective serotonin reuptake inhibitors for more than 6 months has been associated with lower BMD in AN, even after controlling for duration of illness or amenorrhea (Misra et al. 2010).

Adults with AN have an uncoupling of bone turnover, with an increase in bone resorption and a decrease in bone formation markers (Grinspoon et al. 1996a). Conversely, adolescents with AN demonstrate a coupled decrease in bone formation and resorption markers (Misra et al. 2011, 2003b), in contrast to normal adolescence, a high bone turnover state. In adults with AN, one study reported areal BMD T-scores of <-1 at one or more sites in 92% and T-scores of <-2 in 38% of the women (Grinspoon et al. 2000). In adolescents with AN, we have reported Z-scores of <-1 at one or more sites in 52%, and Z-scores of <-2 in about 11% (Misra et al. 2004a). The lumbar spine appears to most severely affected in females with AN, though total hip, femoral neck, and whole body BMD Z-scores are also low in these women. One study (Schorr et al. 2017) examined BMD outcomes in women with AN and atypical AN using both DSM-IV and DSM-5 criteria. BMD Z-scores were <-1 in 78% of AN diagnosed by DSM-IV, 82% of those diagnosed by DSM-5, and 69% of atypical AN.

Recent studies have examined bone geometry and microarchitecture in AN using high resolution peripheral quantitative computed tomography (Faje et al. 2013b; Lawson et al. 2010; Milos et al. 2005; Singhal et al. 2018). At the nonweight bearing radius, compared with controls, adolescents with AN have lower total and trabecular volumetric BMD (vBMD), cortical thickness, trabecular number and thickness, and higher cortical porosity associated with reduced estimated strength (Faje et al. 2013b). At the weight-bearing distal tibia, they have greater cortical porosity, lower total and cortical vBMD, cortical area and thickness, trabecular number, and strength estimates than controls (Singhal et al. 2018). In another study of adolescents with AN, trabecular bone score (measure of bone texture) showed evidence of degraded microarchitecture in over 40% of study participants and correlated with BMD and strength estimates (Donaldson et al. 2015). In adult women with AN, at the distal radius, total, cortical and trabecular vBMD is lower than in controls. They also have lower cortical thickness, trabecular number and thickness, and increased trabecular separation, associated with lower estimated strength (Milos et al. 2005).

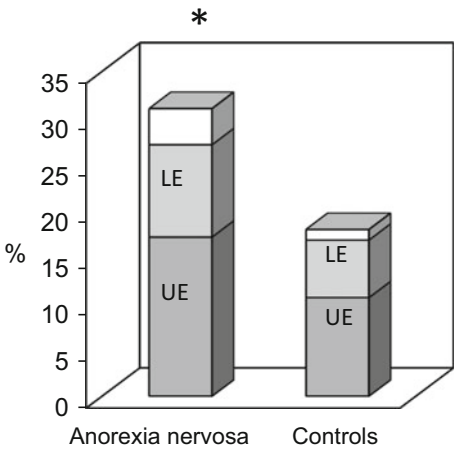

Fig. 5 Prevalence of fractures in adolescent and young adult women with anorexia nervosa (AN) 12–22 years old compared with healthy normal-weight controls. Adolescent and young adult women with anorexia nervosa (AN) 12–22 years old had a higher prevalence of fractures (31%) than normal-weight controls of comparable age (18%); however, the proportion of upper extremity (UE), lower extremity (LE), and nonextremity fractures did not differ between groups. (Adapted with permission from Faje et al. (2014). Copyright © 2014 Wiley Periodicals, Inc.)

Further, vertebral integral vBMD and estimated vertebral strength are lower in AN than in controls, associated with lower BMI and longer duration of amenorrhea (Bachmann et al. 2017).

Lower BMD and impaired bone geometry and structure translate to increased fracture risk in both adolescents and adults with AN (Faje et al. 2014; Vestergaard et al. 2002). One study reported a 31% prevalence of fracture in adolescent girls with AN compared to 19% in controls (60% increase) (Fig. 5), with fracture rates peaking after diagnosis. In adults, the incidence rate ratio of fracture was 1.98 and also increased after diagnosis. This increased risk persisted for 10 years postdiagnosis (Vestergaard et al. 2002). The distribution of fractures is similar to controls, with extremity fractures being the most common (Faje et al. 2014).

Management of Low Bone Mineral Density

Individuals with AN should be assessed for areal BMD using dual energy x-ray absorptiometry (DXA) (Gordon et al. 2017). Because adolescence is a critical window in time to optimize bone accrual towards attainment of peak bone mass, and because deficits incurred during this time may well be permanent, it is important to monitor BMD at least annually in adolescents with AN. However, DXA measurements may also be repeated every 6 months, if clinically necessary (Gordon et al. 2017).

Calcium and vitamin D intake should be optimized in all patients. Vitamin D intake should be at least 600 IU daily and adjusted to maintain 25(OH) vitamin D

levels in the 32–50 ng/ml (80-125 nmol/L) range. Calcium intake should be at least 1300 mg daily. Although studies have shown that in general adolescents and adults with AN do better for calcium and vitamin D intake than controls (Hadigan et al. 2000; Misra et al. 2006c), serum 25(OH) vitamin D levels of <50 nmol/L are associated with lower BMD Z-scores (Gatti et al. 2015).

A critical aspect of management of low BMD in AN is weight gain and menstrual recovery. All individuals with AN should have a treatment team in place that includes an adolescent medicine physician or internist with expertise in managing eating disorders, a dietician, and a psychologist or psychiatrist. An increase in caloric intake is critical to recovery, along with curtailing of exercise activity (Gordon et al. 2017). The goal is to get to a weight that corresponds to >90% of median BMI for age. Even after the patient gets to a "healthy" weight, it may require 6–12 months of weight maintenance or continued weight gain before menses resume. At the time of menstrual recovery, girls are about 2 kg heavier than when they lose their periods (Golden et al. 1997). It is thus important to set realistic expectations of when to expect menstrual recovery.

Weight gain and menstrual recovery are associated with improved bone accrual in adolescents with AN, although residual deficits may persist (Misra et al. 2008c). One study suggests that the effect of weight gain on BMD may be attenuated when 25 (OH) vitamin D levels are < 30 ng/ml (75 nmol/L) (Giollo et al. 2017). In adults, weight gain alone leads to improved hip BMD, whereas menstrual recovery alone results in improved spine BMD. Women gaining weight and resuming menses demonstrate improved BMD at all sites (Miller et al. 2006).

In girls whose BMD Z-scores are <−2 and decreasing over time, and in those with evidence of skeletal fragility, one may consider short-term physiologic estrogen replacement to improve bone accrual (Misra et al. 2011), after a reasonable trial (6–12 months) of nutritional, psychological, and modified exercise intervention (Gordon et al. 2017). When the bone age is at least 14 years, we use the 100-mcg transdermal 17β-estradiol patch applied continuously (changed weekly or biweekly depending on the preparation) with 12 days of cyclic progesterone every month. For the progesterone component of therapy, we prefer 200 mg of micronized progesterone given daily for 12 days of each month; however, a progestogen such as medroxyprogesterone acetate or norethindrone could also be used. Before starting estrogen replacement therapy, contraindications to estrogen administration should be ruled out, and patients counseled about the risks of estrogen and progesterone/progestogens.

Combined estrogen-progesterone containing oral contraceptive pills should not be given for the purpose of achieving regular menses or improving bone outcomes. Regular menses induced by such medications do not help recovery and may mask return of spontaneous menses. Thus, bone loss may persist, particularly if energy deficit is not addressed (Gordon et al. 2017). Further, randomized controlled studies have clearly shown that combined oral contraceptive pills do not increase BMD in AN (Klibanski et al. 1995; Strokosch et al. 2006), although those with very low BMD have gain some benefit. However, adolescents and young women desiring oral contraceptives for birth control should not be denied this option. At the same time, consideration should be given to other forms of contraception, such as an intrauterine

device (IUD). Progesterone-releasing IUDs have gained popularity in recent times; however, they can lead to irregular menses or amenorrhea, masking the timing of menstrual resumption.

When adult women with AN have BMD Z-scores of <-2 or evidence of skeletal fragility, a question is whether they should be treated with pharmacologic options such as bisphosphonates, teriparatide, or denosumab. One study in adults reported a beneficial effect of risedronate (35 mg weekly), with 3–4% an increase in spine BMD and 2% increase in hip BMD over a year compared to placebo (Miller et al. 2011). In contrast, a 12-month study in adolescents reported no increase in lumbar spine BMD and only a small increase in femoral neck BMD with weekly alendronate therapy compared to placebo (Golden et al. 2005). Concerns persist regarding the use of bisphosphonates in adolescents and adult women of childbearing age given their very long half-life, although available data thus far are reassuring.

In a 6-month randomized controlled trial of teriparatide versus placebo in older adult women with AN, 20 mg teriparatide (PTH_{1-34}) SC daily was successful in increasing BMD by 6–10% at the AP and lateral lumbar spine, but not at the hip (Fazeli et al. 2014). The increase in BMD was associated with an increase in bone formation markers. More and longer-term studies are necessary to confirm these findings. In adolescents with AN, teriparatide should not be used, because of the black box warning it carries with respect to risk for osteosarcoma (based on rodent studies). The Endocrine Society guidelines for hypothalamic amenorrhea suggest that short-term use of teriparatide is an option in the setting of delayed fracture healing and very low BMD (Gordon et al. 2017). Studies of denosumab are currently lacking in AN.

Conclusion

AN is associated with alternations in multiple endocrine axes, an adaptive mechanism in this state of severe undernutrition. However, these endocrine changes (together with low BMI and lean mass) contribute to impaired bone metabolism and increased fracture risk. Neuroendocrine changes may also impact neurocognitive and mood outcomes. A multidisciplinary treatment team is necessary for management of AN and to optimize nutritional repletion. Management should include optimizing vitamin D levels. Options for treatment of low BMD in AN are few and include physiologic estradiol replacement with cyclic progesterone (in adolescents with AN), and rarely bisphosphonates or teriparatide (in adults with AN).

Policies and Protocols

In this chapter, we have described the endocrine and bone complications that are associated with anorexia nervosa, and their management. Here we highlight three key aspects of management of low bone density in anorexia nervosa:

1. A multidisciplinary team is necessary to manage the psychological, nutritional, hemodynamic and endocrine consequences of anorexia nervosa. This team includes a psychologist+/- psychiatrist, dietician, eating disorder specialist (adolescent medicine physician/pediatrician/internist), and an endocrinologist. Regular and frequent follow-up appointments are necessary to ensure that weight gain goals are being met. Weight gain and menstrual resumption are a critical first step to optimizing bone accrual and bone density in anorexia nervosa. It may take 6-12 months of being at or above target weight (as determined by the eating disorder specialist) before menses resume.
2. It is important to optimize calcium and vitamin D intake as low vitamin D levels may impair bone accrual during weight regain. Calcium intake should be in the range of 1200-1500 mg/day (dietary and supplements). Vitamin D intake should be adjusted to maintain 25(OH) vitamin D levels between 32-50 ng/ml (80-125 nmol/L).
3. Transdermal 17-β estradiol (100 mcg administered continuously) with cyclic progesterone/progestogen (for 12 days of every month) may be necessary to improve bone accrual rates in adolescent girls whose bone mineral density Z-scores are low and decreasing over time, or if there is evidence of skeletal fragility. Combined estrogen-progestogen containing oral contraceptive pills are not effective in increasing bone density in adolescent or adult women with anorexia nervosa, and should not be administered to 'regulate' menstrual periods. They mask return of spontaneous menses without any beneficial bone effects. Oral contraceptive pills should not be denied to women requesting these for contraception, if other strategies for contraception are contraindicated or not desired. In these situations, women should be informed that oral contraceptive pills may mask the return of spontaneous menses without improving bone health.

Dictionary of Terms

- **Functional hypothalamic amenorrhea** – This is a form of hypogondatropic hypogonadism caused by conditions such as undernutrition, excessive exercise, and emotional stress, where there is no organic pathology. It is a diagnosis of exclusion.
- **Physiologic estrogen replacement** – This refers to replacement of estrogen in doses that mimic physiological levels, with estrogen administered as 17β-estradiol, the natural form of estrogen
- **Combined oral contraceptives** – This refers to oral contraceptive pills that contain ethinyl estradiol (10–35 mcg), and a progestogen (such as norethindrone, levonorgestrel, desogestrel, norgestimate, and ethynodiol diacetate (among others)). Neither the estrogen nor the progestogen is a physiologic form of the hormone.
- **Bone anabolic hormone** – One that increases bone formation
- **Antiresorptive effect** – Effect resulting in decreased bone resorption
- **Anorexigenic** – Appetite suppressing
- **Orexigenic** – Appetite stimulating

Summary Points

- Anorexia nervosa is associated with alterations in several neuroendocrine axes (adaptation to the state of undernutrition)
- Endocrine changes include functional hypothalamic amenorrhea (hypogonadotropic hypogonadism), relative hypercortisolemia, a nutritionally acquired growth hormone resistance with low insulin like growth factor-1 levels, low levels of leptin and oxytocin, and high levels of ghrelin and peptide YY.
- Low body mass index, reduced lean mass, and hormonal alterations contribute to low bone mineral density in adults and reduced bone accrual in adolescents with anorexia nervosa leading to suboptimal peak bone mass acquisition and increased fracture risk.
- A multidisciplinary treatment team is necessary to manage patients with anorexia nervosa.
- Weight gain and menstrual recovery improve bone mineral density in adults and bone mineral accrual in adolescents with anorexia nervosa at multiple sites (though residual deficits persist).
- Calcium and vitamin D intake should be optimized.
- Transdermal 17β-estradiol in replacement doses (100 mcg) with cyclic progesterone or a progestogen may be considered in adolescents with a bone age of at least 14 years, whose bone mineral density Z-scores are low and decreasing over time, or if there is evidence of skeletal fragility.
- Combined oral contraceptives are not effective in increasing bone mineral density and mask spontaneous resumption of menses. They should be avoided except for reasons of contraception.
- Bisphosphonates increase spine and hip bone mineral density in adults with anorexia nervosa, but benefits in adolescents are limited only to the hip; if considered for treatment, they should be administered with great caution given their long half-life.
- Teriparatide increased bone mineral density at the spine in older women with anorexia nervosa in one small study – these data need to be confirmed with additional studies.

Male Anorexia as an Eating Disorder: Similarities and Differences with Anorexia Nervosa in Women

34

Karin Sernec and Špela Brecelj

Contents

Abstract

Anorexia nervosa is a chronic mental disorder manifested as persistent restriction of energy intake leading to significantly low body weight, intense fear of gaining weight or becoming fat, and disturbance in body schema. The title of this chapter, which so explicitly relates to men, aims at overcoming the myth that eating disorders affect only female patients; at the same time, it also suggests that eating disorders, including anorexia nervosa, are nevertheless gender-related. According to some recent studies, men represent as much as one fourth of all anorexia patients. Male anorexia nervosa is similar to female anorexia nervosa in many

respects, but there are also gender- and sex-specific traits related to the history of body weight fluctuations, the type of compensatory behavior used to achieve weight loss, the patient's motivation for weight loss, the frequency of recorded sexual abuse, sexual identity, and sexual orientation, any recognized comorbidity, and the body schema and body image, in conjunction with the increasing frequency of objectification and sexualization of the male body in the media. Since amenorrhea is no longer an essential diagnostic criterion for anorexia nervosa, the diagnosis of this disorder in male patients has become easier. This may be one of the reasons for the increasing incidence of this disorder among men in recent years. It makes sense for this trend to be accompanied by increased attention from researchers and clinicians if they are to meet this population's specific therapeutic needs.

Introduction

Anorexia nervosa (AN) is a chronic mental disorder manifested as a dysfunctional attitude toward food. It represents an external expression of a profound emotional distress and a lack of self-acceptance. Through food restriction and/or purgative behavior, patients maintain an excessively low body weight (below 85% of their ideal weight). This is accompanied by a strong fear of weight gain, along with the signs of an endocrine dysfunction. Clinical experience shows that various eating

disorders (ED) are parts of the same spectrum, they can morph into each other in the same patient and ultimately they all lead to undernourishment. This chapter focuses on AN, in which undernourishment results primarily from restricted intake of micro- and macronutrients. It should be noted that the name anorexia nervosa (lat. from gr. *anorexis* = loss of appetite) is a misnomer, because patients do experience hunger and have appetite. The causes of undernourishment are much more complex and should be sought in a specific interweave of biologic, psychodynamic, and socio-cultural factors.

The title of this chapter, which so explicitly relates to males, aims at overcoming the myth that ED affect only female patients. At the same time, it also suggests that ED, including AN, are nevertheless gender-related. Epidemiological data has shown a significant percentage of men among patients with AN; according to some studies, it is as high as one fourth of all patients (Hudson et al. 2007). The finding that ED are not related exclusively to the female gender goes hand in hand with the finding that ED in males differ from those in females in many respects, and that gender plays a significant role in the development of such disorders (Stanford and Lemberg 2012).

With the present discrepancy between the quantity and quality of literature on AN in male and female patients, it is interesting to note that the first medical description of AN was gender-balanced: In 1689 Richard Morton described two cases of a "Nervous Consumption as a result of Sadness and Anxious Cares" (Silverman 1990, p. 3), one in Mr. Duke's daughter and one in Minister Steele's 16-year-old son (Silverman 1990). The description of a melancholic boy who fasts and starves himself to the extreme limits of his body can also be found in the records of eighteenth century physicians Robert Whytt and Robert Willan (Silverman 1990). The asceticism – which in terms of eating is very close to AN because of its restrictive nature, the fear of gaining weight, and the related disgust – can be recognized in both men and women through a significant part of history (Banks 1996). Siddhartha Gautama, Zarathustra, and Christian hermit saints come to mind. Furthermore, AN can also be recognized in the diary entries of Lord Byron (Morgan 2008) and Franz Kafka (Morgan 2010). In the nineteenth century, AN was not named "anorexia hysterica" exactly because this disorder was also recognized in men, who traditionally could not be characterized as hysteric (Crisp and Burns 1983).

Modern epidemiological studies state a 0.2–0.3% lifetime prevalence of AN among males, whereby the ratio of the genders ranges between 1:3 and 1:12 (Raevuori et al. 2014). It is probable that the differences in data and differences in prevalence rates between the genders at least partially reflect insufficient recognition of AN among male patients, as well as the stigma and shame which prevent many men from seeking medical help for this disorder which is still considered "female" among both lay persons and medical professionals (Wooldridge and Lytle 2012; Raevuori et al. 2014). The difficulties experienced by young men in recognizing their own ED because of inadequate, female-oriented information have been reported (Raisanen and Hunt 2014).

The Problem of Diagnosis

The diagnostic questionnaire EDE-Q proved to have a lower reliability when applied to men (Reas et al. 2012). Similar findings were also noted in the case of EDI-3 (Stanford and Lemberg 2012) and EDE (Darcy et al. 2012). Women received a significantly higher number of points for items related to the desire for being thin and for dissatisfaction with their bodies (Stanford and Lemberg 2012). The majority of diagnostic tools for ED is adjusted to the female population and the specifically female set of symptoms; they are also validated only in women (Boerner et al. 2004). This is because, until recently, it was believed that men represent less than 10% of all persons suffering from ED (Crisp and Burns 1983).

Studies addressing the validity of diagnostic questionnaires for the male population have revealed a need for designing questionnaires that would contain specifically male topics: instead of focusing on the desire to lose weight, they should concentrate more on the patient's desire to increase muscle mass; instead of questions about satisfaction with the appearance of their hips, buttocks, and legs, questions on the patient's satisfaction with his stomach, pectorals, and arms are more informative. Regarding the symptoms of an ED, questions that are more relevant to men are related to compulsive overexercising (Fig. 1), fear of gaining weight on account of fatty tissue (Figs. 2 and 3), and preoccupation with the lean, muscular body ideal (Fig. 4). As proposed by the authors, if such questions were included, diagnostic questionnaires would become more sensitive to men (Darcy et al. 2012; Stanford and Lemberg 2012; Bjork et al. 2012).

The insistence on keeping amenorrhea among the essential diagnostic criteria for AN may be one of the main reasons for the blind spot which developed in the field of male AN in the middle of the previous century (Crisp and Burns 1983).

Fig. 1 Compulsive exercise. Patients feel compelled to overexercise and struggle with guilt and anxiety if they are not able to do so (Illustration by Alba Korošec 2017, published with permission)

Fig. 2 Food restriction without loss of appetite. Due to distorted body schema and morbid fear of gaining weight patients refrain from eating most foods while fantasizing about food most of the time (Illustration by Alba Korošec 2017, published with permission)

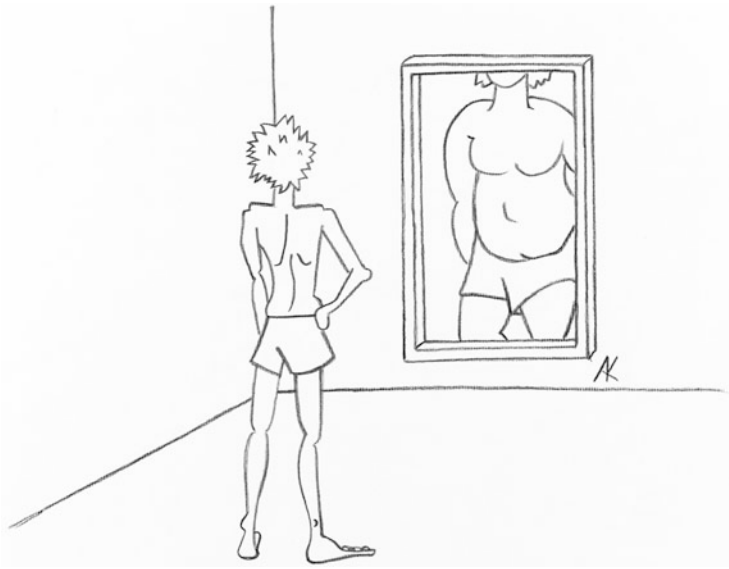

Fig. 3 Distortion of body schema. Patients erroneously perceive themselves as well fed or obese while often being dangerously undernourished (Illustration by Alba Korošec 2017, published with permission)

Fig. 4 Preoccupation with a muscular, lean body ideal. Exposure to the thin ideal and sexual objectification of males in mass media may lead to body dissatisfaction, internalization of the thin ideal, and disordered eating among young men (Illustration by Alba Korošec 2017, published with permission)

Table 1 Comparison of anorexia nervosa in male and female patients: History and presentation

	Male	Female
Pre-morbid history of body mass index	Commonly overweight or obese	Normal range body mass index
Compensatory behaviors	Overexercising	Self-induced vomiting, restriction
Motivation for dieting	Avoidance of obesity-related disease and lean, muscular body ideal	Thinness
Clinical signs of endocrine dysfunction	Loss of sexual interest and potency	Amenorrhoea
Comorbidity	Substance abuse	Depression
	Autistic spectrum disorder	Anxiety
	Underdiagnosed depression	Sexual abuse
	Unrecognized sexual abuse	Underdiagnosed substance abuse

The revised section on Feeding and Eating Disorders, DSM-V (American Psychiatric Association 2013) describes AN as a disorder which develops primarily in young girls, but the criterion of amenorrhea is no longer essential. While stating the frequency of AN in young women, it is added in the latest version of the ICD-10 (World Health Organisation 2016) that this disorder can also be found in adolescents and young men. In addition to amenorrhea, the male correlates of an endocrine disorder, namely loss of sexual interest and potency, have been added to the diagnostic criteria. In prepubescent boys, an endocrine disorder within the scope of AN is indicated by underdeveloped, juvenile genitalia (Table 1).

Clinical Presentation

In the majority of boys with AN, this disorder develops in early puberty, when major shifts in weight are common. Gaining more fatty tissue than muscles appears to be a risk factor for AN in boys and girls alike (Scott 1986). Not all men with AN are obese before the onset of this disorder; however, there are many who are indeed overweight (Fernandez-Aranda et al. 2004; Wooldridge and Lytle 2012). Unlike men, women with AN seldom have a history of obesity, they only feel overweight (Anderson 1990).

It is reported that men hospitalized for AN are on average older than women with the same disorder, they have a higher BMI upon admission, and also higher minimum and maximum BMIs, along with a higher ideal BMI (Raevuori et al. 2014). In men with AN, the duration of hospitalization is usually shorter than in women. Fewer suicide attempts are also reported, along with less somatization, and less frequent obsessive-compulsive symptoms or social anxiety (Raevuori et al. 2014). The same authors also found no differences between the genders in terms of mortality, binging and purging symptoms, and the abuse of laxatives, weight loss products, and psychoactive substances. For both sexes, the possibility of developing AN is higher in twins, triplets, and children with low gestational age at birth. Unlike women with AN, no correlation with the educational degree of the parents or the mother's higher body weight before pregnancy was found in men with this disorder (Raevuori et al. 2014).

Family Environment, Personality Traits, and Psychiatric Comorbidity

One of earlier descriptions of male AN states surprisingly varied family circumstances among adolescent men with AN (Beumont et al. 1972). Even decades ago, studies of family background in young men with AN showed a uniform distribution among all social classes, while women with AN were still perceived to originate from higher social classes (Scott 1986). More recent studies report certain similarities between the families of adolescent men with AN: they often come from single-parent families, and their fathers often live elsewhere or are deceased, while the mothers tend to be excessively controlling and protective, preventing their sons from developing full independence and autonomy, and having high expectations of their sons (Wooldridge and Lytle 2012).

Gila et al. (2005) found that there were no differences between young men with AN and healthy controls in terms of perfectionism and fear of adulthood (both characteristic of women with AN). Yet another group of researchers found a statistically significant association between perfectionism and starving in men (Forbush et al. 2007). Based on the differences in personality traits and comorbidity among women with the restrictive and purgative form of AN (Lavender et al. 2013), one might expect similar differences to be exhibited in men, but such specific studies are yet to be conducted. There are reports of less frequent abuse of laxatives in men, who

rather resort to compulsive physical activity, while the data on the frequency of other purgative behavior in men is not uniform (Murray et al. 2010; Nunez-Navarro et al. 2012, Gueguen et al. 2012).

Based on the mirror-image distribution by gender between autistic spectrum disorders (ASD) and AN, and a similar pattern of social and cognitive functioning, Zucker et al. (2007) posed a hypothesis that autistic spectrum traits are manifested as AN in female patients and ASD in males. Koch et al. (2015) found a higher cooccurrence of AN and ASD in male than in female patients. The cognitive profile of men with AN was also studied by Tchanturia et al. (2012), and they found a higher level of impulsivity in males than in female patients with AN, while compared to healthy controls both genders achieved much lower IGT scores, indicating poor decision-making.

In both genders, AN commonly presents along with depression, anxiety disorders, obsessive-compulsive disorders, personality disorders, and substance abuse. Researchers have found more similarities than differences between the genders in terms of psychopathology and comorbidity (Fernandez-Aranda et al. 2004; Ulfvebrand et al. 2015), but this finding is not universally accepted among researchers. A study on American veterans with ED included 25 men with AN, of whom 92% had at least one other psychiatric diagnosis. The frequencies of mood disorders was comparable to the values for female patients, but there was more abuse of alcohol and other substances, as well as more concomitant schizophrenia or psychotic disorders; this is consistent with earlier reports (Striegel-Moore et al. 1999). In men with ED, Bean et al. (2005) found less marked symptoms of psychopathological comorbidity, but in female patients more successful remission from these symptoms was noted during hospitalization. Study results are therefore not uniform, certainly also because of the relatively low prevalence of AN among men. Strother et al. (2012) consider the related stigma – which compels men to transform their depression and shame into auto- and heteroaggressive behavior and to abuse psychoactive substances – as the possible reason for meager data on the frequency of depression among males with ED. Data on different suicidality rates between the genders is contradictory; Bramon-Bosch et al. (2000) recorded a higher suicidality rate on a sample of 10 men with AN, while others have noted fewer suicidal attempts among males with AN (Gueguen et al. 2012).

Gender Identity, Sexual Orientation, and History of Sexual Abuse

Male AN is probably much more frequent than indicated by research data. One of the reasons why men find it more difficult to seek professional help might be the fear of being incorrectly characterized as homosexual (Birmingham et al. 2004). However, among men suffering from AN there are more heterosexual than homosexual men, and naturally, among homosexual men there are more of those who do not have AN than those who have it. ED thus do not only affect women and men who have sexual relations with men. But the percentage of homosexual, bisexual, and transsexual men among males with AN is indeed higher than in the general population, which

indicates a special vulnerability of these groups to develop ED (Ewan et al. 2014; Wooldridge and Lytle 2012). Wooldridge and Lytle (2012) and Dakanalis et al. (2012) have summarized the possible reasons for such vulnerability: like women, homosexual men are often exposed to greater pressures to maintain an attractive, lean, and muscular body. This population more frequently uses dieting for weight loss and exhibits more depression and dissatisfaction with one's own body. These individuals are also more prone to perceive themselves as sexual objects, and the history of childhood sexual abuse is more common among them. As summarized by Strother et al. (2012), in boys, the history of childhood sexual abuse is frequently associated with issues in forming their gender identity and sexual orientation, because the perpetrators are mostly male. Due to the stigma and shame which are disproportionally greater in male than in female victims of sexual abuse, the frequency of such trauma in males with AN is underestimated. Among patients with ED, approximately 30% have experienced sexual abuse, and a disproportionally greater number of abuse cases is recorded in females than in males (Strother et al. 2012).

Male AN is characterized by low serum testosterone with the resulting loss of sexual desire and impaired sexual function. This state of asexuality can serve to avoid taking on male sexual and social roles (Romeo 1994). The loss of interest in sex may in some cases persist in spite of appropriate body weight during remissions of AN (Beumont et al. 1972). In their study of sexual identity disorder in conjunction with AN in male monozygotic twins, Hepp et al. (2004) posed a hypothesis that starving and maintaining a very low body weight may be how these individuals inhibit their libido, limit the expression of secondary sex signs of their biological sex, and try to come closer to the female ideal of attractiveness. Similar findings have been reported by Ewan et al. (2014) regarding transsexual men in whom AN serves the function of preventing male-pattern weight gain. For this reason, authors recommend that sex change procedures, when appropriate, might be the only way towards remission of AN (Ewan et al. 2014).

Body Schema, Body Image, and Ideals

The problematization of to the objectification and sexualization of the female body in the media did not yield the desired results. The notorious "male gaze," which has transformed women into third-party observers of their own image, is now also directed against men. The number and explicit nature of objectification of men as sexual objects is increasing, and because of this the male body ideal moves even farther away from any realistic standards. Large shifts in the male body ideal are illustrated by action figure design that in the last 30 years developed to produce figures far more muscular than any human bodybuilder at their peak (Pope et al. 1999). Such sociocultural changes are not without consequences; a meta-analysis of 15 studies has shown a small, but statistically significant relationship between exposure to images of ideal male bodies among young men and their body dissatisfaction (Blond 2008).

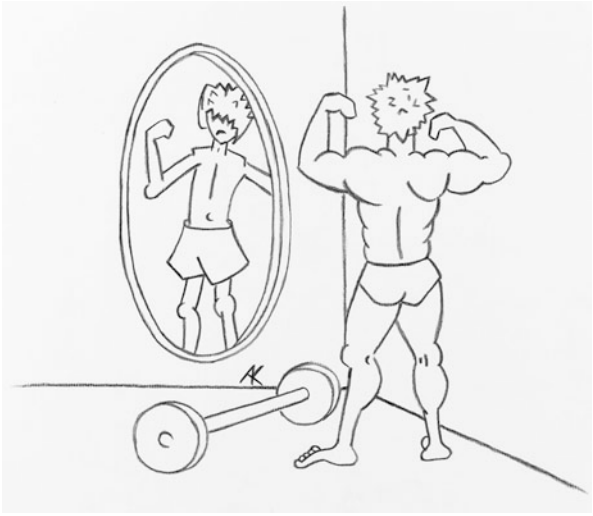

Fig. 5 Reverse anorexia as a body dysmorphic disorder. Unlike anorexia nervosa, bigorexia is characterized by a drive to be muscular, "big," while perceiving oneself as skinny, scrawny. This often leads young men to abuse anabolic steroids (Illustration by Alba Korošec 2017, published with permission)

The level of dissatisfaction with their own bodies among men has been on an increase in the past decades and has reached the level of dissatisfaction observed in the female population (Murray et al. 2010). Unlike women, who wish to be thinner, men more often desire larger and highly muscular bodies. This is often complicated by a disordered body schema. A study that included 17 men with AN, showed that these men do not differ significantly from healthy controls in terms of their ideal body type, but men with AN perceived themselves to be almost twice as fat as they objectively were (Mangweth et al. 2004). A study which compared the symptoms of bigorexia (muscle dysmorphia) and AN found that the only significant difference between these two groups was the marked motivation to gain muscle mass in the case of bigorexia, in which the abuse of laxatives and anabolic steroids is more frequent, while both groups experienced the same level of dissatisfaction with their body image (Fig. 5; Murray et al. 2010). In a study which compared male adolescents with AN to a healthy control group, Gila et al. (2005) found that both groups of young men overestimated the dimensions of their bodies, but those with AN exaggerated much more when estimating the circumference of their shoulders, hips, and thighs. The authors interpreted this difference as an indicator of a special, socioculturally determined meaning of these body parts for men with AN, in particular because these body parts are the same that worry women with AN (Gila et al. 2005).

Peer bullying and criticism regarding body weight is another common risk factor for developing ED. Young men with AN may be especially sensitive to teenage bullying, which targets their once excessive body weight (Sterling and Segal 1985).

Unlike female patients who are driven by a desire for thinness, according to research results summarized by Strother et al. (2012), the main motivation of male

patients to lose weight is to avoid diseases associated with obesity and to achieve better sports results. "Antigravitational" sports pose a high risk for the development of AN, so-called anorexia athletica (Sudi et al. 2004; Weltzin et al. 2012). In addition to sports in which a low body weight and a low body fat constitute a competitive advantage (ski jumps, running, horse riding, wrestling, diving, etc.), those sports in which the athlete's aesthetic appearance is very important (e.g., gymnastics, figure skating, dancing etc.) also represent a risk factor (Sudi et al. 2004; Baum 2006).

Biological Characteristics

Undernourishment during childhood and puberty has many consequences, the most readily visible being growth retardation. In AN, there are many hormonal changes which accompany starving and contribute to growth retardation: low levels of thyroxine (T_4) and triiodothyronine (T_3), increased cortisol levels, and low levels of sex hormones (Modan-Moses et al. 2003). In distinction from undernourishment during childhood, in which restoring of adequate nourishment is followed by accelerated bone growth, through which the patient can achieve the anticipated height (catch-up growth), undernourishment during puberty will lead to permanently reduced height. Since growing boys have greater caloric needs and a longer bone growth period than girls, undernourishment as part of AN may limit growth more in male than in female patients, although study results regarding this difference are not uniform (Modan-Moses et al. 2003).

By measuring bone mineral density in men and women with AN, Mehler et al. (2008) found that osteoporosis is disproportionally more common and more pronounced in men than in women, while the risk for it was proportionate to the patient's age, duration of the disease, and lower body weight. Like the reduced level of serum albumin, pancytopenia, electrolyte disturbances in the purgative type of AN, sinus bradycardia, other ECG abnormalities, and the starving-induced autophagia, which leads to increased serum transaminase levels, osteoporosis is also a common finding in both male and female patients with AN (Table 2; Sabel et al. 2012; Foppiani et al. 2014).

AN is characterized by hypogonadism, and the level of serum testosterone in males may not return to normal even after weight restoration, suggesting a need for testosterone replacement in such patients (Wooldridge and Lytle 2012). In males with AN, markedly reduced testosterone levels can be proved in urine; clinically, this is usually manifested as cessation of spontaneous morning erections, strongly reduced libido, and cessation of masturbation (Crisp and Burns 1983). The results of a longitudinal study monitoring serum leptin levels during weight gain and body fat gain within the scope of AN treatment of three young men (Wabitsch et al. 2001) support the hypothesis that leptin as the regulator of the hypothalamic-pituitary-gonadal function is responsible for normalizing gonadotropin and testosterone levels in men.

Table 2 Some of the relevant biological abnormalities found at admission in addition to low body weight with depleted body fat mass and muscle mass in males with anorexia nervosa

Abnormality at admission	% of patients	Total No. of male anorexia nervosa patients included in the study	Study
Reduced testosterone levels	100	14	Sabel et al. (2012), mean age 24 years, BMI range 11.5–15.9 kg/m^2
	66	3	Wabitsch et al. (2001), mean age 15,3 years, BMI range 12.5–17.3 kg/m^2
Growth retardation	92	12	Modan-Moses et al. (2003), mean age 14.3 years, BMI range 13.5–18 kg/m^2
Leukopenia	79	14	Sabel et al. (2012)
Cortical atrophy	70	10	Siegel et al. (1995), mean age 16 years, BMI range 10.9–16.9 kg/m^2
Anemia	70	10	Siegel et al. (1995)
	57	14	Sabel et al. (2012)
Increased transaminase levels	66	14	Sabel et al. (2012)
Reduced leptin level	66	3	Wabitsch et al. (2001)
Vitamin D deficiency	65	14	Sabel et al. (2012)
Mild-to-moderate hypophosphatemia	50	14	Sabel et al. (2012)
Thrombocytopenia	7	14	Sabel et al. (2012)

Therapy and Prognosis

The course of recovery from ED is slow and repeated admissions to treatment programs are common. The basic therapeutic approach in all AN patients involves the following main objectives: stabilization of the patient's somatic status with weight normalization and alleviation of permanent consequences of undernourishment; changing dysfunctional beliefs and behavioral patterns through the use of cognitive-behavioral therapeutic interventions; and overcoming obstacles to achieve remission of the ED by providing relief from affective disorders, anxiety, and other psychiatric comorbidities using pharmacotherapy in addition to psychotherapeutic management of past trauma, victimization, and any relationships which maintain the disorder (Weltzin et al. 2012). Through the prism of dynamic-analytical psychotherapy, the symptoms of AN are viewed as expressions of the patient's needs and issues, concerning control over one's life, power in interpersonal relationships, self-punishment,

and avoidance of the social role of a grown-up of one's own gender. Because the symptoms of AN are initially usually quite effective in fulfilling these needs, the disorder is egosyntonic, i.e., in harmony with one's own goals and consistent with one's own self-image. It is only after the symptoms become too destructive that the patient begins to be motivated for therapy (Sernec 2012). The management of AN can be done on an outpatient basis, in a hospital or a day hospital, within a live-in facility, or in group or individual psychotherapeutic setting.

Weltzin et al. (2012) suggest male-only therapeutic groups and emphasize that a separate male treatment program helps men overcome the biases of EDs being "female" disorders, and expressing of emotions being a sign of weakness.

In the available literature, less information can be found regarding motivation for treatment in males with AN than one would expect for such an important topic determining treatment outcome (Wade et al. 2009). In addition to insufficient motivation for treatment, resulting in high rate of drop-out (Sly et al. 2013), a possible source of complications in treating severe and enduring AN is also the potentially fatal refeeding syndrome, for which no differences in frequency have been found between the sexes (Sabel et al. 2012).

The full remission of AN, marked by the return of spontaneous menstrual activity in women, is less well defined in men. The increase in body weight to the range within 85% of the expected value may be too mild for the male population. This is because in the male body, fatty tissue accounts for a smaller percentage of total body weight and recovery would therefore be indicated by a weight which is much closer to the ideal body weight (Burns and Crisp 1990). In their study of treatment outcomes in 28 males with AN, Burns and Crisp (1990) posed the criterion of potency, which is indicated by sexual activity (intercourse, masturbation), as the equivalent of the menstrual activity criterion. According to their criteria, good treatment outcomes were achieved in those patients who were regularly sexually active and who restored their body weight to at least 85% of the MPMW (Table 3). Achieving only one of the two remission criteria signified intermediate outcome and failing to achieve either of the two criteria meant poor outcome (Burns and Crisp 1990).

Among 24 male patients included in their retrospective cohort study, Gueguen et al. (2012) reported three deaths, all of which were due to complications of the restrictive subtype of AN, and all of the three patients also discontinued their treatment early. In this study, long-term survival in the severe form of AN did not show any differences between the genders, while higher age, lower BMI upon

Table 3 Comparison of anorexia nervosa in male and female patients: Treatment outcome and recovery

	Male	Female
Indicators of good outcome	Normal weight Regular sexual activity and spontaneous morning erections	Normal weight Regular menstrual activity
Patient's experience of recovery	Exercise without compulsion Less worried about relapsing	More worried about relapsing

hospital admission, and the restrictive subtype of AN were shown to predict poor treatment outcomes (Gueguen et al. 2012).

Bjork et al. (2012) detected a difference between the sexes in how they experienced recovery from ED. Both shared a common understanding of recovery in the sense of acceptance of one's own body, improved confidence, better handling of emotions, better problems solving skills, more relaxed attitude toward food, and improved social life. However, men more often reported being able to exercise without compulsions, and they expressed less concern about relapsing than women (Bjork et al. 2012).

Conclusion

The growing rate of AN among young men is likely to continue in the future. In many respects, male AN is similar to that in women, but it also shows gender- and sex-specific issues that should be addressed in order to provide a comprehensive treatment for this population. The increasing scope of research in this complex field provides ever more pieces of this puzzle, although the pieces are often contradictory and rather than contributing to its understanding, they tend to exacerbate the enigmatic nature of this disorder. The initiatives for more intense research of ED in men, which would shed more light on this particular topic and enable timely, appropriate treatment for men with AN, reflect the current situation in the field of medical research in general, wherein up until recently researchers acted as if sex or gender did not matter and viewed a large majority of disease entities and treatment modalities as directly transferrable from men to women. The pluralism of gender identities, which is manifested as a real factor in the development of ED including AN, may show that the understanding of this phenomenon cannot be adequately approached by merely comparing the two traditional biological sexes and social genders and that it might be prudent to look beyond the dichotomy.

Policies and Protocols

A distinction should be made between life-saving interventions, in which motivation is not crucial, and comprehensive psychosocial management of anorexia nervosa, for which motivation is vitally important.

In men with anorexia nervosa, shame is one of the prevailing emotions, and it partially originates from the general belief that eating disorders are "female disorders." This is why staff working with these patients should be experienced in working with males and should show particular empathy and understanding of their specific issues.

It is important to pay special attention to any masked comorbidities, such as depression and anxiety. The possibility of concurrent abuse of both legal and illegal substances should be considered. The patients should be evaluated for concurrent overexercising and gently asked about their gender identity. In the case of transgender issues, management should include a broad team of specialists needed to lead the patient through the sex change process if appropriate.

Sexual abuse in males is often overlooked and therapists should always ask about it.

The level of sexual activity is an indicator of the seriousness of this disorder and of treatment outcome. Regular sexual activity which includes desire, fantasizing, masturbation, and intercourse reflects the level of testosterone and predicts a good outcome.

Family environment plays a significant role in the development of anorexia nervosa. Family involvement in the treatment of this disorder has beneficial effects on patient motivation and reflects the level of support available, so family members should be invited to participate whenever possible.

Dictionary of Terms

- **Body image** – A person's perception of the attractiveness of one's own body.
- **Body schema** – An internal awareness of the body and the relative shape and position of body parts.
- **Cognitive behavioural therapy** – A therapeutic approach that aims to modify distorted beliefs and cognitive processes that maintain disordered behavior.
- **Compulsive exercise** – Exercise that is continued despite overuse symptoms, injury, or social isolation.
- **Eating disorder** – A chronic mental disorder defined by abnormal, harmful eating habits that impact on daily functioning, usually accompanied by a high degree of anxiety around food and eating, body image distortions, and a preoccupation with food.
- **Impulsive behaviours** – Behaviors that are characterized by little or no forethought, i.e., explosive anger, binging and purging, unprotected casual sex, self-harming behaviors, substance abuse, excessive money spending, etc.
- **Manorexia** – A reference to anorexia nervosa in males.
- **Muscle dysmorphia** – Also known as reverse anorexia or bigorexia, a form of body dysmorphic disorder, but also classified as an eating disorder characterized by a pathological preoccupation with muscularity.
- **Perfectionism** – A multidimensional personality trait characterized by a strong drive for flawlessness, setting excessively high goals and performance standards, being overly self-critical, and concerned about others' evaluation.
- **Psychodynamic psychotherapy** – This therapeutic approach builds on the belief that all behaviors are derivatives of internal conflicts and unconscious motives, while symptoms are assumed to disappear with the completion of working through these issues.
- **Purgation** – Compensatory behavior undertaken in order to "un-do" eating or to compensate for the calories consumed, i.e., self-induced vomiting, misuse of laxatives or diuretics, enemas, and overexercising.
- **Restriction** – The reduction or elimination of certain foods or food groups from one's diet, usually the ones perceived as fattening or unhealthy.

Summary Points

- Anorexia nervosa is a mental disorder which develops mainly in women, although more recent studies have shown that up to 25% of such patients are male.
- Since anorexia nervosa is still considered a "female" disorder by lay persons and frequently also by medical professionals, this bias prevents men and their doctors/therapists from properly recognizing this disorder and providing timely and appropriate treatment.
- In both genders, its clinical presentation is manifested as undernourishment and gonadal dysfunction. However, there are also gender-specific traits that have to be considered in order to offer comprehensive therapeutic management.
- Males with anorexia nervosa commonly struggle with gender identity and sexual orientation issues, but this is not a rule and should not be made into a new stereotype.
- Males with anorexia nervosa more commonly than women have a history of being overweight and were exposed to peer bullying on account of obesity.
- The most common type of compensatory behavior in male anorexia nervosa is compulsive physical activity.
- In addition to an eating disorder, depression and sexual abuse are often overlooked in men.
- More often than in women with anorexia nervosa, male patients also suffer from the abuse of alcohol and other substances, as well as autistic spectrum disorders, schizophrenia, or psychotic disorders.
- In the media, increasing objectification and sexualization of the male body is observed. As the level of dissatisfaction with one's own body increases among young men, it approaches the level observed in women.
- The modern ideal male body involves an extremely lean and muscular physique. Male patients with anorexia nervosa share this ideal, but due to a disturbed body schema, they perceive themselves as much more overweight and as having more fat than is objectively true.
- Appropriate body weight, positive body image, and regular sexual activity indicate successful recovery from male anorexia nervosa.

Screening Tools, Classifications, and Applications

Subjective Global Assessment (SGA) of Malnutrition

35

Narayan Prasad and Archana Sinha

Contents

Abstract

Malnutrition is a highly prevalent and well-recognized problem in hospitalized as well as in general population but often goes unrecognized. Nutrition assessment is a comprehensive approach to define nutritional status using various methods.

Subjective Global Assessment (SGA) is one of the most commonly used methods to assess nutritional status. SGA is a semiquantitative tool to assess nutritional status based on the history and physical examination. Data are scored subjectively and determine nutritional status in three major SGA categories as well nourished (A), mild to moderately malnourished (B), or severely malnourished (C). It is simple, noninvasive, inexpensive, and quickly executable and can be performed bedside by any skilled and trained health-care professional after brief training. It also agreeably goes with the objective methods of evaluating nutritional status. Various modified versions of SGA have been proposed since its conception to improve its precision. It helps in identifying malnutrition, predicting outcomes, and making appropriate recommendations in hospitalized patients as well as in general population.

Introduction

Malnutrition is caused by an imbalance between nutrient intake and demand. “The deficient nutrient intake or uptake results into altered body composition in form of decreased fat-free mass and body cell mass leading to reduced physical and mental function and impaired clinical outcome from disease” (Sobotka 2012). Jensen et al.

(2009) defined malnutrition as "decline in lean body mass with the potential for functional impairment." Malnutrition in hospitalized patients may be different from general population. Butterworth defined malnutrition as the "skeleton in the hospital closet" (Butterworth 1974). It is an unrecognized or poorly identified ailment in hospitals (Waitzberg et al. 2001).

A little improvement has been observed in prevalence of malnutrition reported in 1970–1980s (Bistrian et al. 1974; Weinsier et al. 1979) as compared to few recent reports (Waitzberg et al. 2001; Kyle et al. 2003; Prasad et al. 2008). We have also observed that majority of ESRD patients (74.9%) had some degree of malnutrition at the initiation of dialysis in 1 of our study of 283 patients (Prasad et al. 2008). Exact estimation of the prevalence of malnutrition is challenging. Prevalence of in-hospital malnutrition has been estimated between 15% and 60% at admission (Amaral et al. 2010), and the prevalence goes up to the tune of 75% in patients with prolonged length of stay in hospital (Wysynski et al. 2003). However, this scenario may be different in developed and developing countries. In estimations from developed countries, it has been observed that malnutrition impacts at least one in three patients upon hospital admission (Tappenden et al. 2013; Lim et al. 2012). Two of three experiences further decline if left untreated during the hospital stay. At least, one in three *may become* malnourished who were not malnourished at admission during their hospital stay (Tappenden et al. 2013; Braunschweig et al. 2000). Overall varying from 20% to 50% of hospitalized adult patients may be malnourished (Kirkland et al. 2013).

Assessment of Malnutrition and SGA

Despite high prevalence and a well-recognized problem in hospitalized patients as well as in general population, there is lack of uniform definition and universal standard tool for estimating malnutrition. It poses challenges before clinicians and clinical nurses in quantifying malnutrition, and the assessment of the nutritional status of patients is not routinely carried out (Mowe et al. 2006; Elia et al. 2005). Nutrition assessment is a comprehensive approach to define nutritional status using medical, nutrition, and medication histories, physical examination, anthropometric measurements, and laboratory data (ADA 1994). ASPEN and the ESPEN have made recommendations for good clinical practices in screening of malnutrition (Ukleja et al. 2010; Kondrup et al. 2003).

The exact assessment of nutritional status is cumbersome in day-to-day practice. Severe degree of malnutrition may be clinically obvious, while mild degree of malnutrition is difficult to assess without objective parameters. Diverse nutritional assessment tools varying from anthropometry and biochemical parameters like serum albumin to sophisticated techniques DEXA and BIA to assess body composition are available. Although newer methods like BIA and DEXA give more comprehensive and objectivize values in assessment of nutrition status, however, these methods are technology dependent, time-consuming, and cost-effective in day-to-day practice and as a bedside tool is questionable. The anthropometric tool

(Ulijaszeki and Kerr 1999) and traditional biochemical indices (e.g., albumin, transferrin, retinol-binding protein) become less reliable and often invalid due to the influence of hydration status and coexisting inflammation, particularly in case of critical illnesses. Many non-nutritional factors affect the conventional nutritional tools resulting in their poor sensitivity and specificity (Gibson 1990; Jeejeebhoy 2000). The assessment of nutritional status should be performed with an amalgamation of valid, complementary measures rather than any single measure as no single parameter is sufficiently sensitive or specific to identify malnutrition. The assessment tools become more effective when used in combination (Gibson 1990).

This assessment can be a brief screening, when the patient is comparatively well nourished, or more comprehensive when the patient appears to be malnourished or at risk for malnutrition. It is recommended that nutritional assessment should be performed with easy, simple, rapid, inexpensive, and convenient methods especially when a large number of patients need to be evaluated within a short time. SGA is one of the most commonly used bedside methods to assess nutritional status.

Conventional Subjective Global Assessment

Conventional SGA is semiquantitative tool to assess nutritional status based on the history and physical examination. To surmount the shortcomings associated with traditional nutritional tools like only anthropometry, Baker et al. (1982a) developed this simple tool to assess nutritional status that used a questionnaire encompassing clinical history and physical examinations and classified nutritional status in three different categories well nourished, moderately malnourished, or severely malnourished (Baker et al. 1982a, b). Detsky et al. (1987) further standardized this tool naming it as SGA which encompasses five components of a medical history (weight change in previous 6 months, dietary intake, gastrointestinal symptoms continued for more than 2 weeks, functional capacity, comorbid illness and its relation to nutritional requirements) and three components of a brief physical examination (signs of fat, muscle wasting, and nutrition-associated alternations in fluid balance (presence of pedal/sacral edema/ascites) to assess nutritional status (Fig. 1a). Data are scored subjectively, and patients are classified in terms of the three major SGA categories determining nutritional status as well nourished (A), mild to moderately malnourished (B), or severely malnourished (C) just by subjective consideration of the data collected in the eight areas, without adhering to a rigid scoring system (Detsky et al. 1987). It provides a comprehensive appraisal of nutrition status just based on the features of a medical history and physical examination.

Benefits of SGA

SGA is simple, noninvasive, inexpensive, and quickly executable and can be performed bedside by any skilled and trained health-care professional after brief training. It is capable of identifying malnutrition (K/DOQI-NKF 2000) and gives a

global score of malnutrition. It correlates well with the subjective and objective aspects of medical history and physical examination (McCann 1996). It also agreeably goes with the objective methods of evaluating nutritional status (Enia et al. 1993). SGA can be easily used in routine clinical practice to assess the nutritional status of the patients. Simultaneously, it can also be used in making appropriate recommendations and strategies to prevent malnutrition.

Disadvantages/Limitations of SGA

Subjective nature of SGA limits its precision depending on the experience and skill of the observer in assessing malnutrition (Barbosa-Silva and Barros 2006). The visceral protein levels are not incorporated in this assessment. In spite of extensive use of SGA for initial nutrition assessment, very few studies have reported its use to assess changes in nutrition status over time (Baldwin and Weekes 2012).

a Features of subjective global assessment (SGA) adopted from Detsky et al , 1987

(Select appropriate category with a checkmark, or enter numerical value where indicated by "#.")

A. History

1. Weight change

Overall loss in past 6 months: amount = # _____ kg; % loss = # _____

Change in past 2 weeks: _____ increase,

_____ no change,

_____ decrease.

2. Dietary intake change (relative to normal)

_____No change,

_____Change _____duration = # _____ weeks

_____type: _____ suboptimal liquid diet, _____ full liquid diet

_____ hypocaloric liquids, _____ starvation.

3. Gastrointestinal symptoms (that persisted for >2 weeks)

_____none, _____nausea, _____vomiting, _____diarrhea, _____anorexia.

4. Functional capacity

_____ No dysfunction (e.g., full capacity),

_____ Dysfunction _____ duration = # _____ weeks.

_____ type: _____working suboptimally,

_____ambulatory,

_____bedridden.

5. Disease and its relation to nutritional requirements

Primary diagnosis (specify) _____

Metabolic demand (stress) : _____ no stress, _____low stress,

_____moderate stress, _____high stress.

B. Physical (for each trait specify: 0 = normal, 1+ = mild, 2+ = moderate, 3+ = severe).

_____loss of subcutaneous fat (triceps, chest)

_____muscle wasting (quadriceps, deltoids)

_____ankle edema

_____sacral edema

_____ascites

C. SGA rating (select one)

_____A = Well nourished

_____B = Moderately (or suspected of being) malnourished

_____C = Severely malnourished

Fig. 1 (continued)

b The seven point SGA with more objectivise global assessment (adopted from Lim et al, 2016)).

Fig. 1 (**a**) Features of subjective global assessment. (SGA) (Adopted from Detsky et al. 1987). (**b**) The seven point SGA with more objectivize global assessment. (Adopted from Lim et al. 2016)

Modifications of SGA

Various modified versions of SGA have been proposed since its conception (Detsky et al. 1987). Several attempts were made to convert conventional SGA into a semiquantitative or quantitative tool in order to improve its ability to assess and recognize petite yet significant changes in varying grades of malnutrition in differing clinical scenario.

7-Point SGA

The shortcoming of conventional SGA is that it cannot detect small yet significant changes in nutrition status during follow-up (Visser et al. 1999; Kalantar-Zadeh et al. 1999). To circumvent this drawback of traditional SGA, Churchill et al. (1996) expanded it into 7-point scale to assess the changes in nutrition status of 680 ESRD patients commencing peritoneal dialysis (PD). The 7-point SGA is a modification of the original 3-point ordinal scale SGA (A, B, and C) initially illustrated by Detsky et al. (1987) and Baker et al. (1982a) to 7 points (rating 1 severely malnourished to 7 well nourished (Churchill et al. 1996; McCusker et al. 1996). In this system, four items are scored on a 7-point Likert-type scale, with lower values signifying inferior nutritional status. Parameters were weight loss during the past 6 months, anorexia, loss of subcutaneous fat, and muscle mass. These four items are given subjective weights to produce a global assessment. Scores of 1–2 indicates severe malnutrition, 3–5 mild to moderate malnutrition, and 6–7 normal nutrition. Nutrition assessment performed using the 7-point scale can be aligned with the conventional SGA (i.e., well nourished, moderately malnourished, or severely malnourished).

The 7-point SGA has more potential for classifying patients than does the conventional SGA (de Mutsert et al. 2009). The weight loss pattern has been given more significance in SGA scoring (Detsky et al. 1987). A small improvement or worsening within each category may be identified earlier which can be easily assessed using the 7-point SGA. The 7-point SGA may be much more time sensitive than the conventional SGA in identifying small changes in nutrition status (Campbell 2007a; Lim et al. 2016). Lim et al. (2016) (shown in Fig. 1b) used the 7-point SGA as well as the conventional SGA for nutritional assessment of 67 patients at baseline and reassessed it at 1, 3, and 5 months. It took significantly shorter time to see a 1-point change using 7-point SGA (median value 1 month) as compared to conventional SGA (median, 3 months). The likelihood of at least a 1-point change is 6.74 times greater in 7-point SGA compared to conventional SGA after controlling for age, gender, and medical specialties. Fifty-six percent of patients who had no change in conventional SGA score had changes detected using 7-point SGA. The level of agreement was 100% between 7-point SGA and 3-point SGA and 83% between two-blinded assessors for 7-point SGA.

The overall SGA scoring is not merely a score; it also includes an evaluator's clinical judgment. If the patient deteriorates or improves, the clinician may apply different score to each section to reflect these changes.

Patient-Generated-Subjective Global Assessment

PG-SGA was adapted from the conventional SGA and had been particularly designed for cancer patients in 1994 by Ottery and colleagues. In PG-SGA system, the components of the medical history are completed by the patient himself, and physical examination is performed by health professional either nurses/technician or healthcare professionals. The scored PG-SGA is a further advancement of PG-SGA which provides numerical scoring as well as a global rating in form of well nourished, moderately malnourished, or severely malnourished. For each component of the scored PG-SGA, points (0–4) are awarded depending on the impact of the symptom on nutritional status. A sum of total score provides a guideline to the level of nutritional intervention. The scoring system also allows triaging of the patients. It has been accepted by the Oncology Nutrition Dietetic Practice Group of the American Dietetic Association as the benchmark for malnutrition assessment in oncology patients. A score $\geq$9 indicates the requirement for nutritional intervention (Ottery 1994). The PG-SGA score has also been regarded as one of the most suitable method for identifying nutritional derangements in gynecological cancer patients (Laky et al. 2008). Bauer et al. (2002) reported a sensitivity and specificity of 98% and 82%, respectively, of PG-SGA score for predicting SGA in their study on 71 cancer patients.

Dialysis Malnutrition Score

ESRD patients on dialysis may be different clinically than patients with other medical and surgical illnesses. Kalantar-Zadeh et al. (1999) proposed a modified version of SGA for patients on dialysis which was initially named as modified quantitative SGA and later on as DMS (Kalantar-Zadeh et al. 2001a, 2004b).

All seven features of SGA are evaluated: (1) weight change, (2) dietary intake, (3) gastrointestinal symptoms, (4) functional capacity, (5) comorbidity, (6) loss of subcutaneous fat (triceps, biceps, chest, and below the eyes), and (7) signs of muscle wasting (temples, clavicle, scapula, quadriceps, knee, and interosseous). A score on scale of 1 (normal) to 5 (very severe) is awarded to each of the seven features of SGA. Thus, a total score ranging from 7 (normal) to 35 (severely malnourished) are achieved in each case. Subsequently patients are categorized into (1) normal nutritional status (score 7), (2) mild to moderate malnutrition (score 8–14), and (3) severe malnutrition (score 15–35). The ascites and edema have been deleted from conventional SGA, and dialysis vintage has been added into the comorbidity component.

Malnutrition-Inflammation Score

In order to make DMS scoring system more robust, comprehensive, and quantitative, the evaluation criteria for the seven DMS components were revised in MIS. Three new items BMI, serum albumin level, and TIBC were added. It differs from DMS scoring system in the sense that the number of severity levels of each component was reduced from five to four levels. Thus, the MIS has three

components, each with four levels of severity, from 0 (normal) to 3 (severely abnormal). The sum of all ten MIS components ranges from 0 (normal) to 30 (severely malnourished). A higher score reflects a more severe degree of malnutrition and inflammation. Few studies have reported that MIS score is better correlated with actual nutritional status of patients as compared to the conventional SGA (Kalantar-Zadeh et al. 2001a, 2004a). The MIS is more comprehensive and quantitative and found to be significantly correlating with hospitalization, mortality, and indices of nutrition, inflammation, and anemia as well (Kalantar-Zadeh et al. 2001a; Afsar et al. 2006).

Validity and Reliability of SGA

SGA in either conventional or modified form has been validated as reliable tool for assessing malnutrition in various clinical conditions, cancer patients, postsurgical patients, hospitalized patients, and ESRD patients on dialysis (K/DOQI- NKF 2000; Visser et al. 1999; Ottery 1994; Hirsch et al. 1991; Sacks et al. 2000; Thoresen et al. 2002). SGA gives reproducible results with more than 80% agreement when two-blinded observers have assessed the same patient (Detsky et al. 1987; Mc Cann 1996). The Veterans Affairs perioperative total parenteral nutrition (1991) randomized trial also reported the predictive validity of SGA in malnourished patients of different degrees. Lim et al. (2016) in their study on 67 patients have observed that the 7-point SGA was positively correlated with body mass index and mid-arm circumference with a level of agreement of 100% between the 7-point SGA and 3-point SGA. The inter-rater agreement between two assessors for the 7-point SGA was good, at a rate of 83%.

Hirsch et al. (1991) have validated SGA in a study on 175 patients admitted in medical-surgical gastroenterology and reported a 79% inter-rater reliability between assessments done by residents and nutrition specialists and also confirmed the expediency of SGA even when used by inexperienced professionals. Sacks et al. (2000) have reported a significant correlation between SGA scores and nutritional complications in their study from long-term care facilities. Visser et al. (1999) have found that the 7-point SGA scale has sufficient interobserver and good intra-observer reliability in dialysis patients. Moreover, it also correlates with objective nutritional factors like anthropometric measures and biochemical parameters including prealbumin. The sufficient intra-observer and interobserver reliabilities of the SGA have been documented in various studies regardless of its subjective nature (Visser et al. 1999; Steiber et al. 2007). However, it has been recommended that one observer or a select group of observers should execute SGA to maximize the reliability of SGA (Visser et al. 1999).

Clinical Uses of SGA

SGA can be quickly used in a wide variety of health-care settings such as geriatric patients (Christensson et al. 2003; Stephenson et al. 2001), cancer patients (Bauer

et al. 2002), patients on radiotherapy (Isenring et al. 2003), patients who have liver transplants and chronic liver disease, patients who experience stroke (Davis et al. 2004), pregnant patients, and adult patients undergoing maintenance dialysis (Enia et al. 1993; Visser et al. 1999; Churchill et al. 1996; Cooper et al. 2002). Studies have documented the association of one time SGA on various clinical outcomes including morbidity, hospitalization, and mortality (Steiber et al. 2007; Pifer et al. 2002; Kalantar-Zadeh et al. 2001b). Shirodkar and Mohandas (2005) in their study on 266 cancer patients observed that SGA scores were significantly associated with adverse outcomes like mortality and hospital stay following cancer surgery. In a study on advance colorectal cancer patients, Gupta et al. (2005) reported SGA as an important predictors of survival and also showed that the median survival of patients with SGA-A, SGA-B, and SGA-C was 12.8 months, 8.8 months, and 6 months, respectively. SGA was recommended as the method of choice as compared to Nutritional Risk Index (NRI), anthropometry, and laboratory data in a study on 100 patients undergoing major abdominal surgery (Sungurtekin et al. 2004). In a study (Detsky et al. 1984) in which SGA was initially meant for use in surgical inpatients for assessing malnutrition and predicting postoperative infection, SGA was found to be a better predictor of these complications compared to serum albumin level, delayed skin hypersensitivity, mid-upper arm circumference, creatinine height index, and other prognostic nutritional index. It has also been observed that SGA had the best sensitivity and specificity for predicting infection in post-surgery period (Detsky et al. 1984, 1987). SGA as an independent predictor of mortality in dialysis patients have been reported in several studies (Kalantar-Zadeh et al. 2001a; de Mutsert et al. 2009). It has been also successful in predicting complications and death in ESRD patients on dialysis including HD (Kalantar-Zadeh et al. 1998) and PD (Churchill et al. 1996).

We have observed that peritonitis rate can be predicted as per nutritional status based on SGA. Mean peritonitis rate per patient-year was significantly higher in patients with malnutrition (mean 0.99 episodes per patient-year) compared to patients with normal nutritional status (mean 0.18 episodes per patient-year). Peritonitis-free survival in patients with normal nutrition was significantly higher compared to patients with malnutrition (42 months vs. 21 months) based on SGA (Prasad et al. 2007).

The famous multicenter Canada-USA (CANUSA) study showed that 1-unit decrease in SGA is associated with a 25% increase in mortality risk of PD patients (Churchill et al. 1996). SGA predicts the outcome and the 2-year patients survival rate which was 80.5%, 77.3%, and 47.2% ($P = 0.01$), respectively, in patients with normal nutrition, mild to moderate malnutrition, and severe malnutrition categories assessed by SGA (McCusker et al. 1996). Several other studies also documented that SGA is an independent predictor of patient's survival (Ottery 1994; Kalantar-Zadeh 2001a; Pifer et al. 2002; Chung et al. 2000).

In a different study of 342 patients on PD, authors have observed that the relative risk of death in patient with malnutrition was 3.2 times higher as compared to the patients with normal nutritional status. The 5-year survival of patients with

malnutrition was significantly poor (33%) as compared to well-nourished patients (58%) (Prasad et al. 2010).

SGA has been recommended by K/DOQI- NKF (2000) as one of the panel of nutrition indicators for longitudinal monitoring of CKD patients in view of its strong association with malnutrition (Cooper et al. 2002) and clinical outcomes (Yang et al. 2007). Since initial validation of SGA in HD patients (Enia et al. 1993), SGA has been used as benchmark tool for nutritional assessment in pre-dialysis (K/DOQI-NKF 2000; Cupisti et al. 2004), patients initiating dialysis (Prasad et al. 2007, 2008; Lim et al. 2016; Asgarani et al. 2004; Heimburger et al. 2000) and maintenance dialysis patients as well (Churchill et al. 1996; Pifer et al. 2002; Stenvinkel et al. 1999; Raslan et al. 2010). Malnutrition predicted on SGA has been associated with increased risk of prolonged hospital stay and hospital readmission in a prospective cohort study. Sacks et al. (2000) in their study on 53 facility residents from long-term care facilities have reported a significant association between SGA score and other nutrition-associated complications including death, with severely undernourished residents having the highest mortality rate. The clinical utility of SGA in assessing clinical outcomes on long-term follow-up of dialysis patients is also emerging in a multicenter study (de Mutsert et al. 2009) of incident dialysis patients in which nutritional status was assessed on 7-point SGA at 3 and 6 months after commencing dialysis and every 6 months afterward during 7 years of follow-up. Baseline 7-point SGA was found to be associated with a twofold increase in mortality risk. Time-dependently, the mortality rate in 7 years of follow-up was 11/100 person-years in patients with a normal nutritional, 30/100 person-years with moderate, and 69/100 person-years with severe malnutrition. The stronger time-dependent association indicates that malnutrition was associated with high short-term mortality. SGA appears to be a semiquantitative tool to assess the effect of nutritional status on short-term as well as on long-term outcomes of patients.

Policies and Protocols

Assessment of Components of SGA

All following items of SGA are allocated with a subjective weight: A or 6–7, or normal (well nourished); B or 3–5, or mild-to-moderate malnutrition; and C or 1–2, or severely malnourished.

Weight loss: A score is assigned on a scale from 1 to 7 based on the amount of weight lost or gained compared to previous measurements. A weight loss of >10% over the last 6 months is considered as severe, 5–10% mild to moderate, and <5% normal. Rate of weight loss and its pattern should also be taken into consideration. A recent stabilization or increase in weight after suffering a net weight loss is regarded as well nourished.

Food intake: Food intake of patient is assessed based on the dietary intake compared to patients' usual dietary pattern and intake. Lower scores indicate decreased intake. History of adequate dietary intake meeting nutritional needs with no change or slight change for a short duration is categorized as normal (6 or 7), borderline or decreasing intake as mild to moderately malnourished (3, 4 or 5), and condition of inability to eat and starvation as severely malnourished (1 or 2). The patient is evaluated in detail to quantify and qualify the change in the oral intake.

Gastrointestinal symptoms: Gastrointestinal symptoms (diarrhea, anorexia, nausea, and vomiting) are appraised based on the frequency, duration, and severity. Severe symptoms indicate lower rating. Symptoms persisting on daily basis for >2 weeks is considered to be severe (1 or 2); no/minor/occasional symptoms are considered normal nutrition (6 or 7); degree and symptoms between the two categories is considered as mild-moderate malnutrition (3, 4, 5). Intermittent changes are not regarded as significant.

Physical examination includes loss of subcutaneous adipose tissue and muscle. The tips on the physical examinations are shown in Table 1. Figure 2a–f demonstrates loss of subcutaneous fat, A–C showing changes in subcutaneous fat below the eye and D–F at level of biceps and triceps. Figure 3 shows muscle wasting at level of temple in A, B, and C; at clavicle D, E, and F; at shoulder G, H, and I; at scapula J, K, and L; and at level of interosseous muscle in M, N, and O. Figure 4 shows muscle wasting around knee A, B, and C; quadriceps D, E, and F; and calf G, H, and I.

The different modifications of SGA had been widely used in CKD and dialysis patients. The summary of comparison of description, advantage, and disadvantages of different modifications of SGA has been shown in Table 2.

Dictionary of Terms

- **Nutrition** – It is the science dealing with the role of various foodstuff and various types of nutrients in order to safeguard and maintain human health.
- **Nutrients** – Are the fundamental elements in food (e.g., protein, fat, carbohydrate, vitamins, and minerals) that must be supplied in sufficient quantity to the body to maintain health
- **Malnutrition** – It is the state of imbalance between the nutrient intake and demand. It can be a result of a relative or complete insufficiency or excess of one or more essential nutrients.
- **Nutritional status** – The condition of health of an individual that indicates the balance among the various nutrient intake and their utilization in various health, growth, development, and diseased conditions.
- **Nutritional assessment** – It is a comprehensive and in depth evaluation to determine an individual person's health and health-related issues using different parameters like anthropometry, medical, dietary, clinical history, physical examination, laboratory data, etc.

Table 1 Physical examination consists of subcutaneous fat and muscle wasting. (Adopted from Asgarani et al. 2004)

Physical examination consists of subcutaneous fat and muscle wasting				
Areas of exam	Tips	Severe malnutrition	Mild-moderate malnutrition	Well nourished
Subcutaneous fat				
Below the eye	Look at patient straight on	Hollow look, depressions, dark circles, loose skin (Fig. 2a)	Slightly dark circles, somewhat hollow look (Fig. 2b)	Slightly bulged fat pads. Fluid may mask loss (Fig. 2c)
Triceps/biceps	Arm bent, do not include muscle in pinch, roll skin between fingers	Very little space between folds, fingers touch (Fig. 2d)	Fingers almost touch, some depth to pinch (Fig. 2e)	Ample fat tissue obvious between folder of skin (Fig. 2f)
Muscle wasting				
Temple	Observe straight on, have patient turn head side to side	Hollowing, scooping, depression (Fig. 3a)	Slight depression (Fig. 3b)	Can see/feel well-defined muscle (Fig. 3c)
Clavicle	Look for prominent bone	Protruding, prominent bone (Fig. 3d)	Some protrusion (Fig. 3e)	Not visible in male, visible but not prominent in female (Fig. 3f)
Shoulder	Arms at side, look at shape	Shoulder to arm joint looks square (Fig. 3g)	Acromion process may protrude slightly (Fig. 3h)	Rounded, curves at junctions arm/shoulder/neck (Fig. 3i)
Scapula	Have patient push hands against solid object	Prominent, visible bones, depressions below ribs/scapula or shoulder/spine (Fig. 3j)	Mild depression or bone may show slightly (Fig. 3k)	Lines of bones not prominent, no significant depressions (Fig. 3l)
Interosseous muscle	Pads of thumb/forefinger touching	Depressed area between thumb forefinger (Fig. 3m)	Slightly depressed or flat (Fig. 3n)	Muscle bulges, could be flat in well nourished (Fig. 3o)
Knee, note: lower body is less sensitive to change	Have patient sit with leg propped up, bent a knee	Bones prominent, little sign of musculature around knee cap (Fig. 4a)	Knee cap less prominent more rounded (Fig. 4b)	Muscle protrudes, bones not prominent (Fig. 4c)

(*continued*)

Table 1 (continued)

Physical examination consists of subcutaneous fat and muscle wasting				
Areas of exam	Tips	Severe malnutrition	Mild-moderate malnutrition	Well nourished
Subcutaneous fat				
Quadriceps	Not as sensitive as upper body	Depression on inner thigh, obviously thin (Fig. 4d)	Mild depression on inner thigh (Fig. 4e)	Well rounded developed (Fig. 4f)
Calf	Observe side and front view	Thin, minimal or no muscle definition (Fig. 4g)	Not well developed (Fig. 4h)	Well-developed bulb of muscle (Fig. 4i)
Edema, ascites (HD only) R/O other causes of edema, patient at dry weight	View sacrum in activity restricted patient, ankle in mobile patient	Significant swelling	Mild to moderate swelling	No sign of fluid accumulation

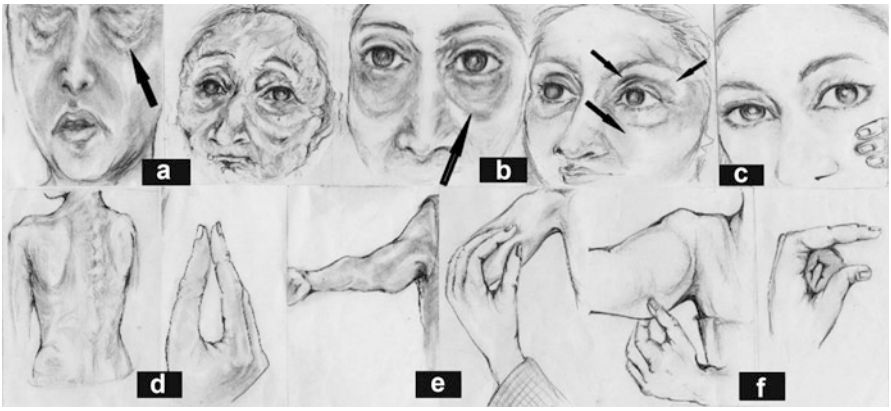

Fig. 2 (**a**–**f**) Figure shows the assessment of the loss of subcutaneous fat. Depression under the eye, darkened area "hollow eyes" (**a**) severe malnutrition; moderate fat loss and slightly dark circle and hollow look (**b**) Mild-Moderate malnutrition; appears slightly bulge (**c**) well nourished. Assessment of the fat stores at triceps/biceps: Small amount of space between fingers. Severe loss of subcutaneous fat tissue, fingers touch (**d**) severe malnutrition; moderate loss of subcutaneous fat tissue, fingers almost touch (**e**) mild-moderate malnutrition, fingers do not touch, ample of subcutaneous fat tissue (**f**) well nourished

- **Glomerular filtration rate (GFR)** – It is estimating the amount of blood that passes through the glomeruli each minute. It is defined as the flow rate of filtered fluid through the kidney and is the indicator of kidney function.

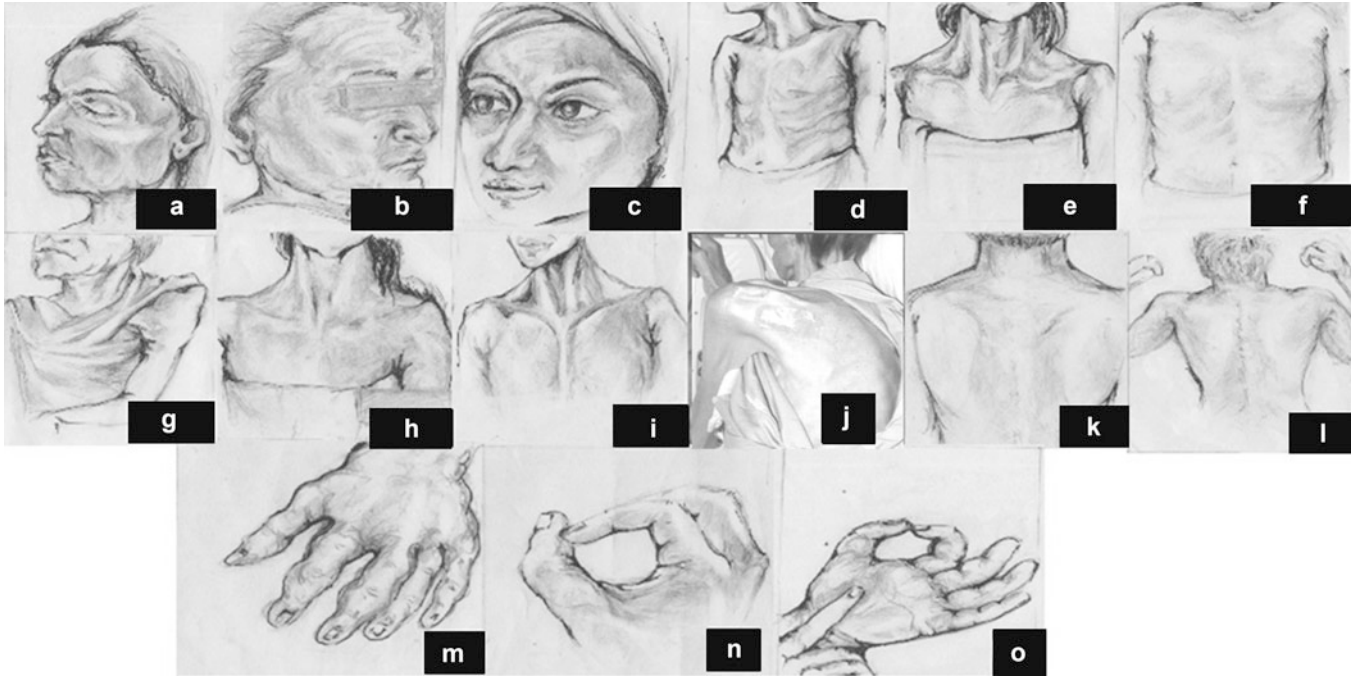

Fig. 3 Muscle wasting at temple shows hollowing and depression (**a**) severe malnutrition; slight depression (**b**) mild-moderate malnutrition; well-defined muscle/flat (**c**) well nourished. At level of clavicle showing protruding, prominent clavicle bone (**d**) severe malnutrition; partially protruded (**e**) mild-moderate malnutrition; barely visible (**f**) well nourished. At level of shoulders showing square shoulders prominent acromion protrusion (**g**) severe malnutrition; acromion protrusion can be evident (**h**) mild-moderate malnutrition; rounded, curves at junctions between the neck and the shoulder joint (**i**) well nourished. At level of scapula showing visible scapula prominent ribs with depressions between ribs/scapula (**j**) severe malnutrition; moderate depression around the bone (**k**) mild-moderate malnutrition; scapula is not prominent (**l**) well nourished. Muscle stores revealing interosseous muscles between thumb and forefinger showing significant wasting and scooping (**m**) severe malnutrition; slightly depressed/scooping (**n**) mild-moderate malnutrition; flat or raised (**o**) well nourished

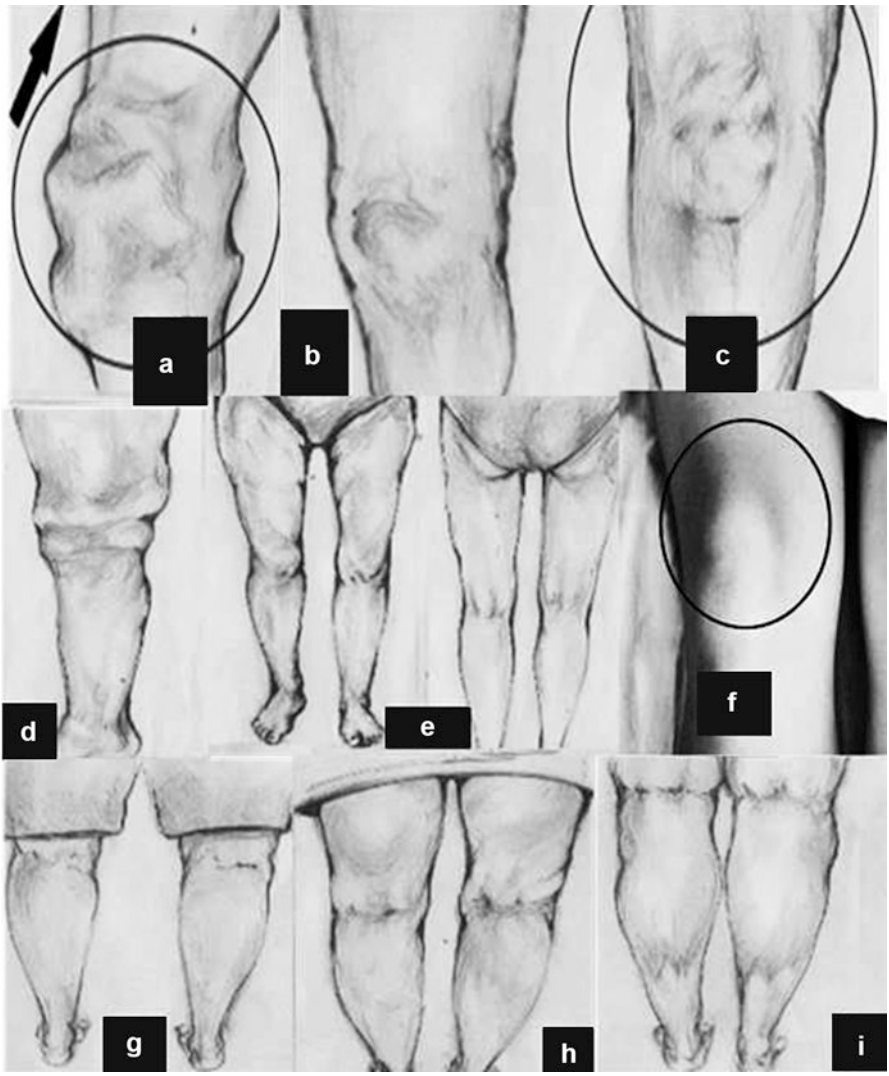

Fig. 4 Muscle stores at knee showing prominent bones and severe muscle wasting (**a**) severe malnutrition; knee cap less prominent – mild-moderate malnutrition; bones not prominent, muscle protruded (**c**) well nourished. At level of quadriceps showing depression, thin (**d**) severe malnutrition; mild depression' (**e**) mild-moderate malnutrition; well rounded, no depressions (**f**) well nourished. At level of calf showing protruded knee bone, and thin calf (**g**) severe malnutrition; protruded knee bone and calf not well developed (**h**) mild-moderate malnutrition; full and solid, calf well developed (**i**) well nourished

- **Chronic kidney disease (CKD)** – It is the condition when kidney is not able to function normally and the GFR value falls either below 60 ml/min/1.73^2 for three or more than 3 months or GFR value is above 60 ml/min/1.73^2 with kidney damage as indicted by presence of albumin in the urine

Table 2 Description, advantages, and disadvantages of SGA-based nutrition assessment tools utilized in CKD. (Adopted from Campbell et al. 2007b)

Tool	Method	Modification from SGA	Advantages	Disadvantages
Retrospective mSGA	Rating A, B, C	Retrospective "self-rating" on A, B, C scale	Conducted as a survey (self-report)	Relies on self-report and carer's physical assessment
7- point SGA	Rating 7–1	Expands the 3 categories of the original SGA to 7 on a Likert-type scale	May delineate levels of nutrition status	May increase interobserver variation
Dialysis Malnutrition Score (DMS)	Scored 7–35	Scores 7 components of the SGA as 1 (normal) to 5 (very severe)	Scored so less subjectivity	Allocation of scores not based on evidence
Malnutrition-Inflammation Score (MIS)	Scored 0–30	10 components, the DMS with BMI, serum albumin, and total iron-binding capacity, scored according to severity 0 (normal) to 3 (very severe)	Includes objectives categories – less reliance on subjectivity	Requires biochemistry (albumin and iron studies), and weight/height measures for BMI
Patient-Generated-Subjective Global Assessment (PG-SGA)	Scored 0–35 and A, B, C	Provides a numerical score, dependant on the impact of each SGA component on nutrition status	Patient completes medical history, scored so less subjective	May require more patient input

- **End-stage renal disease** – It is a stage of gradual and progressive loss of renal function (GFR <15 ml/min/1.73^2) when kidney is unable to function and sustain life, and there is need for long-term dialysis or transplantation.
- **Dialysis** – The procedure done via a machine for removing the excess waste products (toxins) and excess fluid from the body. It is used as a modality to treat renal failure in case when the kidneys are not able to function adequately.
- **Body mass index** – It is the measure of body fatness based on height and weight that applies to adult men and women. It is calculated by dividing the weight in kilograms by the square of height in meters.

Summary Points

- Malnutrition is highly prevalent and a well-recognized problems in hospitalized patients as well as in general population.
- This chapter illustrates the SGA method for assessing malnutrition. SGA in either conventional or its modified form has been validated as reliable semiquantitative tool for assessing malnutrition in various clinical conditions.
- It is designed for the overall evaluation of nutritional status on the basis of history and physical examination on a scale ranging from well nourished to severely malnourished.

- Various modified versions of SGA have been proposed since its conception. The 7-point SGA is a modification of the original SGA in which four items are scored on a 7-point Likert-type scale, with lower values signifying inferior nutritional status (rating 1 severely malnourished to 7 well nourished). The 7-point SGA may be much more time sensitive than the conventional SGA in identifying small changes in nutrition status.
- It helps in identifying malnutrition, indirectly differentiating malnutrition from disease states, predicting outcomes and requirement of nutritional intervention to improve the outcomes of patients. Its applicability has been widely studied in surgical and cancer patients, patients in intensive care unit, patients with CKD, and patients on dialysis.
- It can also be used as tool in making strategies for prevention of malnutrition in general population as well.
- SGA is simple, noninvasive, and inexpensive tool which can be quickly executed in routine clinical practice to assess the nutritional status of the patients.

Abstract

Malnutrition in pediatrics remains a cause for concern due to its considerably high prevalence and deleterious effects on growth, development, and overall health. Early identification of malnutrition risk may prevent nutritional deterioration during hospitalization. There are currently a number of suggested screening tools for use in pediatrics; however, there is no consensus on a single tool that is favorable over others. Thus selection of a screening tool for implementation is perplexing. Presented here is an overview of the screening tools available for use in pediatrics and further actions needed in order to implement the use of screening tools in different settings in pediatrics. Seven screening tools that are intended for use upon admission to the hospital were identified. Two screening tools were designed for specific medical conditions. One screening tool was designed for sole use in ambulatory settings. Of the seven tools identified for use upon hospital admission, some tools were also validated for use in specific medical conditions and one tool was also validated for use in ambulatory settings. Comparison between screening tools failed to offer one tool favorable to others. A model for implementation of nutritional screening in pediatrics in terms of policy change is suggested. In conclusion, there is currently no single nutritional screening tool that is superior to others. When selecting a screening tool, one should consider the setting in which screening will take place, in terms of purposes and applications. Governments and healthcare providers should promote implementation of nutritional screening in pediatrics in all healthcare facilities.

UK90	United Kingdom (growth charts)
WHO	World Health Organization

Introduction

Studies published over the past decade show that malnutrition prevalence upon admission to pediatric hospitals remains considerably high, ranging from 6% to 14% in developed countries (Joosten and Hulst 2011) with higher prevalence rates in infants and toddlers (Hecht et al. 2015). In specific medical conditions the described prevalence is much higher (Joosten and Hulst 2008). Hospital stay has deleterious impact on the nutritional status leading to weight loss during hospitalization even in children affected merely by mild clinical conditions (Campanozzi et al. 2009; Pacheco-Acosta et al. 2014). Early detection of children at malnutrition risk has been discussed by international organizations such as ASPEN (Corkins et al. 2013), ESPGHAN (Agostoni et al. 2005), and ESPEN (Kondrup et al. 2003).

Nutritional screening is a process aimed to identify an individual who is malnourished or who is at risk for malnutrition, to determine if a detailed nutritional assessment is indicated (Teitelbaum et al. 2005). An ideal screening tool should demonstrate good ranking at concurrent validity (the extent to which screening tools agree with each other), predicative validity (the extent to which screening tools predict certain outcomes), reproducibility (agreement between users of a given tool), and applicability in terms of ease and speed of administration (Elia and Stratton 2011).

However widely used in adults, nutritional screening is not routinely conducted in children because of the lack of a simple, properly validated screening tool (Hartman et al. 2012). Also, since there is no one universally accepted definition of malnutrition, there is also lack of consensus on a single definition for nutritional risk (Huysentruyt et al. 2015). As a result, different screening tools were developed for different purposes using different methodological methods (Elia and Stratton 2011), making it nearly impossible to compare between tools in order to favor one tool over the others. Thus, adding to the difficulties to choose an appropriate screening tool there is lack of agreement between tools (Chourdakis et al. 2016) and evidence for an impact of the screening on long-term outcome is lacking. In this chapter we will review the literature on pediatric screening tools and discuss the complexity of choosing a single tool. We will also discuss the policy needed to ensure implementation of nutritional screening in pediatrics.

Nutritional Screening Tools Currently Available for Use in Pediatrics upon Hospital Admission

The main components of the following screening tools are described in Table 1.

1. Nutrition Risk Score (NRS) – Developed by Reilly et al. (1995), the NRS is a screening tool validated for use by the nursing staff to assess the risk of nutritional depletion in hospitalized patients, both adults and pediatrics. The NRS collects data on weight loss (amount and duration), BMI for adults or percentile charts for children, food intake (appetite and the ability to eat and retain food), and stress factors (effect of medical condition on nutritional requirements). Each parameter is given a score affected by the severity of the condition described. The scores are summed and patients are allocated into nutritional risk groups. A course of action is then advised accordingly. The tool was validated on a sample of 20 patients ranging from 6 weeks of age to 79 years. The NRS scores were assessed in comparison to Nutritional Risk Index (NRI) ($r = 0.68$, $p < 0.001$) and a dietitian's clinical impression of the patient ($r = 0.83$, $p < 0.001$). Inter-rater reliability was also assessed by comparing NRS scores conducted by two dietitians ($r = 0.91$, $p < 0.001$). It should be noted that this tool was validated by comparison to the NRI (Wolinsky 1990) which was originally designed for use in geriatrics. Moreover, this tool is not specifically intended for use in pediatrics and the study's sample size was exceptionally small with a large age range. No data on sample size calculations was mentioned in the text.
2. Pediatric Nutritional Risk Score (PNRS) – Originally developed by Sermet-Gaudelus et al. (2000), this tool is designed to identify children at risk of losing 2% or more of their admission weight, during hospitalization. Nutritional risk was

Table 1 Main components of screening tools. Different screening tools take into consideration different nutritional related data when assessing nutritional risk. The table describes the different screening tools with regards to their components

Tools	Effect of disease	Current nutritional intake	Anthropometry measurements	Weight loss	Other components
NRS	٧	٧	٧	٧	GI symptoms, ability to eat
PNRS	٧	٧			Pain
STRONGkids	٧	٧		٧	
PYMS	٧	٧	٧	٧	
STAMP	٧	٧	٧		
PNST		٧		٧	
PeDiSMART	٧	٧	٧		GI symptoms

Key: *NRS* nutrition risk score, *PNRS* pediatric nutrition risk score, *STRONGkids* screening tool for risk on nutritional status and growth, *PYMS* paediatric yorkhill malnutrition score, *STAMP* screening tool for the assessment of malnutrition in pediatrics, *SGNA* subjective global nutritional assessment, *PeDiSMART* the pediatric digital scaled malnutrition risk screening tool, *GI* gastro intestinal

assessed prospectively in 296 children within the first 48 h of admission. Various nutritional-related factors were assessed regarding their ability to predict weight loss during hospitalization. Multivariate analysis indicated that food intake below 50% of dietary allowance, pain, and the severity of the disease were found to be the most significant predictors of weight loss greater than 2% during hospital stay ($p = 0.0001$ for each). It should be noted that although authors described this tool as simple and easy to use, it has some downfalls. First, the tool is not applicable upon admission since it requires monitoring nutritional intake over the first 48 h of hospitalization. Thus, by using this tool, children who could benefit from early intervention may be overlooked. Second, authors does not specify the resources needed to implement the screening procedure; however, it appears trained personnel is required to implement the tool, if not only to assess dietary intake compared with recommended allowance (Hartman et al. 2012). Third, there is no data on reproducibility, inter-rater reliability, and the sensitivity of the tool (Hartman et al. 2012; Joosten and Hulst 2014).

3. Screening Tool for Risk on Nutritional status and Growth (STRONGkids) – Developed and tested by Hulst et al. (2010) in a prospective observational multicenter study including 424 children admitted to 7 academic and 37 general hospitals across the Netherlands. The STRONGkids consists of four items each given a numeric score: subjective clinical assessment, high-risk disease, nutritional intake, and weight loss. Weight and height were also measured and z-scores were calculated. Risk scores were then compared with z-scores. Hulst et al. showed that z-scores decreased with the rise in risk score ($rs = -0.25$, $p < 0.001$), suggesting the higher the score according to STRONGkids, the greater the risk according to anthropometric measurements. In addition, length of hospital stay (LOS) was significantly shorter in children in the low-risk score group compared to children with a moderate or high risk score ($p < 0.001$). This was also demonstrated by Cao et al. (2014) who used STRONGkids to analyze nutritional risk in hospitalized children and its relationship with clinical outcome. Cao et al. showed that children in the high-risk group demonstrated higher complication rate, longer hospital stays, greater weight loss, and greater hospital expanses, compared with children with moderate or low risk ($p < 0.001$).
   Hulst et al. (2010) described this tool as practical and easy to use; however, it should be noted that both subjective clinical assessment and determining the severity of the disease rely on expert knowledge and experience and thus might not be suitable for use by all healthcare workers in different settings.
4. Paediatric Yorkhill Malnutrition Score (PYMS) – Developed by Germasimidis et al. (Gerasimidis et al. 2010), the PYMS consists of four parameters: BMI, weight loss history, changes in nutritional intake, and the severity of the underlying disease and its impact on nutritional status. The tool was validated by comparing its allocation to nutritional risk groups, with that determined by full nutritional assessment. Inter-rater reliability was determined by comparing the PYMSs' scores as rated by the nursing staff with those rated by dietitians. PYMSs' allocation into nutritional risk groups was also compared with other commonly used tools (STAMP and SGNA). The study included 247 children, of whom

nurse-rated PYMS identified 59% of those rated at high risk by full nutritional assessment. Of those rated at high risk by nurse-rated PYMS, 47% were confirmed at high risk by the full nutritional assessment. These results could be interpreted that approximately 40% of children considered at high risk were not identified by nurse-rated PYMS. Moreover, 53% of children were falsely identified at high risk by nurse-rated PYMS and inadequately referred to dietitians (Hartman et al. 2012). PYMS demonstrated a moderate agreement with full dietitians' assessment ($k = 0.46$) and inter-rater reliability ($k = 0.53$) when nurse-rated PYMS was compared with dietitian-rated PYMS.

5. Screening Tool for the Assessment of Malnutrition in Pediatrics (STAMP) – Developed by McCarthy et al. (2012), STAMP consists of three steps and gathers information aimed to detect low percentile weight for age, reported weight loss, discrepancy between weight and height percentile, recently changed appetite, and the expected nutrition risk of clinical diagnoses. All were identified as predictors of nutrition risk, in the development phase of the tool. Nutritional risk is translated into the need for a referral to a full nutritional assessment. No outcomes were evaluated in the validation study (Hartman et al. 2012). The tool was validated in a cohort of 238 children upon admission to hospitalization. STAMPs' allocation to nutritional risk groups was compared with a classification determined by a registered dietitian. The tool demonstrated fair to moderate reliability ($k = 0.54$), and sensitivity and specificity were estimated at 70% and 91%, respectively. It should be noted that this tool assesses growth parameters using specific charts that were developed for this purpose (based on either UK90 or CDC charts). Therefore one might claim implementation of such tool requires resources, such as time and money, in order to train healthcare staff accordingly. However, McCarthy et al. (2012) claim STAMP utilizes information that should be routinely collected by nursing staff upon admission, thus introduction of the tool required minimal training. Moreover, in the validation study, STAMP was completed by different members of the nursing staff, including student nurses and nursing supporting staff, suggesting implementation of the tool requires no specific training.
6. Pediatric Nutrition Screening Tool (PNST) – Developed by White et al. (2016), PNST consists of four dichotomous (yes/no) nutritional screening questions and requires no data collection on medical condition or anthropometric measurements. The PNST was validated on 295 hospitalized children from birth to 16 years in Australia. The pediatric SGNA and anthropometry were chosen as the gold standards in defining nutritional risk. The sensitivity and specificity for the PNST compared with the pediatric SGNA were moderate and high, scoring 77.8% and 82.1%, respectively. However, it should be noted that screening procedure was performed by the same investigator using both PNST and SGNA. No clinical outcome was investigated.
7. The Pediatric Digital Scaled Malnutrition Risk Screening Tool (PeDiSMART) - Developed and validated by Karagiozoglou-Lampoudi et al. (2015), the PeDiSMART is a software that consists of four elements: weight for age z-scores, nutrition level intake, overall disease impact, and symptoms affecting intake.

Other than anthropometric data, all other parameters are described as categorical variables rated 0–4. In order to validate the tool, PeDiSMART was compared to bioelectrical impedance phase angle (BIA PhA) on 161 hospitalized children aged 1 month to 17 years in Greece. Data showed inverse correlation between the tool and PhA values ($R = -0.582$, $p < 0.001$). PeDiSMART was then compared to STAMP, PYMS, and STRONGkids screening tools in 500 hospitalized children. Patient allocation to nutritional risk groups on admission was associated with clinical outcomes such as weight loss or nutritional support and LOS. ROC curves showed sensitivity of 87% and specificity of 75%, ranking better than STRONGkids and STAMP. In regards to outcome measurements, PeDiSMART accuracy in predicting weight loss/nutritional intervention was higher than PYMS and comparable to STAMP and STRONGkids. PeDiSMART accuracy in predicting LOS > 7 days was higher than STAMP and STRONGkids and comparable to PYMS. Inter-rater reliability was evaluated in 57 patients by two dietitians and showed moderate agreement of $k = 0.474$. Authors claim PeDiSMART is rapid, easy to use, and suitable for use by all clinical staff members. Since the software incorporates information documented on electronic medical files automatically, the authors suggest the use of this technology may facilitate and possibly improve the prediction of nutritional risk.

It should be noted that although some may refer to the Subjective Global Nutritional Assessment (SGNA) tool published by Secker and Jeejeebhoy (2007) as a nutritional screening tool, we chose not to describe this tool as it resembles a nutritional assessment tool rather than a nutritional screening tool. In fact, it was sometimes used as a gold standard for validation of a new tool, as was performed in the validation of the PNST (White et al. 2016).

While a number of screening tools had emerged in the field of nutritional screening upon hospitalization in the last decade, very few focused on nutritional screening in community settings. Randall Simpson et al. (2008) developed the nutriSTEP, a parent-administered questionnaire intended for nutritional risk screening in preschoolers. However, we choose not to focus on this tool since it is intended to be solely used in community settings and was validated for that purpose only. Despite Rub et al. (2016) validated STAMP for ambulatory use in pediatrics, further research in the field is necessary before a definitive recommendation can be made.

Comparison Between Different Screening Tools

Since nutritional screening is widely recommended by numerous organizations such as ASPEN (Corkins et al. 2013), ESPGHAN (Agostoni et al. 2005), and ESPEN (Kondrup et al. 2003) a number of papers were recently published comparing different screening tools in the hopes of identifying one tool that can be considered superior to others. Examining the volume of these papers fails to yield consistent results. The comparison between the tools brings forward the complexity of prioritizing one tool over the other due to the different design and evaluation methods

Table 2 Aims of the nutritional screening tools. Different screening tools were developed for different aims, thus providing different uses. Table 3 describes the different screening tools with regards to their aims

Tools	Determine nutritional status	Identify need for nutritional intervention	Predict clinical outcome without nutritional intervention
NRS		٧	
PNRS		٧	٧
STRONGkids		٧	٧
PYMS	٧	٧	٧
STAMP	٧	٧	
PNST	٧	٧	
PeDiSMART	٧	٧	

Key: *NRS* nutrition risk score, *PNRS* pediatric nutrition risk score, *STRONGkids* screening tool for risk on nutritional status and growth, *PYMS* paediatric yorkhill malnutrition score, *STAMP* screening tool for the assessment of malnutrition in pediatrics, *SGNA* subjective global nutritional assessment, *PeDiSMART* the pediatric digital scaled malnutrition risk screening tool

used. As was previously proposed by (Elia and Stratton 2011), different screening tools were designed for diverse purposes, for use by people with different backgrounds and for application by one or more settings, one or more age groups, and one or more disease groups.

With regards to the aims of the tools, while NRS, STAMP, PYMS, and STRONGkids are designed to be completed upon admission, PNRS requires the assessment of nutritional intake over the first 48 h of hospitalization. Ergo, using the PNRS requires time and resources spent on nutritional intake documentation and analysis, suggesting this tool has greater resemblance to a nutritional assessment tool rather than a nutritional screening tool. The aims of the aforementioned screening tools are displayed in Table 2.

Within the aforementioned tools STAMP, SGNA, and PYMS include anthropometric measurements thus identifying nutritional status upon admission, while the other tools merely provide the perceived risk of deterioration. PNRS, PYMS, and STRONGkids were also designed to prognostically predict clinical outcomes (without nutritional intervention) such as weight loss of >2% or LOS. However, it should be noted that LOS may not function as a direct assessment of nutritional risk because it may be influenced by many other factors and a causative relation has not been shown (Huysentruyt et al. 2015).

Another complexity arising from comparison is the validation methods used for each tool. There is currently no agreed upon "gold standard" for the assessment of malnutrition and malnutrition risk (since there is no universally accepted definition of malnutrition). In the absence of a nutrition screening tool that can act as a "gold" standard, information on the agreement between tools (concurrent validity) is used, especially when the comparison involves tools developed for the same purpose and when no judgment is made about the superiority of one tool over another (Elia and Stratton 2012). For example, the NRS was compared to NRI for validation, the

Table 3 Studies comparing different screening tools with regards to clinical outcomes. The table presents studies recently published comparing different screening tools in regards to their ability to predict clinical outcome, in the hopes of identifying one nutritional screening tool superior to other. Different studies compared different tools with regards to different outcomes

	NRS	PNRS	STRONGkids	PYMS	STAMP	PNST	PeDiSMART	Clinical outcome
Chourdakis et al. 2016			٧	٧	٧			Anthropometry, LOS, infection rates

Galera-Martinez et al. 2017			٧		٧			Anthropometry, LOS
Thomas et al. 2016				٧	٧			Anthropometry
Ling et al. 2011			٧		٧			Anthropometry, nutritional intervention

Key: *NRS* nutrition risk score, *PNRS* pediatric nutrition risk score, *STRONGkids* screening tool for risk on nutritional status and growth, *PYMS* paediatric yorkhill malnutrition score, *LOS* length of (hospital) stay, *STAMP* screening tool for the assessment of malnutrition in pediatrics, *SGNA* subjective global nutritional assessment, *PeDiSMART* the pediatric digital scaled malnutrition risk screening tool

STRONGkids was compared to WHO cutoff reference for malnutrition, STAMP was compared with a dietitian's nutritional assessment, and PYMS was compared to a dietitians' assessment as well as to both STAMP and SGNA.

In the absence of a universally agreed upon reference, attempts have been made to rank nutritional screening tools by their ability to predict outcome. Summary of the studies comparing the different tools with regards to clinical outcome measured is displayed in Table 3. For instance, the PNRS was designed to predict weight loss of more than 2% during hospitalization. Also, as part of its validation study, STRONGkids' allocation into nutritional risk groups was compared to LOS showing higher risk group had longer hospitalizations. Chourdakis et al. (2016) recently evaluated PYMS, STAMP, and STRONGkids compared with and were related to anthropometric measurements and clinical variables such as LOS and infection rates. Children categorized in medium and high-risk groups according to all tools were found to have significantly longer LOS compared with children in low-risk group. However, authors stated that a considerable portion of children with subnormal anthropometric measures were not identified by neither tool. Thus the use of these tools is not recommended by the authors. Using LOS as a means to rank nutritional screening tools raises some reservations. First, LOS as well as other clinical outcomes is subjected to many confounders and can be influenced by the medical staffs' policy or even by work load and availability of medical staff to discharge patients. This was also supported by Huysentruyt et al. (2015) who chose not to consider LOS as a direct assessment of nutritional risk, in their systematic review comparing PNRS, STAMP, PYMS, and STRONGkids. Moreover, when LOS as an outcome measure was controlled for confounders in the PeDiSMART validation study (Karagiozoglou-Lampoudi et al. 2015), it was found not to be significantly associated with nutritional risk. Another reservation is that a tool that is good at predicting outcomes in the absence of nutritional interventions is not necessarily good at predicting outcomes induced by nutritional interventions (Elia and Stratton 2012). Karagiozoglou-Lampoudi et al. (2015) used weight loss or nutrition support during hospitalization as an outcome measure and showed it was independently associated with the malnutrition risk groups' allocation on admission, regardless of the tool used for allocation.

In terms of practicality, a screening tool should be fast and easy to use and should be suitable for use by untrained personnel. In terms of time needed for administration, original validation studies did not report speed of administration. Ling et al. (2011) reported time of administration by two trained investigators, and found that while STAMP took 10–15 min due to anthropometric measurements, STRONGkids took merely 5 min. These findings were supported by Huysentruyt et al. (2013) that reported median time of 3 min for administration of STRONGkids in a validation study in Belgium. In terms of personnel needed to perform nutritional screening, while STAMP and PYMS were developed for use by nurses, the PNRS requires qualified personnel to assess nutritional intake, and STRONGkids was originally developed to be completed by junior physicians or pediatricians. Nevertheless, in a different validation study (Huysentruyt et al. 2013) STRONGkids was administered by nurses and was found to be easy to

use with substantial intra- and inter-rater reliability rates. Furthermore, in another very recently published study by Galera-Martinez et al. (2017), STAMP and STRONGkids were assessed for reproducibility and inter-rater reliability between expert staff specialized in pediatric nutrition (physicians and dietitians) and clinical staff nonexpert in nutrition. Agreement between expert and nonexpert staff was good: 94.78% for STRONGkids ($k = 0.72$ [$p < 0.001$]) and 92.55% for STAMP ($k = 0.74$ [$p < 0.001$]). These findings suggest whether STRONGkids was originally developed for administration by qualified personnel, it can be used for practice by clinical staff, as it is already widely used in current clinical practice by nurses (Joosten and Hulst 2014). The PeDiSMART was claimed to be appropriate for use with all clinical staff members. Nonetheless, it was validated for use by certified dietitians (Karagiozoglou-Lampoudi et al. 2015). Further research is needed to assess PeDiSMARTs' inter-rater reliability between a dietitian's assessment and other members of the clinical staff.

Not all nutritional screening tools describe the course of action that is advised according to screening results, and the ones who do, describe different follow-up care plans. The care plans advised by the different nutritional screening tools are displayed in Table 4.

Nutritional Screening Tools for Specific Medical Conditions

Different screening tools are designed for different purposes, to be used on one or more underlying disease (Elia and Stratton 2011). Some tools were originally designed to be used upon specific conditions such as SCAN, nutritional screening tool for childhood cancer (Murphy et al. 2016), or the nutrition risk screening tool in cystic fibrosis (McDonald 2008), while other tools were later on validated for specific purposes. For example, PeDiSMART was validated in 30 children with chronic kidney disease (Apostolou et al. 2014). Moderate inverse correlation was found between PeDiSMART score and PhA ($p = 0.001$), MUAMC ($p = 0.008$) as well as protein intake ($p = 0.016$). STAMP was also validated in 51 pediatric spinal cord injury (SCI) patients admitted to a tertiary SCI center (Wong et al. 2013). STAMP had moderate agreement with dietitians' assessment ($k = 0.507$). STAMP, PYMS, and PMST (modified STAMP) were tested in acute pediatric setting in 300 children (Thomas et al. 2016).

The tools were compared to WHO growth reference cutoffs for malnutrition. Those who scored medium or high risk by the tools were compared with those who could be considered malnourished or at risk of malnutrition using the WHO's definitions. The results showed poor sensitivity and specificity rates; however, it should be noted that WHOs' definitions for malnutrition assess current state rather than the risk for malnutrition. Thus it may not be the most suitable reference to test validity. Moreover, the majority of children at PICU are at nutritional risk of some degree, thus it may be more effective to directly perform nutritional assessment in the form of growth and intake assessment rather than nutritional screening.

PNRS, PYMS, STAMP, and STRONGkids were also tested in children with IBD (Wiskin et al. 2012). The tools were tested on 46 children and risk score was

Table 4 The care plans advised by the different nutritional screening tools according to screening result. Each screening tool offers a specific care plan according to the allocated risk group. The table presents the course of action advised by each tool according to the different risk groups allocated

Tools	Low risk	Moderate risk	High risk
NRS	N/A	N/A	N/A
PNRS	None	Weight surveillance, report intake, consider dietetic consult	Nutritional assessment, monitor intake, consider nutritional intervention
STRONGkids	Repeat screening weekly	Check weight twice a week, consider referring the child to a dietitian	Refer the child to a dietitian
PYMS	Repeat screening weekly	Repeat screening after 3 days	Refer the child to a dietitian
STAMP	Repeat screening weekly	Monitor the child's nutritional intake for 3 days, repeat screening after 3 days	Refer the child to a dietitian/ nutritional support team/ consultant
PNST	None	Not relevant (moderate risk category does not appear in the PNST)	Refer the child for further nutritional assessment, check if child was previously cared for by a dietitian, measure weight and height, commence food and fluid intake record
PeDiSMART	Check weight status weekly	Check weight status twice a week, repeat the screening after a week	Refer to a dietitian

Key: *N/A* no care plan available, *NRS* nutrition risk score, *PNRS* pediatric nutrition risk score, *STRONGkids* screening tool for risk on nutritional status and growth, *PYMS* paediatric yorkhill malnutrition score, *LOS* length of (hospital) stay, *STAMP* screening tool for the assessment of malnutrition in pediatrics, *SGNA* subjective global nutritional assessment, *PeDiSMART* the pediatric digital scaled malnutrition risk screening tool

compared to the degree of malnutrition according to WHO's definition (as expressed in ICD-10). The tools showed good agreement with one another ($k = 0.6$); however, no agreement was found between each tool and anthropometric measures ($k < 0.1$). Nevertheless, it should be noted that authors compared nutritional risk as assessed by the aforementioned tools, with criteria of nutritional assessment such as set by the WHO's definition for malnutrition.

Policies and Protocals

Implementation of Nutritional Screening in Pediatrics

In this chapter we have described recently published research in the field of nutritional screening in pediatrics, and the complexity of comparing the different tools in the hopes of identifying one screening tool that can be considered superior to others.

Below we describe the detailed policies that should be adopted in order to make implementation of nutritional screening in pediatrics feasible in various settings. Policy should acknowledge a number of main areas:

- The government's role in prioritizing nutritional screening and allocating resources for that matter
- The standardization of nutritional screening across different healthcare facilities
- The role of healthcare facilities in implementation of nutritional screening
- The need to establish follow-up protocol when advised and the means to do so
- The assessment of long-term nutritional outcomes

As nutritional screening in pediatrics is recommended by international organizations (Corkins et al. 2013; Agostoni et al. 2005; Kondrup et al. 2003), it should be made into a governmental policy in order to reduce disease complications (Sermet-Gaudelus et al. 2000; Cao et al. 2014), LOS (Hulst et al. 2010; Cao et al. 2014; Karagiozoglou-Lampoudi et al. 2015; Chourdakis et al. 2016), and overall economic burden on the healthcare system (Ahmed et al. 2012). To this date the majority of nutritional screening tools in pediatrics are suitable for use in specific healthcare facilities. Ergo, some tools are suitable for use in primary healthcare centers while other tools are suitable for ambulatory setting. Government should allocate resources to validate one nutritional screening tool for pediatrics that can be feasible for use in different healthcare settings. The use of a single screening tool in different healthcare settings will allow follow up and monitoring of nutritional status when child is being transferred from one healthcare facility to another. Government should also instruct that nutritional screening become mandatory upon arrival or admission to healthcare facilities, and should enforce implementation upon periodic inspection. Nutritional screening should be named as a quality measure at the national state, to ensure quality of care.

Different healthcare facilities should incorporate nutritional screening as part of their routine patient care. In order to do so, healthcare facilities should introduce nutritional screening tools and initiate training sessions on performance of such tools to all healthcare staff. All healthcare staff should be educated on the importance of nutritional screening in order to promote adherence. Healthcare facilities should develop a follow-up protocol which will define tendency required and the actions taken to ensure follow-up takes place. It is advised that each child will be assigned a case manager (such as the primary physician), who will supervise the process. Healthcare facilities should create a system that will allow physician minimal time consuming, easy and effective means to supervise nutritional status of children under their care, such as a computerized alert system for instance.

Only after nutritional screening is widely implemented, research can focus on long-term effects and assess whether early recognition of malnutrition risk produced appropriate nutritional intervention. Resources should be allocated, in the national and institutional level, to the study of nutritional risk screening effect on clinical outcomes such as rate of childhood infections, readmissions to hospitals, LOS as well as long-term outcomes such as long-term health parameters, social and academic achievements, and overall economic burden.

Dictionary of Terms

- **Malnutrition** – A state of over- or undernutrition that is accompanied by micro- and or macronutrient deficiencies, and causes malfunction at the level of the cell and/or the organ and/or the body.
- **Malnutrition risk** – The risk of deterioration into a state of over- or undernutrition.
- **Nutritional assessment** – The assessment of current nutritional status of a subject. Full nutritional assessment is usually a subjective process performed by a clinical dietitian and includes nutritional intake, review of nutrition-related blood tests, and anthropometric measurements.
- **Screening tool** – A questionnaire, form, or method that enables early identification of subject with specific conditions within a large group.
- **Length of hospital stay (LOS)** – Duration of hospitalization to a healthcare institute. This term is commonly used to represent clinical outcome of assigned intervention.
- **Anthropometry** – A term that describes measurements of the human body such as weight, height, mid-upper arm, or waist circumferences. Anthropometric indices are usually used for the purpose of nutritional assessment. In children anthropometric measurements are vital to assess growth and development.
- **Inter-rater reliability** – The degree of agreement between different raters when performing the same procedure.
- **Intra-rater reliability** – The degree of agreement between repeated tests performed by the same rater.
- **Concurrent validity** – The degree of agreement between a method and previously described methods aimed at testing the same thing.
- **Predictive validity** – The degree in which a certain test corresponds with measurable clinical outcome.
- **Reproducibility** – The degree in which a certain test can be reproduced to yield the same results either by the same rater or by different raters.
- **Sensitivity** – The proportion of positive observations recognized by the screening process among all the true positives in the population. For instance, the proportion of children with high risk for malnutrition as recognized by a certain screening tool applied, among all the children with high risk for malnutrition (combination of the children who were recognized by screening and those who were not).
- **Specificity** – The proportion of negative observations recognized by the screening process among all the true negatives in the population. For instance, the proportion of children with low risk for malnutrition as recognized by a certain screening tool applied, among all the children with low risk for malnutrition (combination of the children who were recognized by screening and those who were not).
- **Z-scores** – A term that describes distance from the mean as expressed by standard deviations.

- **Clinical outcome** – The effect of a certain intervention on the clinical state of a patient, as expressed by infection rate, comorbidity, duration of hospital stay, and so forth. The effect can be either short or long term.
- **Subjective clinical assessment** – An assessment of the clinical state of a subject which is determined by subjective impression of physical examination. In nutritional assessment this can include signs of physical wasting such as muscle or fat atrophy.
- **Gold standard** – The best available test/method/practice in a specific field.
- **Bioelectrical impedance phase angle (BIA PhA)** – A measurement used to assess muscle mass as part of the nutritional assessment procedure. The device applies a low-frequency current to the body and assesses the proportion of reactance and resistance. The result reflects the ratio of the body's cell mass to fat-free mass.

Summary Points

- Nutritional screening is recommended by multiple international organizations.
- While widely used in adults, nutritional screening is not routinely practiced due to the lack of a universally accepted, validated, easy-to-use screening tool.
- Over the past two decades many different screening tools emerged. Each tool designed for different purposes, to be used by different members of the clinical staff, on different healthcare settings.
- Comparison between the tools is complex due to the different methodology methods used, thus recent research was unable to properly compare between tools or demonstrate the superiority of one tool over the other. In choosing a screening tool one should take into account predictive and concurrent validity, reproducibility, and applicability in terms of ease and speed of application. Tools should also specify advised course of action.
- Further research should validate the use of a single screening tool in different healthcare facilities in order to facilitate continuous patient care between different settings.
- Nutritional risk screening should be administered on admission to healthcare facilities.
- Outcome measures should integrate the screening process and the nutritional interventions that follow the screening process.
- Follow-up of nutritional risk screening should be performed at the frequency suitable for the healthcare facility (frequently performed during hospitalization and less frequent on community settings).
- The implementation of nutritional risk screening in pediatrics should be made into governmental policy as a primary prevention strategy.
- Following implementation, research should focus on nutrition-related outcomes to investigate cost-effectiveness.

Prealbumin and Retinol Binding Protein as Screening Tools for Malnutrition

37

Sylvie Siminkovitch and Borislav Vladimirov

Contents

Abstract

Prealbumin (transthyretin) and retinol-binding protein are mainly secreted from the liver for what they are also called as hepatic proteins. Different hepatic or visceral proteins are increasingly used for the screening of malnutrition, according to many national and international guidelines from 1995 up to now. On the other hand, the screening is a clinical process and cannot be based only on

a single marker. The clinical and economic impact of the application of different biochemical markers for malnutrition assessment in a variety of clinical settings has been extensively studied. Several previously published nutrition screening tools have been validated in a variety of clinical conditions and patient populations. The current approach to malnutrition screening encompasses a combination of screening tools with laboratory investigations.

Prealbumin · Transthyretin · TTR · Retinol-binding protein · RBP · Malnutrition · Hepatic proteins · Biochemical screening

List of Abbreviations

AGP	α1-acid glycoprotein
AMA	Automated malnutrition assessment
APACHE II	Acute Physiology and Chronic Health Evaluation II (scoring system)
ASPEN	American Society for Parenteral and Enteral Nutrition
BMI	Body mass index
CBG	Corticosteroid-binding globulin
CPK model	Corey-Pauling-Koltum model
CRABP	Cellular retinoic acid-binding protein
CRBP	Cellular retinol-binding protein
CRP	C-reactive protein
ELISA	Enzyme-linked immunosorbent assay
HR	Hazard ratio
IL	Interleukin
IGF-I-BP	Insulin-like growth factor I-binding protein
LBM	Lean body mass
mRNA	Messenger ribonucleic acid
PA	Prealbumin
PEM	Protein energy malnutrition
PINI	PROGNOSTIC Inflammatory and Nutrition Index
RARs	Retinoic acid receptors
RBP	Retinol-binding protein
RXRs	Retinoic X receptors
SGA	Subjective Global Assessment
SIRS	Systemic inflammatory response syndrome
SOFA	Sequential Organ Failure Assessment (scoring system)
STRA 6 receptor	Stimulated by retinoic acid 6 receptor
TBG	T4-binding globulin
T3	Triiodothyronine
T4	Thyroxine
TNF α	Tumor necrosis factor alpha

TTR	Transthyretin
VA	Vitamin A
γ-interferon	Gamma interferon
TPBA	Thyroxine-binding prealbumin

Introduction

Prealbumin is also called transthyretin (TTR). It was first recommended as a malnutrition marker in 1972 by Ingenbleek et al. in a clinical observation of 40 children with pre-kwashiorkor. Several years later, the same author published the results of an observation which studied the use of retinol binding protein as a malnutrition marker. The authors investigated and compared the use of albumin, prealbumin, and transferrin and retinol-binding protein (RBP) for the biochemical screening of malnutrition (Ingenbleek et al. 1975). In 1995, the first set of recommendations regarding the application of TTR were published in the consensus document, "Measurement of visceral protein status in assessing protein and energy malnutrition: Standard of care: Prealbumin in nutritional care consensus group" (Bernstein et al. 1995). This document defined the necessity of applying some laboratory indices in the malnutrition screening and monitoring. The First International Transthyretin Congress dedicated to the clinical use of transthyretin took place as recently as in 2001 in Strasbourg, France.

According the WHO definition, malnutrition is a highly prevalent condition in developing countries (Blössner and de Onis 2005). In western countries, malnutrition is also found frequently, especially in some vulnerable populations – elderly people, patients admitted to hospital, patients with chronic diseases, etc. This strongly underlines the need for separate diagnostic approaches and screening tools for the different patient populations.

There is a huge amount of research aimed at describing the development of malnutrition in different diseases and its long- and short-term effects on potential complications and clinical outcomes (Jensen 2006). ASPEN provided an etiologically based definition of malnutrition (Jensen et al. 2010). As the screening per se is a process for the assessment groups of individuals to identify a disease, the clinicians should use a number of tools, methods, and markers for the clinical assessment of malnutrition, especially in risk groups. Guidelines recommend the use of different screening tools, such as Malnutrition Universal Screening Tool, Nutritional Risk Screening 2002, Mini Nutritional Assessment®, Short Nutritional Assessment Questionnaire©, Malnutrition Screening Tool, and the Subjective Global Assessment. Biochemical screening performed through the analysis of TTR, independently or in combination with RBP, albumin, and transferrin, is recommended as an additional test (Jensen et al. 2010). Contrary to the screening applied to big cohorts, there is a need for an individual approach to evaluate the specificities in each patient. From this point of view, we could say that there is no universal marker serving any case. In

order to explain properly the biochemical screening markers, it might be necessary to look back into the works of the pioneers in experimental medicine. What, and who discovered the structure and properties of our proteins of interest, and when?

TTR and Retinol-Binding Protein Structure and Functions

TTR was discovered in human cerebrospinal fluid in 1942. The name prealbumin originated from its place just before albumin on electrophoresis (Kabat et al. 1942). Promptly afterwards, it was also identified in serum samples. German authors described the main physicochemical characteristics of TTR. They also found a high proportion of tryptophan in its structure (Schönenberger et al. 1956). In the 1950s and 1960s, it was found that prealbumin, like albumin, participates in thyroxine transport at a considerably lower degree than the thyroxine-binding globulin. This discovery led to modification in the name of prealbumin to thyroxine-binding prealbumin TPBA (Ingbar 1958). By the end of this period, it was found that prealbumin has another transporting function (Kanai et al. 1968). Prealbumin forms a complex with a smaller molecule carrier of vitamin A and for this reason received the name retinol-binding protein (Fig. 1). The discovery of the TTR physiological role of thyroxine- and retinol-transporting protein led to the acceptance of the modified name trans-thy-retin in 1981 (Robbins 2002). Prealbumin and transthyretin are used as synonyms in literature. In 1974, Kanda et al. described the amino acid sequence of transthyretin. The gene related to TTR synthesis was identified on the long arm of the chromosome 18q23 (Wallace et al. 1985). The mature TTR molecule comprises four identical subunits (Fig. 2), each of them of 127 amino acids, which are noncovalently linked (Sasaki et al. 1985). The molecular mass of prealbumin is 55 kDa. In physiological conditions, the central part of transthyretin molecule has two identical thyroxine linking sites (Robbins 2002). The RBP-retinol complex binding parts are situated in the lateral parts of the

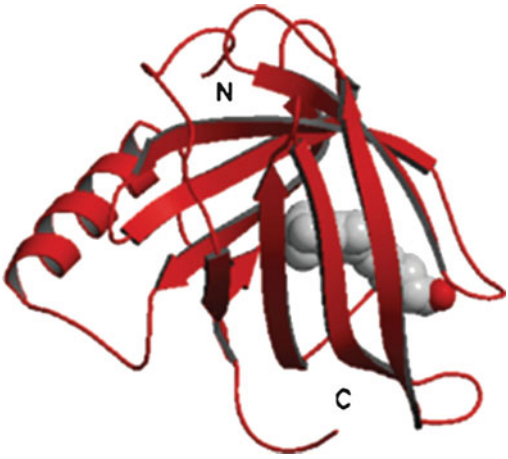

Fig. 1 Ribbon diagram of the retinol-binding protein molecule. The retinol molecule is represented as a CPK model (Corey-Pauling-Koltum model) (Monaco 2002 with permission)

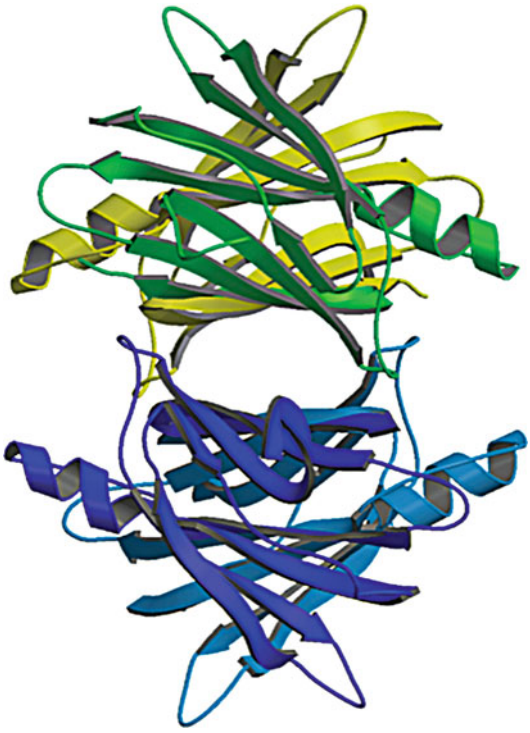

Fig. 2 Ribbon representation of the transthyretin (TTR) tetramer. This is the view down the z axis of the TTR tetramer (Monaco 2002 with permission)

transthyretin molecule. The RBP-retinol complex interacts with only one of the sites at any moment. The three components of the retinol circulating complex have a total molecule mass of 76 kDa and they circulate bound in the proportion of 1:1:1. Crystallographic studies showed that the in vitro binding capacity of one molecule TTR is with maximum two RBP molecules (Monaco 2002), Fig. 3. The molecule mass of the retinol binding protein (RBP) is approximately 21 kDa. RBP belongs to the lipocalin protein family, known for its capacity to bind hydrophobic ligands (Newcomer and Ong 2000). RBP is produced mainly in the liver, where it is released linked with retinol. In normal conditions, RBP is completely saturated with retinol. The expression of RBP in the liver is dependent on vitamin A and the nutritional status (Ronne et al. 1983; Noy and Xu 1990). Retinol is bound to RBP in the Golgi apparatus of the liver cell, from where it is secreted, bound to a second protein TTR (Noy 2000). In the case of vitamin A deficiency, RBP is accumulated in the endoplasmic reticulum of the liver cell. The presence or absence of retinol determines only the secretion, but not the synthesis of RBP (Ronne et al. 1983). More recently other sites of RBP synthesis were identified. These are the kidneys, peritubular and Sertoli cells in the testicles, the retina epithelium, the choroid plexus of the brain (Newcomer and Ong 2000), and adipose tissue (Burtis et al. 2012, p. 526) among others. RBP in blood circulation (named also RBP4) ensures the provision of tissues with retinol. In target tissues, RBP binds to a membrane receptor identified as STRA 6 (Fig. 4),

Fig. 3 Quaternary structure of the (RBP)2-TTR hexamer present in the crystals of the chimeric complex chicken RBP human TTR. The TTR molecule is oriented as in Fig. 2 (Monaco 2002 with permission)

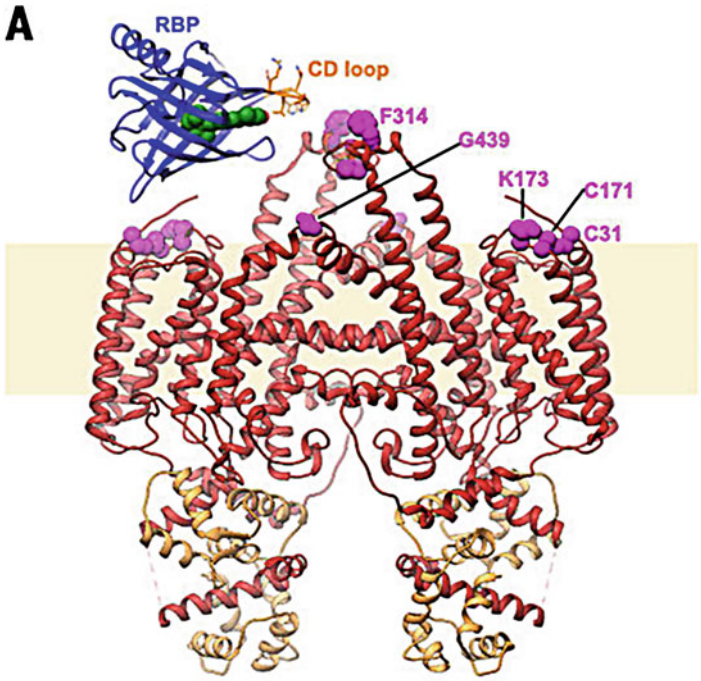

Fig. 4 Possible mechanism for STRA 6-mediated retinol uptake. Ribbon representation of the STRA6-CaM complex, viewed from the plane of the membrane, with STRA6 colored in *red* and CaM in *gold*. Residues previously shown to be important for RBP binding are shown as *magenta spheres*. *Green spheres*, retinol. The abbreviations used are the following: *STRA 6* stimulated by retinoic acid 6, *CaM* calmodulin, *RBP* retinol-binding protein (Chen et al. 2016 with permission)

which promotes the cellular adhesion of retinol (Sundaram et al.1998; Kawaguchi et al. 2015; Chen et al. 2016). Cellular retinol-binding proteins (type I, II, III, and IV) facilitate the intracellular transport of retinol (Noy 2000). Figure 5 represents a scheme of vitamin A absorption, digestion, and transport to the liver and delivery to target tissues together with main sites of cellular RBPs. After the retinol is released from the protein complex, it is quickly dissociated and the residual RBP rapidly catabolized in the kidneys. Depending on whether it is bound to retinol or not, in the circulation both forms, holo-RBP (bound to retinol) and apo-RBP (not bound to retinol), can be observed (Zanotti and Berni 2004).

The biological half-life of TTR is 2 days; in contrast to it, the half-life of RBP is 12 h. The half-life of apo-RBP, released from the retinol ligand, is only 3.5 h (Burtis et al. 2012, p. 522).

Reference Ranges and Cutoff Points

Ritchie et al. (1999) found that TTR levels in adults are different according to gender and age. Currently proposed reference ranges for adults for TTR are 0.2–0.4 g/L (Burtis et al. 2012, p. 527; Ledue and Collins 2011) and 0.03–0.06 g/L for RBP respectively. Children's reference ranges for TTR are presented in Table 1. RBP levels at birth are 0.011–0.034 g/L (1.1–3.4 mg/dL), and at 6 months they increase to 0.018–0.05 g/L (1.8–5.0 mg/dL) (Burtis et al. 2012, p. 527).

Bernstein and Ingenbleek (2002) suggested the criteria (cutoff points) for TTR interpretation to determine the malnutrition risk in the initial assessment. They are presented in Table 2.

Analytical Methods

TTR can be measured by nephelometric or by turbidimetric assays. The same methods are applicable to modern automated biochemical analyzers routinely used in practice.

RBP can be also measured by nephelometry, or by ELISA. The radial immunodiffusion methods are not currently preferable in routine practice (Burtis et al. 2012, p. 526).

Factors Influencing the Transthyretin and Retinol-Binding Protein Levels

Hepatic Function

TTR is produced mainly in the liver and the choroid plexus. Small amounts of TTR are synthesized in the beta-cellular structures in the pancreas, and retina. It is known that the control of the liver and the choroid plexus TTR production is independent (Buxbaum and Reixach 2009).

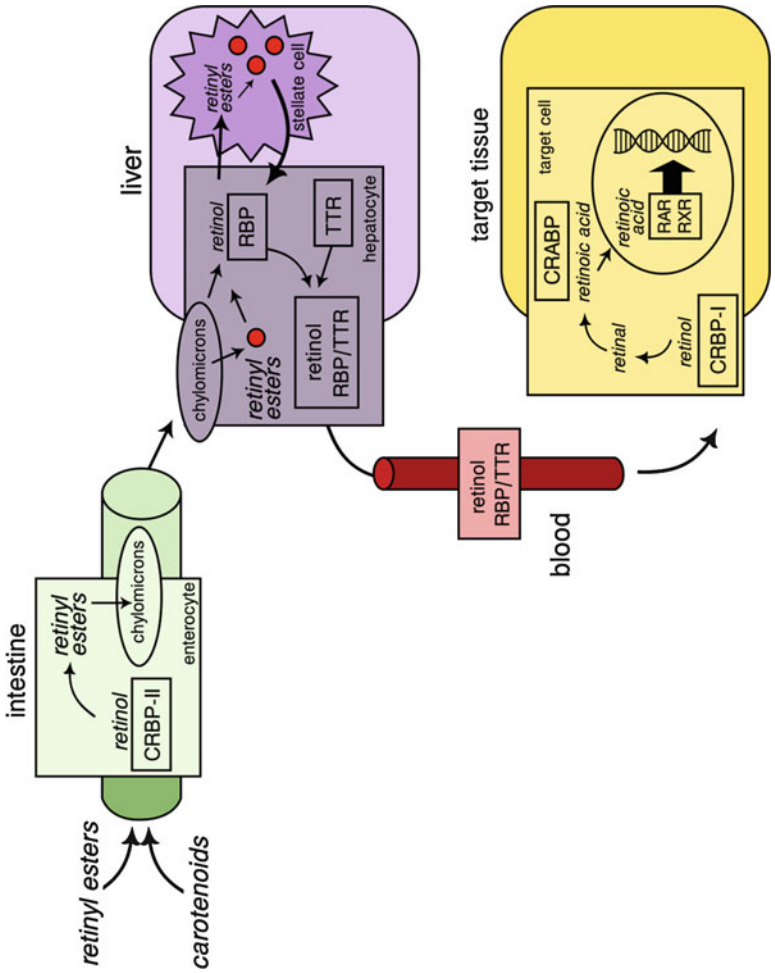

Fig. 5 Schematic drawing representing vitamin A absorption, digestion, transport to the liver and delivery to target tissues. Vitamin A metabolism can be classified into three major processes – intestinal uptake, hepatic storage, and tissue-specific metabolism. Cellular retinol-binding proteins (CRBPs) are important for the vitamin A metabolism. CRBPs have a similar structure and size ~14.6 kDa. Each of them contains a single binding site for one molecule retinoid (retinol,

Table 1 Reference ranges for transthyretin

	Reference ranges transthyretin	
Age	mg/dL	g/L
<1 month	7–39	0.07–0.39
1–6 months	8–34	0.08–0.34
7 months–6 years	12–36	0.12–0.36
Adults	20–40	0.2–0.4

Adapted from Davis et al. (1996) and Burtis et al. (2012, p. 527)

Table 2 Transthyretin levels for nutritional assessment

Transthyretin		Interpretation
mg/dL	g/L	
<5	<0.05	Critical
5–10	0.05–0.1	High risk
11–19	0.11–0.19	Mild
20–40	0.2–0.4	Normal

Bernstein and Ingenbleek (2002) with permission

Low serum levels of transthyretin and RBP are accepted as signs of liver injury, and a primary liver disease should be ruled out in case of low levels. Albumin is the most frequently used protein to assess the hepatic function and has a survival prediction role (Castera 2011; Dooley et al. 2011, p. 110). Albumin is part of the Child-Pugh scoring system for severity of liver disease. The progression of liver disease (i.e., decompensated cirrhosis, acute alcoholic or toxic hepatitis) is accompanied with reduced hepatic synthetic function. The consequence is the reduction of the values of all visceral proteins. The nature of the changes observed in the protein levels (albumin, TTR, and others) during the progression of a hepatic disease reflects mainly its severity (Yovita et al. 2004; Dooley et al. 2011, p. 21). On the other hand, hepatic insufficiency in liver cirrhosis is associated with prevailing catabolic processes, persistence of subacute or chronic inflammations, and clinically overt malnutrition in different grades (Toshikuni et al. 2014).

Fig. 5 (continued) retinal, or retinoic acid). CRBP-I is expressed in the adult in multiple tissues: liver, kidney, lung, reproductive organs, choroid plexus in the brain, and in pigment epithelium cells in the eye. In contrast, in the adult, CRBP-II is restricted to the small intestine, where it is located in mature enterocytes on the villi of the mucosal epithelium (Noy 2000). CRBP-III and CRBP-I have overlapping expression in heart, muscle, adipose, and mammary tissue. Cellular retinol-binding proteins (type I, II, III, and IV) facilitate the intracellular transport of retinoid inside the cell. Retinol is transformed in the target cell through a series of specific reactions to the retinoic acid, which interacts in the nucleus via specific transcription factors, called retinoic acid receptors (RARs) or retinoic X receptors (RXRs). The abbreviations used are the following: *CRBP-I and -II* cellular retinol-binding protein I and II, *RBP* retinol-binding protein, *TTR* transthyretin, *CRABP* cellular retinoic acid-binding proteins, *RAR* retinoic acid receptors, and *RXR* retinoic X receptors (Bellovino et al. 2003 with permission)

TTR and RBP Against the Background of Protein Insufficiency

Many experimental studies in the 1980s and 1990s support the idea that the limitation of the protein import to the body leads to reduction of the protein synthesis (Smith and Lunn 1984). The limited intake of amino acids in the context of protein-energy malnutrition without any juxtaposed inflammation leads to reduction of the nitrogen pool. It is also accompanied by suppressed hepatic production of transthyretin mRNA (De Jong and Schreiber 1987) and corresponding reduction of the export of TTR molecules to the circulation (Straus et al. 1994). On the other hand, the total nitrogen pool in the human body correlates closely to the lean body mass (LBM) or fat free mass. Ingenbleek and Young (2002) concluded that transthyretin could serve as a marker for the LBM which is linked with the free nitrogen in average relationship equal to 6.25. This data undoubtedly support the hypothesis that the circulating proteins produced by the liver cells reflect the dynamic changes in energetic and protein metabolism of the body.

Reduced Values Due to Inflammation

Several immunological and biochemical phenomena play a key role with respect to the TTR and RBP levels in acute or chronic inflammation, regardless of whether overt of clinically subtle.

Role of Cytokines

The inflammation, irrespective of the underlying causes, usually begins with leukocytes activation and cytokine release (Bienvenu et al. 2000). The influence of cytokines on protein metabolism correlates with the durability and severity of the main process. A variety of systemic diseases leads to enhanced secretion and/or release of interleukin-1, tumor necrosis factor alpha, interleukin-6, and gamma interferon. Cytokines are known to rearrange the protein metabolism (Gabay and Kushner 1999). It was previously reported that cytokines could control and stimulate the production of acute-phase proteins (CRP, α1-acid glycoprotein (AGP), fibrinogen, haptoglobin, α1-antitrypsin, antichymotrypsin, and others (Bienvenu et al. 2000) frequently called positive acute-phase proteins. Simultaneously with the enhanced synthesis of positive acute-phase proteins, cytokines could also cause a decrease in albumin, transferrin, prealbumin, and retinol-binding protein synthesis. The latter proteins are called negative acute-phase proteins. Interleukin-6 (IL-6) is accepted as a key mediator in acute and chronic inflammation. Its serum level is accepted as a reliable marker in determining the inflammatory state (Ohzato et al. 1992; Clarke et al. 2011). It was shown in animal models that the stress-induced increase of IL-6 led to rise of acute-phase reactants levels with the reciprocal suppression of TTR synthesis (Murakami et al. 1988). Further clinical experiments confirmed these observations (Banks et al. 1995).

Hormonal Alterations

Proinflammatory cytokines stimulate the supersecretion of regulatory hormones, such as glucocorticoids, cathecolamines, glucagon, and growth-hormone. This could happen in response to the hypoglycemic and anabolic effect of the secreted insulin and therefore contribute to insulin resistance in healthy tissues (Gelfand et al. 1984). Independently from the moderate hyperglycemia, glucose and amino acids are redistributed to the damaged tissues having protective and restorative functions. TTR, RBP, T4-binding globulin (TBG), and CBG have an effect on the overall early endocrine reaction during the inflammation. Within the first 3–4 days of sepsis or severe injury, plasma concentrations of TTR, RBP, CBG, and TBG decrease by half. These low plasma values are also associated with decreased binding capacity for FT4, retinol, and cortisol. On the other hand, in the extracellular fluids elevated concentrations of free cortisol, FT4, and free retinol occur, together with the increased intracellular levels of the free mediators. All T4-, retinol-, and cortisol-dependent processes are magnified during the inflammation, which enhance the immune response in the areas with inflammation and regulate energy expenditure and anabolic processes in healthy tissues (Ingenbleek and Bernstein 1999; Fig. 6 and Table 3).

Prevailing Catabolic Processes and Development of Negative Nitrogen Balance

Acute infections like SIRS, for example, lead to predominantly protein catabolism, which affects the muscular tissue and results in amino acids release (Arnold et al. 1993) The peak of increased urine excretion of nitrogen-containing substances (urea, ammonia, and creatinine, together with trimethylhistidine, hydroxyproline, and free amino acids) is usually detected between the 3rd and 5th (8th) day. These changes correspond to the low transthyretin levels. Urine nitrogen secretion and transthyretin levels return to their normal levels when the inflammatory process declines. In the case of persisting inflammation, sepsis, or metabolic complications, the catabolic processes substantially prevail and transthyretin levels do not return to normal ranges (Ingenbleek and Bernstein 2015).

ASPEN's recommendation does not actively support the application of transthyretin for nutritional status assessment in intensive care units. Nevertheless, some clinical observations have proven that transthyretin negatively correlated with the length of stay, APACHEII score, SOFA score, and mortality (Devakonda et al. 2008).

In many cases of clinical practice, the influence of nutritional inflammatory factors on the hepatic synthesis of TTR and RBP is simultaneous. Therefore, serial measurements were recommended, rather than single determination of biochemical malnutrition markers. Routine daily dynamic monitoring by serial measurements is preferable in severely ill patients. Twice weekly biochemical monitoring would be wise for those with moderate inflammation. Adequate therapeutic and nutritional intervention corresponded with the gradual trend of transthyretin increase, compared to the lowest measured value. On the other hand, the maintenance of low transthyretin concentrations over days and weeks indicates ongoing catabolic processes or the presence of underlying comorbidity (Ingenbleek and Bernstein 2015).

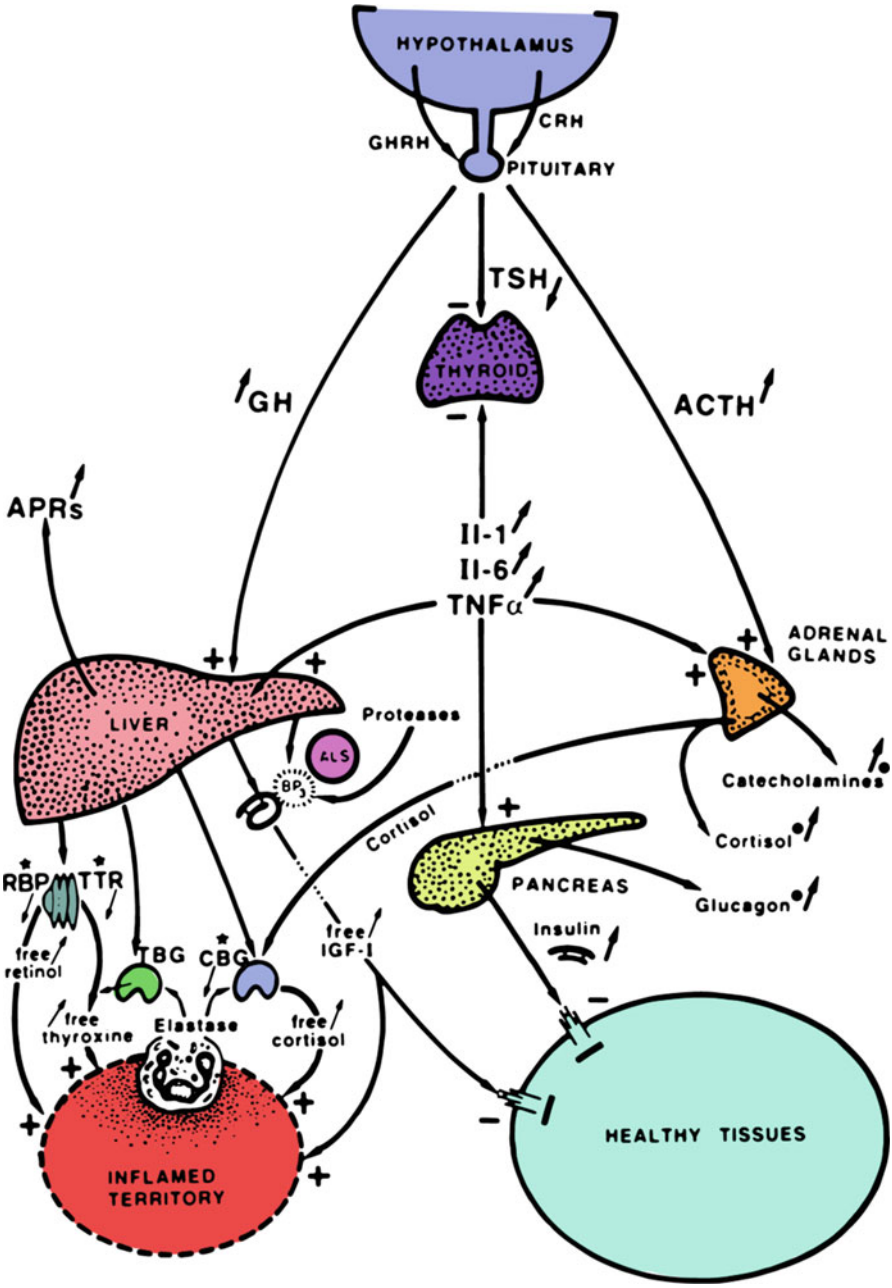

Fig. 6 Schematic diagram of the metabolic dichotomy found during stress. The three main cytokines (interleukin-1 [IL-1], IL-6, tumor necrosis factor-α [TNF-α]) stimulate the hypersecretion of insulin and glucagon by the pancreas and that of cortisol and catecholamines by the adrenal glands. In healthy tissues, stress-induced insulin postreceptor defect (—) creates a stage of insulin

Table 3 Main physicochemical and metabolic characteristics (healthy adult man) of three carrier proteins involved in the stress response

	CBG	TTR	RBP
Molecular mass (Da)	42,650	54,980	21,200
Conformation	Monomeric	Tetrameric	Monomeric

Influence of Renal Function on TTR and RBP Levels

It is known that the chronic kidney disease (CKD) affects TTR and RBP levels, due to their delayed elimination (Cano 2002). Therefore, the assessment of the renal function is the third important factor to be taken into account in order to interpret the results correctly.

Objective evaluation, concordant with clinical observations in predialysis and dialysis patients, illustrates how the adoption of strict criteria compliant with a specific biochemical profile of a disease contributes to the correct interpretation and clinical

Fig. 6 (continued) resistance and hyperglycemia strengthened by counterregulatory hormones (•). Inhibition of thyroid activities, working in concert with insulin resistance and rising growth hormone (GH) levels, downregulates most anabolic pathways, allowing them to reduce protein breakdown and to drive the whole body economy upon lipolytic dependency (RQ ~ 0.7). Inflamed territory is characterized by upregulation of anabolic processes aimed at promoting defense mechanisms and tissue repair, grounded on increased requirements of energy from glycolytic sources (RQ ~ 1). Cytokines rearrange the liver synthetic priorities, favoring overproduction of acute-phase reactants (*APRs*) at the expense of acute-booster reactants (*ABRs*) (★). Following the free hormonal theory, depressed secretion of transthyretin (*TTR*), retinol-binding protein (*RBP*), and corticosteroid-binding globulin (*CBG*) releases substantial amounts of ligands readily available to cells, enhancing thyroid-, retinoid-, and steroid-dependent pathways at the site of inflammation. The local endocrine tone is still reinforced by the elastase-induced digestion of specific carrier proteins (*CBG*, thyroxine-binding globulin [*TBG*]) belonging to the serpin superfamily. Enzymic cleavage of insulin-like growth factor-binding protein-3 (*IGFBP-3*) in the bloodstream increases the supply of free insulin-like growth factor 1 (*IGF-1*) and potentiates mitogenic processes and N accretion. These last effects fail to develop in healthy tissues due to cytokine-induced IGF-1 postreceptor defect (—). Symbols: Increased (↑) or decreased (↓) concentrations. Stimulation (+) or inhibition (−) of effector tissues (Ingenbleek and Bernstein 1999 with permission)

use of the transthyretin values. Current studies (Rambod et al. 2008; Lee et al. 2016) mainly support earlier recommendations for transthyretin use as a malnutrition and prognostic biomarker for CKD patients (Sreedhara et al. 1996; Mittman et al. 2001).

Other Factors

While discussing the main factors which influence TTR and RBP serum levels (gender, age, limited protein administration, hepatic synthetic function, inflammation, zinc deficiency, and renal function) we have to mention additional factors. Nonsteroid anti-inflammatory medicines, cortisol, and anabolic steroids, among others lead to an increase in TTR and RBP levels (Burtis et al. 2012, p. 526).

Interestingly, obesity also influences RBP levels. RBP is secreted not only by the liver but also by the adipose tissue. In cases of obesity, impaired glucose tolerance, and diabetes mellitus type 2, the RBP levels measured in serum correlate with the grade of insulin resistance (Graham et al. 2006). In obese or diabetic patients, RBP levels could be increased. These observations might be of importance in the obesity epidemic in recent years.

TTR and RBP as a Part of an Integrated Approach to Diseases

The application of TTR and RBP screening alone or in combination with various inflammatory markers such as CRP, IL-6, procalcitonin, and anthropometric data with malnutrition screening tools could add a lot, depending on specific clinical context. Practically, it is impossible to make a correct interpretation of TTR and RBP values out of the specific clinical context of the disease. In many cases, malnutrition and inflammation are mutually potentiating factors, exerting a synergic influence on the outcome of the disease (Jensen 2006).

An example of a complex approach to the disease is the application of TTR as a screening and prognostic marker in cancer patients. A number of studies support earlier data that TTR levels between 180 and 200 are critical. Lower levels imply a higher risk of fatal outcome. Levels below 110–100 reveal depletion of LBM stores (Ho et al. 2003). A study in renal cancer patients reveals that low basic levels of prealbumin dependently predict the overall survival (HR 1.963; 95% CI, 1.140–3.381; $P = 0.015$) and the progression free survival (HR 2.021; 95% CI, 1.227–3.329; $P = 0.006$, Cai et al. 2017). Similar results were also shown for patients with gastric (Esfahani et al. 2016; Zhou et al. 2017), colorectal (Shimura et al. 2016), and other types of cancers.

Elderly people are also a target group which may benefit from the use of transthyretin as a screening tool for malnutrition assessment. The prevalence of malnutrition in this group is between 29% (Guigoz et al. 1994) and 50% (Visvanathan et al. 2004). In elderly population, the latent malnutrition associated with low or reduced transthyretin levels is related and potentiates the increase of homocysteine. In the last decade, extensive research has analyzed the correlation between transthyretin and homocysteine, as well as between lean body mass and

homocysteine (Ingenbleek et al. 2002). As the link between homocysteine and vascular disease is known, the above data features a new discussion on the relationship between malnutrition and the increased thrombovascular events, i.e., cardiovascular risk in the elderly.

A classic example for the use of transthyretin and retinol-binding protein as malnutrition markers is the studies of vitamin A levels and its deficiency. Retinol-binding protein has been recommended for individual application as a marker that reflects the vitamin A status (Almekinder et al. 2000). Serum RBP levels strongly correlate with serum retinol ($r = 0.88$) in healthy individuals. This correlation remains significant in different conditions like HIV-1 infection, protein-energy malnutrition (PEM), and acute inflammatory response (Baeten et al. 2004). The clinical scientists involved in vitamin A deficiency research in developing countries in the 1990s underlined that PEM always accompanied the deficit of micronutrients to different extents. That leads to the conclusion that the control of both should be simultaneous (McLaren and Kraemer 2012, p. 148). In this context, the concomitant analysis of RBP and TTR for the diagnosis of the vitamin A deficiency plays a key role (Ingenbleek and Young 1994).

TTR and RBP in Indices and Score Systems

Calculating CRP and TRP ratio is among the easiest and most accessible methods of assessing malnutrition and inflammation effects. Férard et al. suggested in 2002 a cutoff CRP/TTR value = 1 in acute inflammatory conditions. Earlier an AGP and TTR ratio was proposed for assessment of the chronic inflammatory diseases (Charet et al. 1996). These indices could give an approximate estimate of the impact of inflammation on the changes in the biochemical markers. Although not widely accepted, they are quite convenient for routine clinical practice.

It was previously discussed that in cases of vitamin A deficiency the molar ratio RBP:TTR contributes to the evaluation of the inflammatory effect on serum vitamin A levels (Rosales and Ross 1998). The suggested cutoff level is 0.36 or less for the RBP/TTR ratio. Accordingly, the value could be used to monitor the efficacy of vitamin A supplementation and also to select persons with critical vitamin A deficiency. Later study validated a cutoff value of 0.37 for the RBP/TTR ratio in adults (Zago et al. 2002).

Prealbumin is a part of several score systems for the assessment of malnutrition:

- Maastricht Index (21 − 0.24 × albumin − 19 × transthyretin (prealbumin) − 1.9 × lymphocytes − 0.04 × percentage of ideal weight) proposed initially by De Jong et al. in 1985.
- Prognostic Inflammatory and Nutrition Index (PINI) (Ingenbleek and Carpentier 1985)

$$\mathrm{PINI} = \frac{\mathrm{CRP(mg/L)} \times \mathrm{AGP(mg/L)}}{\mathrm{SA\ (g/L)} \times \mathrm{TTR(mg/L)}}$$

PINI is a coefficient, integrating two of the most frequently used markers for the assessment of inflammation grade CRP (mg/L) and AGP (mg/L). AGP is an acute-phase protein, whose production depends mainly on the concentration of interleukin-1. AGP's half-life is between 5 and 7 days. CRP is a nonglycosylated protein, whose production depends mainly on the presence of interleukin-6. The half-life of CRP is much shorter: 4–6 h. Normally, the values of PINI are below 1. Values exceeding 30 indicate serious and life-threatening conditions (Ingenbleek and Young 1994 with permission).

David et al. (2013) suggested the use of a combination of laboratory and anthropometric data in AMA. In the initially published model, the main visceral protein was albumin, but the authors also reported results with prealbumin.

Transthyretin is often included in panels of biomarkers, developed by proteomic analysis (Bakry et al. 2011). A new generation surface-enhanced laser desorption/ionization time-of-flight (SELDI-TOF) mass spectrometry (MS) was used to discover the specific and unique combination of serum biomarkers characteristic for different diseases. In the next step, the markers were identified by matrix-assisted laser desorption/ionization (MALDI-) coupled with time-of-flight mass spectrometry (TOF-MS) and finally immunologically verified. The aim was to develop panels of new prognostic biomarkers able to improve the diagnosis and to predict the likelihood of different clinical outcomes. This approach has been already applied in ovarian cancer (Zhang et al. 2004), esophageal cancer (Kelly et al. 2012), and breast cancer (Chung et al. 2014) patients, as well as in other nonmalignant diseases like chronic pancreatitis (Hartmann et al. 2007), etc.

Conclusion

Malnutrition, in particular the reduction of LBM, can be a consequence of insufficient protein and calorie intake, inevitably leading to reduced protein synthesis. It could be also cytokine-induced, a result of a tissue-associated proteolysis, negative nitrogen balance, and prevalence of catabolic processes. Malnutrition might be a combination of these two factors acting to different extents. TTR level depends on its hepatic production which, in return, is influenced by protein intake and by inflammation. Since the initial experimental and clinical observations of transthyretin functions in the 1990s, many nutritionists and physicians successfully apply this marker in routine practice as a screening and predictive tool. With this review, which does not claim to be fully detailed, we have tried to demonstrate the application of transthyretin in the daily clinical practice of different medical specialities. Any screening tool, including one used in malnutrition, has its advantages and limitations. In this context, we cannot recommend a universal approach. Due to its unique biochemical nature, transthyretin is a marker that reflects protein losses in a variety of diseases. It is worth using it for establishing of predictive disease models based on the protein analysis, but also in software-based models and formulas, such as the AMA case.

Polices and Protocols

In this chapter, we have described the significance of biochemical screening via assessment of transthyretin and retinol-binding protein and the main factors influencing their levels. Application depends on national policies and local guidelines. It is important to know that measurement of transthyretin and retinol-binding protein is useful for malnutrition screening, prognosis, and monitoring of therapeutic interventions in combination with other data. The additional data set depends on the screened population, cohorts, and disease-specific characteristics.

Dictionary of Terms

- **Biochemical screening for malnutrition** – The serum concentrations of several proteins that are synthesized in the liver are used as indicators of protein-calorie status – albumin, prealbumin (transthyretin), transferrin, and retinol-binding protein.
- **Hepatic synthetic function** – The ability of the liver to produce proteins including coagulation factors, lipids, bile acids, and other molecules. The most common used hepatic synthetic function tests are albumin and prothrombin.
- **Negative acute phase response proteins** – A group of proteins whose levels decrease during inflammation. This includes albumin, prealbumin, retinol-binding protein, transferrin, and apo-AI lipoprotein.
- **Positive acute phase response proteins** – A group of proteins whose levels increase during inflammation. This includes C-reactive protein, α1-acid glycoprotein, interleukin-1, interleukin-6, tumor necrosis factor-α, γ-interferon, and others.
- **Visceral proteins** – These are also named as hepatic proteins (which are produced in the liver) and include albumin, prealbumin, retinol-binding protein, and transferrin.

Summary Points

- Prealbumin, also called transthyretin, is a protein with a molecular weight of 55 kD. It transports around 10% of thyroid hormones and more than 90% of retinol.
- The three components of the retinol circulating complex which include transthyretin, retinol-binding protein, and retinol have a total molecular mass of 76 kDa. They also circulate in blood, bound in a proportion of 1:1:1.
- Both transthyretin and retinol-binding protein are produced mainly by the liver cells. Together with albumin and transferrin, transthyretin and retinol-binding protein are used for biochemical screening for malnutrition. Current guidelines suggest application of biochemical laboratory data, together with other screening tools for malnutrition.

- Many factors influence levels of transthyretin and retinol-binding protein: gender and age, liver function, starvation and nutrient deprivation, acute or chronic inflammation, renal function, drugs (such as nonsteroid anti-inflammatory drugs), cortisol, and anabolic steroids. All these influencing factors should be taken into account when interpreting the clinical values of TTR and RBP levels. Because of their short half-lives, transthyretin and retinol-binding protein are accepted as rapid responders to therapeutic interventions.
- Serial measurements reflect more correctly the balance between catabolic and anabolic processes and lean body mass fluctuations.
- Incorporation of transthyretin or retinol-binding protein into panels of biomarkers, developed by proteomic analysis or software based models, will direct future research in this area.

Abstract

Measurement of mid-upper arm circumference (MUAC) was originally proposed in the 1960s to assess the nutritional status of children between the age of 1–5 years. It was based on the assumption that it was closely related to muscle mass and also that it varied little with age, making rapid nutritional assessment possible in populations where age is not known with precision. Development of MUAC growth reference curves later showed that the assumption of age independence was not correct and MUAC was progressively abandoned. Weight-for-height z-score (WHZ), which is determined independently of age, became the gold standard for the assessment of acute malnutrition. However, more recently, results of several community studies comparing anthropometric indices to identify children with highest risk of dying have renewed interest in MUAC. Comparison of the receiver operator characteristic (ROC) curves of different indices showed that MUAC was consistently superior to WHZ in identifying children with a high risk of dying. These studies also showed that correction of MUAC for age or for height did not improve its prognostic value. The superior performance of MUAC to identify high-risk children could be due to its preferential selection of younger and/or more stunted children, or to the close relationship of MUAC with muscle and fat mass. These two explanations are not mutually exclusive as young and stunted children tend to have a low muscle mass in relation to body weight which makes them more vulnerable to malnutrition. The performance of WHZ can also be affected by differences in body shape not linked to wasting, by hydration status or by measurement errors. Following these mortality studies, a paradigm shift has taken place in populations with high malnutrition-related mortality, such as in famine situations. The priority then is to identify high-risk children in need of urgent treatment to prevent short-term death. In this context, identification by WHZ, measuring a statistical deviation from a standard, has less practical relevance. Available evidence also suggests that children with a low MUAC can be rapidly identified by community- or facility-based health workers, or by mothers and that children identified by MUAC put on weight rapidly when treated. They should be the priority target for nutritional programs.

Mid-upper arm circumference · MUAC · Nutritional status · Risk · Mortality · Children

List of Abbreviations

AUC	Area Under the Curve
BMI	Body mass index
CMAM	Community-based management of acute malnutrition

DEXA	Dual-energy X-ray absorptiometry
MUAC	Mid-upper arm circumference
ROC	Receiver operating characteristics
RUTF	Ready-to-use Therapeutic Foods
SAM	Severe acute malnutrition
WHO	World Health Organization
WHZ	Weight-for-height z-score

Introduction: Assessing Nutritional Status by Measuring Arm Circumference

The idea of using mid-upper arm circumference (MUAC) for nutritional status assessment was first put forward in a World Health Organization (WHO) monograph published in 1966 (Jelliffe 1966). The rationale was that MUAC was highly correlated with muscle mass, which was then regarded as the body component most relevant to assess nutritional status. Measures of creatinine excretion and limb circumference, which are related to muscle mass, suggested that muscle mass increased proportionately more than body weight during malnutrition treatment (Standard et al. 1959). This suggested that measure of limb circumference was a more reliable measure of nutritional status than body weight. The 1966 WHO Monograph suggested a simple equation to measure muscle arm circumference as a proxy of muscle mass and the idea was later developed to estimate muscle arm area and validated by dual-energy X-ray absorptiometry (DEXA) (Rolland-Cachera et al. 1997) (Fig. 1). The 1966 WHO monograph presented in its annex the expected MUAC in children under 5 years old in relation to age based on a sample of Polish children.

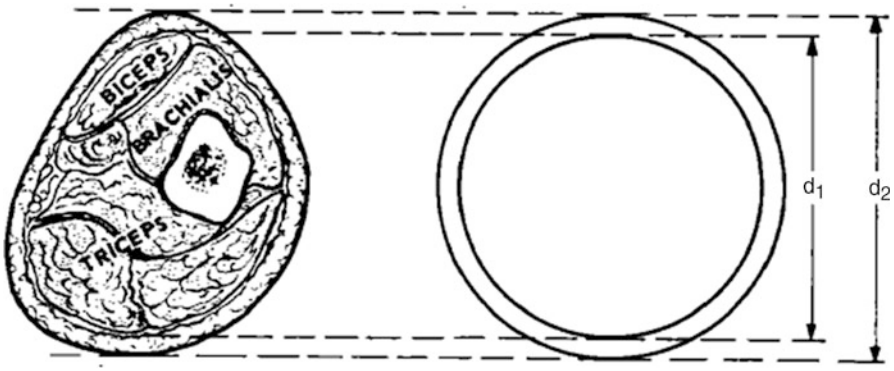

Fig. 1 Schematic cross section of the upper arm. Muscle circumference (MC) can be estimated from MUAC and skinfold thickness (SF) by the formula: MC = MUAC – π SF (Jelliffe 1966). The muscle arm area (MA) can be calculated with the formula (Rolland-Cachera et al. 1997). $MA = (MUAC)^2/4\pi - MUAC \times SF/2$

Using MUAC to assess nutritional status looked simple and quickly attracted attention. In 1969, in a special section of the December issue of the Journal of Tropical Pediatrics, surveys which assessed nutritional status with MUAC were reported from Ethiopia, Uganda, Tanzania, Zambia, Caribbean, Malaysia, Tunisia, Nigeria, Lebanon, Congo, and Haiti. In the same issue, MUAC growth data from Polish children were presented with a smoothed curve which suggested that between the ages of 1–5 years, MUAC grows only by 1 cm (Burgess and Burgess 1969). This led to the suggestion to use MUAC with a single threshold in this age range to detect malnutrition in situations where age is not known with precision (Jelliffe and Jelliffe 1969). In the same issue of the Journal of Tropical Pediatrics, it was proposed to adjust MUAC for height using a specially designed measuring height stick called the "QUAC stick" (Rainer 1969). This method of nutritional assessment was used extensively during the Nigeria civil war of 1969 and led to a rapid mapping of zones most affected by famine (Davis 1971). Such a mapping would have been logistically impossible using weight-for-height z-score (WHZ) and has never been repeated to such an extent in more recent crises.

To further simplify nutritional assessment, Shakir and Morley later suggested using the same MUAC cut-offs to define three degrees of malnutrition in children aged 12–60 months (Shakir and Morley 1974). The proposed cut-offs, 125 and 135 mm, were chosen to be consistent with the then existing classification of malnutrition based on weight-for-age (Shakir 1975). Shakir and Morley also suggested to use a tricolored cord with a green, yellow, or green zone, and Zerfas proposed to use an "insertion tape" (Zerfas 1975). This led to the development of currently used tapes.

The enthusiasm for using MUAC as a simple measuring tool declined when new MUAC growth curves were developed showing that MUAC increases with age more than initially estimated. The MUAC reference curves of the National Center for Health Statistics and also data from Malawi showed that in the age range 1–5 years, the total increase is about 2 cm compared to 1 cm in the Polish sample (World Health Organization 1995). Also, several studies had reported that MUAC gave discordant results compared with weight-for-height, which at that time was the reference criterion to diagnose acute malnutrition in hospital settings (Lindtjørn 1985;Carter 1987; Bern and Nathanail 1995). The 1995 WHO Technical Report on nutritional assessment noted that MUAC selects more children as malnourished compared to WHZ in younger age groups and recommended MUAC-for-age for nutritional assessment (World Health Organization 1995). Progressively, MUAC was abandoned in favor of WHZ, which was perceived to be a more rigorous measure of nutritional status. In its 2000 report on Management of Nutrition in Major Emergencies, WHO recommended to measure of MUAC adjusted for age to assess nutritional status only in situation where weight and height cannot be measured and advised not to use MUAC uncorrected for age (World Health Organization 2000). The rationale for rejecting MUAC was that it did not identify the same children diagnosed as malnourished when using WHZ, although previous reports had shown that WHZ itself did not reflect the clinical judgement of nutritional status any better than MUAC (McDowell and King 1982; Van Loon et al. 1987).

Identifying High-Risk Children with Anthropometric Indices

In the 1980s and 1990s, several studies aimed to determine which nutritional index would best predict children with a high risk of death. The objective was to select a small group of children who would benefit most from a nutritional intervention. All these studies had the same design. After enumerating all children in a community usually within the age range of 6–60 months by an exhaustive census, a full set of anthropometric measures was taken and after a follow-up of several months, survival was assessed. In most cases, this follow-up after nutritional assessment was repeated several times, including in each round all children who reached 6 months and excluding those above 60 months. All these studies took place before the development of community-based management of acute malnutrition (CMAM) and reflect outcome in absence of treatment. At the end of the follow-up, receiver operatic curves (ROC) plotting sensitivity against 1-specificity of each nutritional index to detect children who died were used to compare the value of each nutritional index to identify children with a high risk of death (McNeil et al. 1975). In practical terms, 1-specificity is the proportion of children below a given cut-off who will survive, and sensitivity is the proportion of these children who will die absence of treatment. The most useful anthropometric index will classify below any cut-off the largest number of children who are at risk of dying and the smallest number of children who will survive. In other words, the most useful anthropometric index will have the highest ROC curve.

Several community studies examining the relationship between anthropometry and mortality in untreated children (Table 1). They took place in Bangladesh (2 studies) (Bairagi 1981; Alam et al. 1989), Uganda (Vella et al. 1994), and Senegal (Briend et al. 1989). A review of these studies published in 1994 concluded that "in comparing across studies and across the various comparative criteria, the most consistent observation is that WHZ is the least effective predictor of mortality. For the criterion that is common to all studies (ROC curves), it appears that at high specificities simple MUAC is superior to height-for-age and weight-for-age" (Pelletier 1994, 2073–2074). Another study from Malawi did not include MUAC, but MUAC for age and also found it superior to all other indices (Pelletier 1994; Pelletier et al. 1994). These findings were reconfirmed in two later studies, one in Democratic Republic of Congo (Van den Broeck et al. 1996) and another one in the Gambia in children aged less than 6 months (Mwangome et al. 2012) (see section below).

These studies also showed that correcting MUAC for age did not improve identification of high-risk children. This was shown for the first time by Bairagi in Bangladesh who showed that ROC curves for MUAC and MUAC-for-age were virtually identical (Bairagi 1981). Later on, with a different data set, also from Bangladesh, a logistic regression model showed that correcting MUAC for age or height for did not improve the assessment of the risk of dying (Briend and Zimicki 1986). This suggested that using the QUAC stick was no more effective than using simple MUAC to identify high-risk children.

In 2006, WHO released new growth standards, with potential changes in the relationship between different anthropometric indices and the risk of dying. A reanalysis of the original data of the studies from Senegal and from Congo confirmed the

Table 1 Community studies examining the relevance of different anthropometric indices to identify children with a high risk of death

Study	Country	Age range (months)	Follow-up period (months)	Ranking of ROC curves at high specificity levels
Bairagi 1981	Bangladesh	12–23	24	MUAC > WA > HA > WFH
Alam et al. 1989	Bangladesh	12–59	6	MUAC > HA > WA > WHZ
Briend et al. 1989	Senegal	6–59	6	MUAC > WA > HA > WHZ
Vella et al. 1994	Uganda	6–59	12	MUAC > WA > HA > WHZ
Pelletiet al. 1994	Malawi	0–60	6	MUACA > WA = WHZ > HA
Van den Broeck et al. 1996	Democratic Republic of Congo	12–30	6	MUAC > WA > WHZ
Mwangome et al. 2012	Gambia	1.5–3	Up to the age of 12 months	MUAC > WHZ

Adapted and updated from Pelletier 1994. WA: weight-for-age; HA: height-for-age; MUACA: MUAC-for-age. All these studies used NCHS references to calculate anthropometric indices

superiority of MUAC over other indices to assess the risk of dying (Briend et al. 2012) (Schwinger et al. 2016). The lack of effect of age on risk assessment was also re-examined by a study from Guinea Bissau using MUAC-for-age calculated with the 2006 WHO growth standards. This study confirmed that using MUAC-for-age did not improve the detection high-risk children compared to MUAC (Rasmussen et al. 2012).

Community studies to determine the relationship between different anthropometric indices and the risk of death among untreated children can no longer be ethically repeated now that CMAM is available. Importantly, studies among children who have been selected for treatment by one anthropometric criterion cannot give information on the mortality relationships of other indices.

Hospital based studies, with a recruitment independent of initial WHZ or MUAC, have also shown that MUAC is superior to other nutritional indices in predicting inpatient death (Briend et al. 1986) (Berkley et al. 2005) (Sachdeva et al. 2016). However, hospital-based studies, while potentially informative for that setting, are to be interpreted with caution with respect to understanding the general relationships between anthropometry and mortality, as they are receiving treatment based on the anthropometry and are a sample of children unrepresentative of the general population.

Balancing Benefits and Risk of Treatment

Ideally, screening of children should aim at identifying among high-risk children those with the highest chance of benefiting from an intervention. This information is now difficult to obtain, as it would require comparing groups of treated and untreated

children, and in practice, the risk-based approach is used to identify individuals who may be eligible for interventions.

Selected children should also not be exposed to undesirable secondary effects of treatment. In this respect, fear of treating low-MUAC children with a WHZ above the usual definition of malnutrition with high-fat Ready-to-Use Therapeutic Foods (RUTF) has led some experts to advise not to treat young or stunted children (Myatt et al. 2006). The concern was that these children were not acutely malnourished, that RUTF will fail to generate rapid weight gain and may lead to excessive fat deposition. These concerns, however, were not based on evidence. In programs where short children received RUTF on the basis of their low MUAC independently of their height, weight gain was independent of height (Dale et al. 2013) (Binns et al. 2016) (Fabiansen et al. 2016). Fat deposition is highly energy demanding, and the high weight gain seen in short children suggests it represents only a small portion of weight gain during treatment. In the long term, children treated for SAM often have metabolic abnormalities associated with a reduced proportion of lean mass which may predispose them to chronic diseases (Lelijveld et al. 2016), but there is no evidence this is a special concern for children selected by MUAC.

Towards a Paradigm Shift: From Detecting Malnourished Children to Those with a High Risk of Death

The finding that MUAC was better than other nutritional indices to detect high-risk children has the potential to facilitate the roll out of CMAM programs aiming at reducing the malnutrition related mortality. Children with a low MUAC are easy to identify, have a high risk of death, and respond to treatment, and they should be treated independently of their WHZ when the objective is to reduce malnutrition-related mortality. Such a MUAC-based approach, however, raised concern as children with a low MUAC are not the same as those with a low WHZ. Among children who have either a WHZ less than −3 or a MUAC less than 115 mm, which is the current WHO definition of non-edematous severe acute malnutrition (SAM) (World Health Organization 2009) about 45% only have a WHZ less than −3 and will not be identified by a screening based only on MUAC less than 115 mm. Also, this degree of overlap varies between populations (Grellety and Golden 2016). That these two indices do not identify the same children, however, also explains why MUAC is better that WHZ at identifying high-risk children. If the selected children were the same, the risk would be the same. The move to MUAC requires a paradigm shift, i.e., one has to abandon the objective of detecting the most "malnourished" children, as defined by statistical deviation from a standard, in favor detecting those with the highest risk of death.

The lack of agreement between MUAC and WHZ led most national programs and some nongovernmental organizations to strictly follow the WHO definition of SAM (MUAC <115 mm or WHZ < −3 or edema) and use these two criteria to select high-risk children. Using MUAC alone, however, seems more effective than using a combination of MUAC and WHZ for detecting high-risk children. This is suggested by a reanalysis of the Senegal data which showed that a screening scheme using

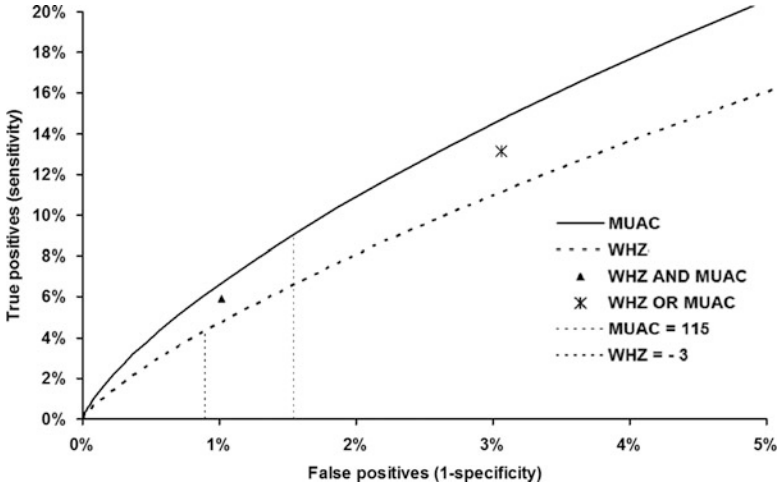

Fig. 2 ROC curves of MUAC, WHZ, and their combinations for assessing the risk of death. ROC curves show sensitivity (% of children below cut-off among those who died) plotted against false positives (1-specificity = % of children below cut-off among those who survived). Data from the Senegal study (Briend et al. 2012). The combination WHZ < −3 OR MUAC <115 mm (*) is more sensitive (i.e., detected more children who died) than using MUAC <115 mm alone. However, this combination is located below the MUAC curve, which means that using MUAC only with a slightly higher cut off (119 mm) selected more children who died while selecting the same number of children who survived. MUAC only is better at detecting high-risk children than combining MUAC and WHZ. WHZ calculated with WHO growth standards

MUAC <115 mm OR WHZ < −3 had a greater sensitivity for death than using MUAC only, i.e., identified more children who eventually died, but this was at the expense of specificity, i.e., the number of selected children greatly increased. This combination of these two diagnostic criteria has a specificity and a sensitivity located under the ROC curve of on MUAC only. This suggests that instead of adding children with a WHZ < −3 to those with a MUAC <115 mm, it is better to include all children with a MUAC <119 mm, irrespective of their WHZ. This will lead to the same number of children to be referred to treatment but among them more would die in absence of treatment (Briend et al. 2012) (Fig. 2).

Protocol: Measuring Arm Circumference

When the measure of MUAC was first proposed, it was advised to do the measurement on the left arm and that the mid-peer arm should be precisely located at mid-distance between the tip of the acromion process and the olecranon process of the ulna (Jelliffe 1966). The rationale for this recommendation was that subcutaneous fat around the arm is not uniformly distributed, and also, it was assumed that the left arm is less influenced by physical activity and would better reflect nutritional status. Although it is not clear that these considerations are relevant in children, these

recommendations have been regularly reproduced in most training documents for health workers. This practice has been challenged recently by a study showing that choosing the left arm and measuring exactly the mid-point did not change significantly the measure in children (Blackwell et al. 2015). Also, in the study showing the closest relationship between MUAC and the risk of death, MUAC was not measured systematically on the left arm and the mid-upper arm not determined precisely as recommended in the initial guideline (Briend et al. 1987). The choice of the tape to measure MUAC is important. It should be done in thin flexible and nonstretchable material. Preference is given to colored insertion tapes, with a window where the precise circumference can be read easily (Zerfas 1975). These tapes usually have three colors corresponding to the locally used cut-off to define severe and moderate malnutrition.

Why is MUAC Better than WHZ to Identify High-Risk Children?

The constant finding that MUAC is better than WHZ at identifying high-risk children can be explained in different ways. Possible explanations are not mutually exclusive and may all be related to the closer link between MUAC, muscle mass, and survival (Briend et al. 2015).

Relationship Between MUAC, Muscle and Fat Mass, and Survival

MUAC is related to arm muscle circumference and subcutaneous fat, and to a lesser extent to bone circumference (Fig. 1) (Jelliffe 1966). This close relationship between MUAC and muscle and fat was one of the main reasons for introducing MUAC as an indicator of nutritional status (Jelliffe and Jelliffe 1969). This relationship has been confirmed by DEXA among healthy well-nourished children (Rolland-Cachera et al. 1997; Jensen et al. 2015) and seems closer for MUAC than for WHZ. Muscle in children represents only 23% of body weight (FAO-WHO-UNU Expert Consultation 1985) and variations in muscle mass will have only a small effect on WHZ compared to its effect on MUAC. Also, weight-based indices may not reflect well muscle wasting in malnourished children who often have an excess of body water (Waterlow 1992).

In absence of infection, fat stores seem to be the main determinant of survival. Carbohydrates disappear after a few hours of fasting, and proteins provides only about 4% of energy in fasting malnourished children. Fatty acids and ketone bodies produced by the metabolism of triglycerides stored in body fat become the main fuel for most organs (Cahill 2006) (Kerr et al. 1978). When malnutrition is associated with infection, or any other aggression (injury, trauma), muscle proteins are mobilized to make free amino-acids available for acute phase proteins synthesis (Reeds et al. 1994). In these clinical situations, muscle mass seems to be the main factor limiting survival (Heymsfield et al. 1982; Briend et al. 2015).

Only two epidemiological studies attempted to assess the respective role of muscle and fat mass as determinant of survival. In the first study in Senegal, triceps skinfold thickness was associated with survival in univariate analysis but this association disappeared in multivariate analysis when arm circumference was introduced in the model. The authors concluded that survival is mainly determined by muscle mass (Briend et al., 1989). A second study examined this association in different times of the year using indices of "fatness" and "muscularity" derived from MUAC and skinfold thickness and found that fat was the main determinant of survival in the dry hungry season whereas muscle was more important in other seasons with a higher prevalence of infections (Van den Broeck et al. 1998). This observation fits well with the hypothesis that whereas fat is the main factor limiting survival in starvation, muscle may be more important for survival when malnutrition is associated with infection.

The Age Effect

MUAC increases continuously with age and selection of children based on a fixed cut-off will always select preferentially younger children. This bias in favor of young children is well described in the 1995 WHO report on the use and interpretation of anthropometry (World Health Organization 1995). In all populations, mortality declines with age in children and this selection bias in favor of young children tends to select a group with a higher mortality when exposed to malnutrition. This effect, however, is likely to be minimal. First, the decline in mortality with age is slow after the first 6 months, and is unlikely to explain the high gradient of mortality associated with low MUAC. Also, the correction of MUAC for age does not affect the value of MUAC to identify high-risk children, whereas it should remove it if the main effect of MUAC was only to select younger children. Importantly, the good prognostic value of MUAC is also observed in adults, when it cannot be due to an age effect. Age may have an effect of muscle mass. Infants and young children, however, also have a low muscle mass compared to adults: about 23% vs 43% (FAO-WHO-UNU Expert Consultation 1985) and this different body composition is likely to make them more likely to die from the association of malnutrition and infection. This suggests that for deciding about an intensive nutritional support, this selection bias in favor of young children with a low muscle mass is advantageous.

The Effect of Body Shape

Differences in body shape can also explain why some children can have a low WHZ while having a MUAC above the malnutrition threshold. This has been well described in the case of leg length: children with long legs have a lower WHZ on average, which may be common in some parts of Africa (Myatt et al., 2009). This can lead to classifying wrongly as malnourished children who have leg length above average, as children with long legs are usually in better health and nutritional status

than average (Bogin and Varela-Silva 2010). On the opposite, stunted children who usually have shorter legs can have an artificially high WHZ although they are likely to have a low muscle mass. Children treated for SAM and who remain stunted have a smaller arm and calf circumferences compared to sibling controls, suggesting a lower muscle mass (Lelijveld et al. 2016).

The effect of leg length on WHZ was highlighted in the context of diagnosing malnutrition in some parts of Africa but is presumably not the only factor related to body shape affecting the relationship of WHZ with nutritional status. Chest and abdomen circumference are also known to influence WHZ and could explain the low prevalence of low WHZ observed in Brazil (Post and Victora 2001). This effect will influence WHZ independently of muscle mass as there are only few muscles in chest and abdomen. Other subtle differences in body shape, not well described by simple length or circumference measures, may also influence WHZ independently of nutritional status and this would warrant further investigation using modern 3D modelling of body volumes.

MUAC in Other Age Groups

Infants Less than 6 Months

The risk of mortality associated with MUAC in early infancy is less well understood. In the half a century (1966–2016) of studying MUAC, most studies and surveys have systematically excluded infants under 6 months and as a result little data is available to describe MUAC's and other anthropometric indices performance in this age group. The main reason for this exclusion has been the perception that malnutrition is rare within this age group because optimal breastfeeding is practiced universally. With the introduction of the WHO growth standards in 2006, data was reanalyzed and this perception was challenged: studies observed a much higher proportion of undernutrition in the under 6 months than previously reported. Using the WHO standards increased the prevalence of severe wasting in the under 6 months by a factor of 3.5 (de Onis et al. 2006; Kerac et al. 2011).

Although limited, there is strong evidence for introducing the use of MUAC in the under 6 months as well. Recent studies of MUAC in the under 6 months have attempted to replicating experimental designs reproduced observations made with previously used in studying MUAC in older children (6–59 months). They have compared MUAC to WHZ performance to assess the risk of death and used similar analysis methods used in the historical studies. Using a ROC curve analysis method, in a cohort of community Gambian infants, MUAC taken at the point of vaccination between 6 and 14 weeks better predicts mortality occurring before 12 months of age than WHZ (Mwangome et al. 2012). The reported Area Under the Curve (AUC) of the ROC curves for predicting mortality for MUAC was 0.64 (95% CI 0.55 to 0.73) compared to 0.55 (95% CI 0.46 to 0.65) for WHZ. In this study a MUAC cut-off of $<$110 mm was proposed for diagnosis of SAM in infants under 6 months. The poor outcome associated with a MUAC less than 110 mm in children less than 6 months

has been confirmed in a clinical trial in Kenya which examined the effect of cotrimoxazole prophylaxis on posthospital mortality in children with SAM. In this sample, 24.5% of children aged 2–5 months with a MUAC less than 110 mm died during the 6 month follow-up, with no beneficial effect of cotrimoxazole prophylaxis (Berkley et al. 2016).

Adults

There are no community studies which examined the respective value of different anthropometric indices to identify malnourished patients with a high risk of death in absence of nutritional support. Several studies, however, suggest as well that MUAC is a good prognostic indicator, and better than body mass index (BMI). A study done among patients admitted in emergency to a London hospital found that MUAC was a significant predictor of mortality either alone ($P = 0.002$) or after adjustment for BMI ($P = 0.007$), but that BMI was not (Powell-Tuck and Hennesy 2003). Another study done in a therapeutic feeding center in South Sudan found that the AUC of ROC curves for MUAC to predict death was 0.71 for MUAC compared with 0.57 for BMI and 0.51 for weight (Irena et al. 2013). As patients in this study were selected with MUAC, extrapolation of this result to the community should be cautious.

A third study also examined MUAC and WFH in adult patients with tuberculosis in Guinea Bissau and found MUAC to be a good predictor of death. Although this study did not formally compare the ROC curves of these indices to identify high-risk patients, they advised the use of MUAC as it was not possible to measure height in some patients who were unable to stand up (Gustafson et al. 2007). Outside the context of malnutrition, muscle arm area was found to better identify elderly patients at a high risk of death in Australia (Miller et al. 2002). Eventually, in patients with Chronic Obstructive Pulmonary Disease, arm muscle area was also found to be a better predictor of the risk of death than BMI (Soler-Cataluña et al. 2005).

Conclusion: Towards a Frequent Decentralized Nutritional Status Assessment with MUAC to Identify Children in Need of Treatment

MUAC is comparatively easy to measure and requires only a simple tape. This contrasts with WHZ which requires the presence of two trained people for measuring height. Also, MUAC does not require calculations, which beyond simplicity has the advantage of not adding errors on different measures. This is a problem especially in children aged less than 2 years, for WHZ is strongly affected by measurement errors on height which is difficult to measure (Mwangome and Berkley 2014). Illiterate mothers given colored tapes can correctly classify children in different MUAC categories (Blackwell et al. 2015) and using mothers to measure MUAC has the huge advantage of making possible frequent screening, which is more difficult with community health workers, and impossible outside research context with WHZ. The association between anthropometry and the risk of death is closer for shorter duration

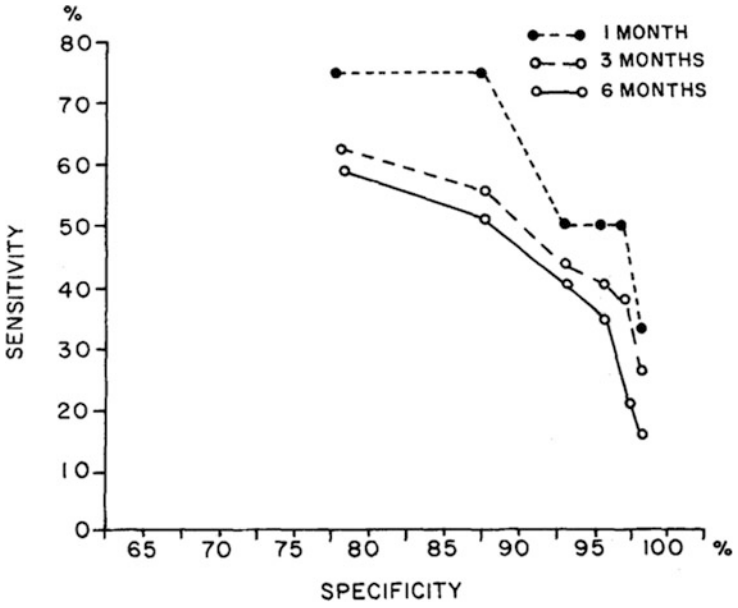

Fig. 3 Effect of durations of follow-up from 1 to 6 months on the position of the ROC curve of MUAC to identify children with a high risk of death. The higher position of the ROC curve for shorter follow-up duration indicates a better identification of high-risk children. This suggests that the best identification will be obtained by frequent measures. The same phenomenon is likely to occur with other nutritional indices, in particular WHZ, but their frequent measure in the community is not possible in practice (Data from Bangladesh (Briend and Zimicki 1986))

of follow-up for all nutritional indices (Pelletier et al. 1994). This has also been shown for MUAC with an improvement of the ROC curves when duration of follow-up is shortened to 1 month (Briend and Zimicki 1986) (Fig. 3). Pilot programs with detection of SAM carried out by mothers with MUAC have shown that this approach resulted in a decreased hospital admission (Alé et al. 2016), suggesting that early detection of high-risk children allowed an early initiation of treatment before the occurrence of complications. This decentralized detection approach seems the way forward for early detection and treatment of these high-risk children.

Summary Points

- MUAC was initially proposed to assess nutritional status as it was believed to be closely related to muscle mass
- It was also initially assumed that MUAC varied little between 12 and 60 months and that it could be used without correction for age in nutritional assessment in populations where age is not known with precision but this assumption is not correct.

- MUAC increases with age and does not identify as malnourished the same children as WHZ which is often considered as a "gold standard" for nutritional assessment
- All community studies examining the relationship between anthropometry and mortality in absence of treatment showed MUAC is better than WFH to identify children in need of treatment to prevent death.
- The superiority of MUAC to identify children at risk of inpatient mortality was confirmed in hospital-based studies using a sample of children selected independently of anthropometry
- Early work suggests that MUAC identifies high risk infants less than 6 months
- The relationship between MUAC and risk of death may be due to its association with body composition or to a preferential selection of younger and more stunted children with a higher risk of death; these two explanations are not mutually exclusive
- Identification of high-risk children seems more effective for short follow-up periods, suggesting that frequent screening would reduce risk.
- MUAC can be measured frequently by minimally trained health workers or by mothers, which allows the rapid evaluation of high-risk children.

Nutrition Screening and Assessment in Hip Fracture

39

Jack Bell

Contents

Abstract

Protein-energy malnutrition is prevalent in one in two patients admitted with a hip fracture; commonly observed inadequate postoperative protein/energy intake leads to further incident inpatient malnutrition. This condition is reported as the most costly comorbidity in hip fracture. The complex, multimorbid population limits the usefulness of routinely applied malnutrition screening tools. Given the

high cost, prevalence, and incidence of malnutrition, and poor sensitivity of most screening tools, routine comprehensive nutrition assessment of all acute hip fracture inpatients is recommended. There is no gold standard for malnutrition diagnosis in the clinical setting in hip fracture. Malnutrition diagnosis is complex in this patient population, and often requires triangulation of multiple nutrition assessment measures from a variety of sources over multiple time periods. Single variable measures should not be relied upon to diagnose malnutrition, and commonly applied index measures may still require a subjective clinical judgment to inform a final diagnosis.

Malnutrition in Hip Fracture

In the UK alone, hip fractures annually cost £1.1 billion in the acute care setting; estimates suggest a doubling or tripling of this figure after accounting from broader health and social care costs (Hernlund et al. 2013; Leal et al. 2016). Forward estimates suggest an increase in annual UK hip fracture rates from 79, 000 to 104, 000 within the next decade (Hernlund et al. 2013).

Protein/energy malnutrition or undernutrition (malnutrition) is the most costly comorbidity in hip fracture inpatients, the comorbidity most likely to prolong hospital stay, and is an independent predictor of increased morbidity and 12-month mortality (Table 1).

One-third to half of hip fracture inpatients admitted to hospital are malnourished (Avenell et al. 2016; Bell et al. 2014a, 2016). Inadequate inpatient oral intake is

common and resistant to intervention; this has been observed to lead to further nutrition decline in the inpatient setting (Bell et al. 2013b).

Despite demonstrated impact on patient and healthcare outcomes, malnutrition has not been prioritized in international registry data or guidelines until recently (Australian and New Zealand Hip Fracture Registry (ANZHFR) Steering Group 2014; Johansen et al. 2017.; National Institute for Health and Clinical Excellence 2011; Scottish Intercollegiate Guidelines Network 2009). Limitations in malnutrition screening and assessment processes are considered to have contributed to this limited attention toward clinical nutrition care (Avenell et al. 2016; Bell 2014).

Nutrition Screening in Acute Hip Fracture Inpatients

Nutrition screening should be a quick and easy process able to be applied to large numbers of people to identify those at significant risk of malnutrition (Elia and Stratton 2011; Mueller et al. 2011). In the hospital setting, a positive nutrition screen should routinely lead to further detailed nutrition assessment, diagnosis, and initiation of medical nutrition therapy where significant patient and cost benefits are expected (Jensen et al. 2013; Mueller et al. 2011). There is neither a gold standard nor a single purpose for inpatient nutrition screening; the usefulness of each tool is dependent on the population, nutrition issue(s), context, and treatment aims and outcomes (Elia and Stratton 2011; Rasmussen et al. 2010). A broad number of validated screening tools have been applied across hip fracture settings; these report substantially different proportions of "at-risk" patients (Table 2).

The Malnutrition Screening Tool (MST) (Ferguson et al. 1999), Nutrition Risk Screen (NRS) 2002 (Kondrup et al. 2003), and Malnutrition Universal Screening Tool (MUST) (Elia 2003) are applied in a number of studies, although have recently been reported as inadequately sensitive to identify malnutrition in a representative cohort of acute hip fracture inpatients (Bell et al. 2014c). The comprehensive Mini Nutritional Assessment requires considerable time to complete and may be less suitable for application in routine clinical nutrition care than the short-form version (Kaiser et al. 2009). The Mini Nutritional Assessment Short-Form (MNA-SF), although reported as poorly specific in hip fracture, is adequately sensitive, and consequently may be best placed to apply if screening is to be relied on rather than proceeding directly to nutrition assessment (Bell et al. 2014c; Koren-Hakim et al. 2016).

Factors adversely affecting nutrition screening tool acceptability, sensitivity, specificity, reliability, and completion rates, when applied in hip fracture inpatients in routine clinical practice, are highlighted in Fig. 1 (Bell 2014).

Nutrition Assessment in Hip Fracture

A comprehensive nutrition assessment for the purpose of diagnosing malnutrition should consider a systematic approach to collecting and recording the data obtained from patients, clients, family members, caregivers, and/or other individuals and

groups (Cederholm et al. 2017; White et al. 2012). Commonly applied assessment measures and markers are listed in Table 3.

Clear nutrition diagnoses are considered helpful to guide nutrition treatment goals, interventions, and monitoring and evaluation strategies (Mueller et al. 2011). A detailed diagnosis of malnutrition should include the problem (protein/energy malnutrition) and ideally should also be accompanied by one or more etiologies (root causes) along with documentation of supporting signs and/or symptoms (White et al. 2012).

The overarching etiology of malnutrition in acute hip fracture patients can be attributable to wasting, cachexia, or a combination of the two (Bell 2014; Cederholm et al. 2017; Jensen et al. 2013). Diagnostic nomenclature may consider acute and chronic disease-related malnutrition (with or without inflammation), and/or malnutrition without underlying disease (Cederholm et al. 2017; White et al. 2012). The hip fracture population demography can make the challenge of differentiating

between malnutrition, frailty, and ageing and disease processes difficult (Cederholm et al. 2017). A diagnosis of protein/energy malnutrition should only be made in cases where there is either insufficient intake or uptake of protein/energy (wasting), increased metabolic requirements for protein/energy, which are not being met (cachexia), or both (Cederholm et al. 2017; White et al. 2012).

The many underlying potential contributors to malnutrition observed in hip fracture are diverse, as highlighted in Table 4 (Bell et al. 2013a).

Nutrition Assessment Parameters Applied in Hip Fracture: An ABCDE Approach

A – Anthropometric: Physical and Functional Measures

A variety of anthropometric measures are applied for the purpose of nutrition assessment in hip fracture. A recent review detailed clinical considerations regarding application and interpretation of these measures when applied in hip fracture patients (Bell 2014). These are summarized in Table 5.

The association between weight loss and poor patient and healthcare outcomes are broadly reported following acute hip fracture (Nikkel et al. 2012). However, factors detailed in Table 5 require attention to avoid misclassification of nutrition status based on weight or weight changes.

Stadiometer height should not be considered the gold standard in hip fracture; the significant underestimate of height related to kyphosis is considered to increase the likelihood of BMI misclassifications and underdiagnosis of malnutrition (Bell 2014). Recently documented or self-reported height may be appropriate where considered realistic; however, the accuracy of self-reported estimates in hip fracture inpatients needs to be carefully considered (Bell et al. 2013a). Consideration should also be given to the overreporting of height in older patients attributed to age-related height reduction. Calculated heights or surrogate measures of height including knee height, demi-span, half-arm span, arm-span, ulna, humeral, tibia, and fibula lengths, and combinations of these, are also reported across hip fracture studies (Bell 2014). Ulna measurements, demi-span, and half-arm span are most commonly recommended and reported. In a patient population prone toward osteoarticular disease, kyphosis, and cognitive impairment, calculated heights from ulna measurements may provide the most practical alternative to apply in clinical practice (Auyeung et al. 2009).

BMI (body mass index) is the second most commonly applied nutrition assessment measure applied for the purpose of describing malnutrition in hip fracture populations after albumin (Bell 2014; Rasmussen et al. 2010). Many prognostic studies identify a positive association between weight-for-height measures and poor patient and healthcare outcomes following hip fracture (Bell 2014). BMI is reliant on accurate height and weight data; underreporting of height may underestimate true BMI in hip fracture inpatients (Bell 2014). This measure fails to differentiate between adiposity and lean body mass, or fluid shifts. Identifying the appropriate cutoff points for individuals and population groupings using weight-for-height measures remains a challenge in response to ethnic variances, the obesity paradox, and age- and disease-related recommendations. Most importantly, reliance on BMI will fail to identify healthy weight or overweight malnutrition (Bell et al. 2014a). The lower than median reported prevalence for BMI-reported malnutrition versus other measures may suggest that healthy weight or overweight malnutrition is masking the true prevalence of malnutrition in hip fracture inpatients (Bell 2014; Bell et al. 2014a).

Calf circumference or mid-upper arm circumference measures may provide useful alternatives to BMI in hip fracture (Kaiser et al. 2009; Rasmussen et al.

Table 5 Clinical considerations or concerns when applying weight, BMI, and other anthropometric measure applied in routine clinical evaluation of acute hip fracture patients (A number of clinical factors that should be considered when collecting or interpreting weight, BMI, and other anthropometric measure applied in routine clinical evaluation of acute hip fracture patients are highlighted (Source: Adapted from Bell 2014; used with permission))

Consideration/concern	Potential cause
No measures easily identified	Devolution of accountability High measurement cost High patient acuity Inadequate access to equipment or trained operators Lack of accountability Lack of clear process Limited patient mobility Pain Poor documentation processes Poor attention to regular measurements by health professionals or facilities
Incorrect or unreliable measures	High interobserver variability Inadequate training/skills/practice Inappropriate equipment Incorrect documentation Incorrect, inaccurate, or misleading patient reported data Kyphosis Limited attention to calibration of equipment Physiological/physical limitation Poor technique
Fluid shifts	Postoperative overhydration/fluid overload Dehydration Multimorbid population (e.g., Chronic kidney disease, Heart failure, liver disease) Medications, e.g., diuretics
Fat versus fat free mass redistribution	Ageing Disease processes Physical (in)activity Hormonal/metabolic changes Medications Rapid weight gain or loss Insufficient protein versus total energy intake
Reference values	Lack of suitable age, gender, ethnicity, or disease-specific reference ranges
Healthy/overweight/obese malnutrition	Wasting/cachexia observed in patients with higher BMIs

2010). However, circumference measures also appear to report lower malnutrition prevalence data when compared with other measures, and appear less likely to prognosticate negative nutrition related outcomes post hip fracture (Bell 2014; Bell et al. 2014a).

Triceps skinfolds measures are often combined with the mid-upper arm circumference to calculate the mid-arm muscle circumference to estimate total body protein stores (Bishop et al. 1981; Blackburn et al. 1977). These measures need to be

cautiously applied in routine clinical practice due to interobserver variation, limited sensitivity in articulating acute nutrition status changes, the need to account for edema, and limited availability of population-specific reference ranges (Bell 2014). Studies in hip fracture tend to associate nonsignification over positive associations between low skinfolds/arm circumference values and poor outcomes (Bell 2014).

Bioelectrical impedance analysis studies in hip fracture report high exclusion criteria resulting in a research population not considered representative of those found in routine clinical practice. This may result from difficulty in applying, for example, to hip fracture patients with agitated delirium (Bell 2014). This method may provide an underestimate of malnutrition in hip fracture patients prone to overhydration. Differences in individual body morphology and fat distribution can also impact accuracy (Hoekstra et al. 2011). Finally, the requirement for specialized equipment and trained operators may limit applicability in some clinical settings.

Dual-energy X-ray absorptiometry measures total body protein, total body fat, electrolyte levels, and water content. Although both considered gold standards for research purposes, these methods are not routinely applied in clinical practice assessment in hip fracture.

Even basic anthropometric data can be difficult to obtain and interpret in the multimorbid hip fracture inpatient. Basic pragmatic measures should consider measured weight and weight changes, ulna length or patient/first degree relative reported heights, and BMI or calf circumference measures. However, insightful clinicians will avoid routine reliance on single anthropometric measures as stand-alone markers of malnutrition.

B – Biochemical Markers

Albumin synthesis is compromised in nutrition depletion, and is the most highly reported nutrition marker in hip fracture studies (Weimann et al. 2017; Yuwen et al. 2017). The need to consider the limitations of this measure is highly disregarded across many studies (Table 6) (Bell 2014).

Although "quick and easy" to access and report, there is a growing call for clinicians and researchers to discontinue relying on albumin as a stand-alone marker of nutrition status in hip fracture, particularly in older patients with acute infection or inflammation (Bouillanne et al. 2011; Marshall 2008).

Prealbumin (transthyretin), total protein, transferrin, and retinol-binding protein are also reported as markers of nutrition status across hip fracture studies. Low levels of these markers are generally nonsignificantly or negatively associated with poor outcomes (Bell 2014). However, sensitivity to the acute phase response, cost of testing, and limited availability of these measures should be considered as limitations to reliance on these proteins as single-point malnutrition diagnostic measures in clinical practice (Marshall 2008).

A decline in insulin-like growth factor (IGF-1) is inconsistently associated with reduced nutrition status, sarcopenia, postoperative outcomes, and increased risk of hip fracture, and may be positively influenced by nutrition intake (Chevalley

Table 6 Advantages and disadvantages of albumin as a nutrition marker in hip fracture (Commonly reported advantages and limitations of albumin as a marker of malnutrition in patients following an acute hip fracture are highlighted (Source: Adapted from Bell 2014; used with permission))

Perceived/reported advantages	Limitations
Associated with patient, clinical, and healthcare outcomes Easy to access retrospectively Inexpensive to test Routinely available Simple quantitative measure	Does not routinely deplete in long-term malnutrition Impacted by synthetic function Impacted by fluid shifts/blood product support Poorly sensitive to short-term nutrition changes Reduced levels in acute phase/inflammation/infection Reduced levels with renal losses Sensitive to fluid shifts and redistribution between intracellular/extracellular compartments

et al. 2010; Myint et al. 2013). However, cost and availability of testing combined with suppression in the acute inflammatory state may impact the utility of this measure as an independent measure of malnutrition in routine clinical practice.

Creatinine height index and nitrogen balance studies appear limited to highly controlled, efficacy-focused hip fracture studies (Bell 2014).

The multimorbid nature of hip fracture patients necessitates regular consideration of a broad variety of additional laboratory measures to assess vitamin and mineral deficiency or redistribution states, and to support supplementary nutrition diagnoses in addition to that of protein/energy malnutrition.

Many laboratory measures provide useful support in facilitating comprehensive nutrition assessment, monitoring, and evaluation. However, the proclivity of clinicians and researchers toward application of laboratory measures as independent malnutrition diagnostic measures, with lack of attention to confounders, requires attention.

C – Clinical History and Physical/Functional Assessment

Current and previous medical and surgical conditions, medications, and identification of barriers and facilitators to nutrition care should be considered (Bell 2014). Patient perceptions of nutrition and their opinions regarding nutrition support options should also be sought (Bell et al. 2013a). A multidisciplinary orthogeriatric service has been considered best placed to source this data, although further work is required to establish the usefulness of interdisciplinary or transdisciplinary models of care (Bell et al. 2014b; Hoekstra et al. 2011; Choi and Pak 2007).

Indirect calorimetry is increasingly applied across research and clinical settings, although remains outside the scope of most clinicians and their patients in acute hip fracture settings (Bell 2014). Estimates of energy expenditure suggest an increased metabolic requirement in hip fracture patients; however, reported estimates do not routinely account for additional thermic effects of food, physical activity, or multimorbid states (Bell 2014). Study populations also appear highly selected and may not be reflective of those encountered in current routine clinical practice (Bell 2014).

Complex equations to estimate energy do not always relate to measured requirements or the actual requirements of individuals observed through careful monitoring and evaluation processes. For this reason, it may be more judicious to choose a simple estimation method, such as 25–35 cal/kg or 1.2–1.5 g/kg protein, and focus resources toward monitoring and evaluation strategies instead (Dietitian/Nutritionists from the Nutrition Education Materials Online team 2014).

Direct observation of muscle wasting and fat stores, skin integrity, wound healing, hair and nail deformities, and other specific bedside observations will facilitate identification of macro- and micronutrient deficiencies.

Physical and functional measures applied to facilitate nutrition assessment in hip fracture include muscle strength, exercise tolerance, and immune response. Handgrip strength or dynamometry may be useful in some hip fracture settings (Duncan et al. 2006; Gumieiro et al. 2012). However, the heterogeneity of findings combined with a population demographic prone to delirium, dementia, cognitive impairment, and osteoarticular disease may limit the routine application of this technique in clinical practice (Bell 2014).

Numerous hip fracture studies report associations between lymphocyte count and/or delayed cutaneous hypersensitivity as markers of nutrition status (Bell 2014; Foster et al. 1990). Although associated with nutrition depletion and morbidity and mortality, the use of lymphocyte count and delayed hypersensitivity as independent measures of nutrition status in routine clinical practice is not recommended (Marshall 2008).

D – Dietary Information

Dietary intake assessment of hip fracture inpatients will need to consider preadmission intake for the purpose of nutrition risk screening and diagnosing malnutrition prevalence, and inpatient intake for the purpose of ongoing nutrition risk screening, nutrition support, and diagnosis of malnutrition incidence.

Adapted visual estimate methods recording quartile or proportional intake of served meals are the most commonly reported nutrient intake estimation method applied in hip fracture settings (Duncan et al. 2006; Eneroth et al. 2005). Highlighted limitations have included difficulties capturing intake between main meals, limited training of data collectors, and inconsistent approaches to describing attribution of macronutrient values (Bell 2014).

Chronological 24-h recalls are also commonly reported, in addition to multiple pass 24-h recalls, recorded or photographed intake data, food frequency questionnaires, and diet history interviews (Chevalley et al. 2010; Hoekstra et al. 2011; Rutishauser 2005). However, the accuracy and reliability of dietary recall data obtained from elderly inpatients prone to delirium, dementia, cognitive impairment, and affect optimization should not be assumed (Bell et al. 2013a; Sivakumar et al. 2013).

Although weighed food records are considered as gold standard intake measures, these are considered both time and resource intensive (Williamson et al. 2003). Menu records, estimated records (or unweighed food records), and adapted weighed food records may be more useful in the clinical and pragmatic research environments (Rutishauser 2005).

E – Environmental

A robust nutrition assessment will consider social, psychological, and environmental information; however, in a patient population where the majority may have delirium, dementia, or cognitive impairment, accurate and adequate collection of historical data may be difficult to achieve (Hoekstra et al. 2011; Sivakumar et al. 2013). Triangulation of data from a variety of sources should be routinely undertaken where required. This will help to guide a final clinical judgment diagnosis inclusive of the problem, etiology, and signs and symptoms (White et al. 2012).

Index Scores or Global Assessment Measures

In the absence of a single measure "silver bullet" diagnostic measure, index scores or global assessment methods may be considered more appropriate for the purposes of diagnosing malnutrition in hip fracture. These are described in Table 7.

Nutrition Screening and Assessment: Summary

Barriers to appropriate nutrition screening and assessment measures in hip fracture inpatients are numerous (Fig. 2). These have contributed to the highly divergent reported prevalence of malnutrition risk or malnutrition of 0–99% across studies and measures (Bell 2014). This justifies the need for a more considered approach toward nutrition screening and diagnostic tool selection and application in hip fracture. Conflicting and lacking data will challenge nutrition assessment processes in an acutely unwell, multimorbid population prone to delirium, dementia, cognitive impairment, affect optimization, and frailty. There is no malnutrition screening or diagnostic gold standard. However, the lack of a gold standard should not be considered an opportunity to seize single "quick and easy" techniques that do not adequately assess individuals for malnutrition or consider well-established confounders. Hip fracture patients are multimorbid and require multimodal, multidisciplinary care. Routine nutrition assessment will require triangulation of multiple nutrition assessment measures from a variety of sources over multiple time periods. Many cases will still, however, necessitate a clinical judgment diagnosis of malnutrition which may require some divergence from standardized criteria

Table 7 Key advantages and limitations of index scores reported across hip fracture studies (Reported advantages and limitations of index scores when applied in hip fracture patients are outlined)

Index score	Description	Observed/ reported advantages	Potential or perceived limitations	Examples
Mini Nutritional Assessment[a]	Numerical scoring system for both nutrition screening and malnutrition diagnosis No nutrition risk Nutrition risk Malnutrition	Demonstrated predictive and concurrent validity Broadly recommended, implemented, and reviewed across settings Highly sensitive screening component Allows for international benchmarking Objective numerical measure	Some parameters difficult to obtain/ confirm in hip fracture inpatients Length of time to administer Low specificity reported across a number of studies Low completion rates reported in a number of studies	Helminen et al. 2017; Gumieiro et al. 2013; Guo et al. 2010; Hoekstra et al. 2011; Duncan et al. 2006
Mini Nutritional Assessment-Short Form[b]	Numerical scoring system for both nutrition screening and malnutrition diagnosis (short-form version) No nutrition risk Nutrition risk Malnutrition	Less than 5 min to administer Limited training required Ease of use by a variety of health professionals Objective numerical measure	Some parameters difficult to obtain/ confirm in hip fracture inpatients Limited application in hip fracture with mixed predictive/ concurrent validity reported May underidentify malnutrition in hip fracture	Nuotio et al. 2016; Formiga et al. 2005; Koren-Hakim et al. 2016; Bell et al. 2014a
Subjective Global Assessment[c]	Subjective assessment completed by trained assessor. Includes weight, intake, GI symptoms, functional capacity, and physical evaluation components. Categorizes patients as:	Demonstrated predictive and concurrent validity Broadly recommended, implemented, and reviewed across settings Allows for international benchmarking Reported good intra- and	Some parameters difficult to obtain/ confirm in hip fracture inpatients Requires training to administer Subjective interpretation necessitates clinical judgment capacity and evaluation of reliability for study purposes	Eneroth et al. 2006; Bell et al. 2014a; Bell et al. 2016

(*continued*)

Table 7 (continued)

Index score	Description	Observed/ reported advantages	Potential or perceived limitations	Examples
	SGA A (well nourished) SGA B (suspected or mild-moderate malnutrition) or SGA C (severe malnutrition)	interrater reliability Relatively easy to administer by trained clinicians Subjective nature allows clinical judgment diagnosis Takes 5 - 10 minutes to complete	Categories may require adaptation to meet diagnostic criteria for case-based reimbursement funding	
International Statistical Classification of Diseases and Related Health Problems Criteria[d]	Subjective assessment completed by trained assessor. Includes BMI or weight, intake, and physical evaluation components.	Allows clinical judgment diagnosis Demonstrated predictive and concurrent validity Linked to case-based reimbursement funding	Less commonly reported in hip fracture Some parameters difficult to obtain/ confirm in hip fracture inpatients	Bell et al. 2014a; Nikkel et al. 2012
ASPEN/AND Consensus Statement[e]	Subjective assessment completed by trained assessor. Includes assessment across six domains with two or more domains to be met for diagnostic purposes	Allows clinical judgment diagnosis Includes consideration of etiology of malnutrition within diagnostic component	Limited application or evaluation in hip fracture settings	Bell et al. 2014a

[a]Guigoz et al. (1994)

or index measures. Consultation and confirmation with other members of the multidisciplinary team prior to documentation may be helpful in such cases. Malnutrition is the most costly comorbidity in hip fracture; the additional effort required to secure a correct diagnosis should be considered time well spent.

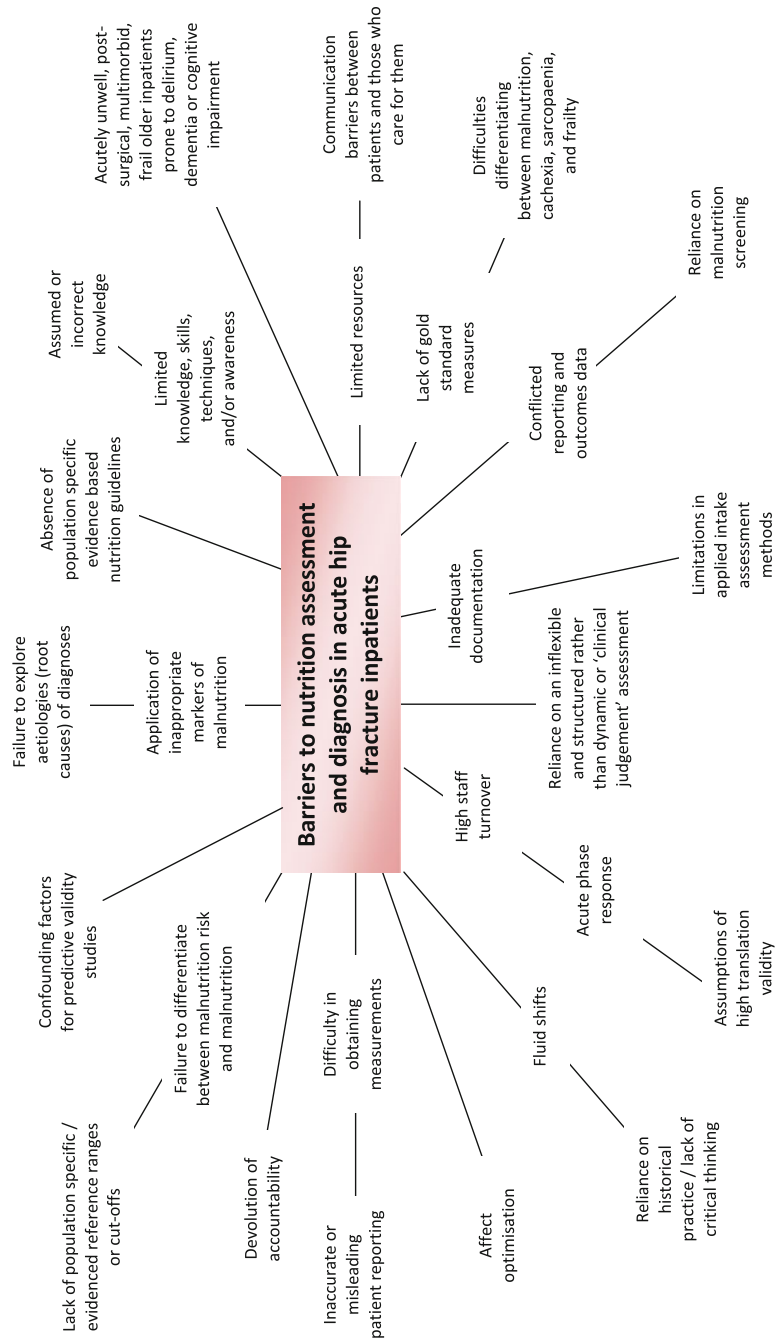

Fig. 2 Potential barriers to nutrition assessment and diagnosis in hip fracture inpatients (Source: Adapted from Bell 2014; used with permission)

Protocol: Nutrition Screening and Assessment in Hip Fracture

Purpose

Identify hip fracture inpatients at risk of malnutrition or with a malnutrition diagnosis to facilitate timely delivery of clinical nutrition care

Procedure

- Systematic, multidisciplinary nutrition assessment and intervention should be undertaken on admission for all hip fracture inpatients wherever resources allow
- Malnutrition diagnosis criteria should be applied by a trained medical officer, dietitian, or delegate, using a tool that:
- has demonstrated adequate predictive and concurrent validity in hip fracture
- is not limited to a single measure or marker
- allows for clinical judgment
- If screening is to be relied upon, a screening tool should demonstrate adequate sensitivity in the population in which it will be applied to minimize false negative, missed diagnoses. This should be conducted by a trained member of the multidisciplinary team
- A thorough nutrition assessment should apply the ABCDE format prior to informing a nutrition diagnosis
- Physiological barriers, psychosocial and workplace cultural factors, environmental considerations, and patient/healthcare provider perceptions, biases, and misconceptions should be considered within scope of nutrition assessment
- Nutrition assessment should include consideration of the patient's treatment goals and intentions
- All malnutrition diagnosis are to be clearly documented, including the problem, etiology, and justifying signs/symptoms
- Patients identified as at risk or malnourished should routinely receive clinical nutrition support that combines systematized, multidisciplinary processes with individualized nutrition care where appropriate
- Processes should be in place for weekly nutrition rescreening, reassessment, and monitoring and/or evaluation

Dictionary of Terms

- **Cachexia** – Sarcopenia resulting from an unmet increased metabolic demand associated with acute or chronic clinical condition(s)
- **Malnutrition** – Malnutrition broadly envelopes undernutrition, overnutrition, or nutrient imbalance states, across macro- and micronutrients. The definition in this chapter is limited to protein/energy malnutrition or undernutrition as defined by a tool broadly recognized and validated for that purpose in the population being applied

- **Multidisciplinary** – For the purpose of this review "multidisciplinary" is inclusive of engagement of team members from more than one professional discipline, either within a multidisciplinary, interdisciplinary, or transdisciplinary context
- **Multimorbid** – Having multiple medical conditions or disease states which are considered to have substantial impact on patient and/or healthcare outcomes
- **Nutrition assessment** – A systematic approach to collecting and recording the data obtained from patients, clients, family members, caregivers, and/or other individuals and groups across a number of domains for the purpose of informing a nutrition diagnosis, clinical nutrition interventions, and/or monitoring and evaluation purposes
- **Nutrition screening** – A quick and easy process able to be applied to large numbers of people, with limited training, to identify those at significant risk of malnutrition
- **Sarcopenia** – Loss of skeletal muscle mass, strength, and/or function that can be attributable to either nutritional or nonnutritional factors
- **Wasting** – Sarcopenia resulting from insufficient protein and/or macronutrient intake or uptake, or increased losses

Summary Points

- Malnutrition diagnosis in hip fracture is a key predictor of poor patient and healthcare outcomes
- The majority of hip fracture patients are at high risk of malnutrition and inadequate oral intake
- Where resources allow, nutrition screening should be replaced with routine assessment
- There is no gold standard for nutrition screening or diagnosis of malnutrition
- There are multiple barriers and confounders to commonly applied nutrition screening and nutrition assessment measures and markers
- Multimorbid hip fracture patients require a comprehensive nutrition assessment triangulating data from multiple sources across multiple time points
- A clinical judgment diagnosis of malnutrition may require some divergence from standardized criteria

Abstract

The skinfold thickness in different locations like tricep, bicep, subscapular, suprailiac, and calf generally measures the subcutaneous fat deposition in the body. These skinfold parameters may be used to assess nutritional status in children as the subcutaneous fat deposition varies with the changes in nutritional status of children. Santals are backward tribal community of India, and in the present review the growth of the skinfold thickness of Santal children has been considered to evaluate the status of skinfold in undernutrition. Undernutrition does not affect the skinfold thickness in different locations uniformly, and the sensitivities of skinfold thickness of some locations are good markers (triceps skinfold, TRSF, and subscapular skinfold, SBSF), while others may not be changed with undernutrition (suprailiac skinfold, SPSF; biceps skinfold, BCSF; and calf skinfold, CSF). SBSF and TRSF were strongly associated with the nutritional status (HAZ) in Santal boys, whereas in Santal girls, TRSF appeared to be strong predictor to assess nutritional status. TRSF is a sensitive indicator of undernutrition in both the boys and girls, and SBSF is less sensitive to identify undernutrition in girls but not in boys. The triceps-for-age z-score (TAZ) appears to be better indicator of undernutrition than that of height-for-age z-score (HAZ) and weight-for-age z-score (WAZ) in Santal children. The growth and velocity of growth of different skinfold thickness in well-nourished Santal children was found to be changed in undernourished Santal boys and girls.

Introduction

The nutritional status of children can be assessed by different methods such as nutritional anthropometry (measuring anthropometric parameters), biochemical estimation, clinical diagnosis, and dietary measurements (Lee and Nieman 2007). Nutritional anthropometry is one of the simple methods for measuring the nutritional status. It comprises of the measurements of physical dimensions and the gross composition of the body (Gibson 1990). As the growth is a major characteristic of childhood and it is dependent on adequate supply of nutrients, the measurement of growth by anthropometric measurements usually represent an idea about the nutritional status of a child (Jelliffe 1996).

The growth and development of children depend both on exogenous (nutrition, socioeconomic factors, geographical environment, etc.) and on endogenous (genetic, hormonal, etc.) factors. The favorable environmental conditions help the child to grow fullest, whereas unfavorable conditions try to depress it. Height is a measure of linear growth of the body and the degree of the skeletal development, and weight is a measure of total body mass including sum of protein, fat, water, and bone mineral mass. Hence, height and weight are sensitive to changes in muscle mass, fat, body fluid, and the skeleton of the body (Shils and Shike 2006). Weight reduction can easily occur as the result of impairment of metabolism, decrease in nutrient intake, or increase requirement of the same. Immediate decrease in weight reflects current nutritional status (Gibson 1990). Another anthropometric parameter, mid-upper arm circumference (MUAC), has been used for nutritional anthropometry as it assesses the degree of muscle and fat around the bone in the mid-upper arm region. A decrease in MUAC may reflect a reduction in muscle mass, a reduction in subcutaneous tissue, or both. In developing countries, where the amount of subcutaneous fat is frequently small, the changes in MUAC reflect the parallel alteration in muscle mass, and hence MUAC is particularly useful in the assessment of nutritional status (Lohman et al. 1988). The measurement of head circumference is important for nutritional assessment because it is closely related to brain size and can be used as an index of chronic undernutrition. Chronic undernutrition during the first few months of life, or intrauterine growth retardation, may decrease the number of brain cells and may result in an abnormal low head circumference. If undernutrition continues, it affects the total head circumference in later ages (Gibson 1990). The body mass index (BMI) proved to be useful in ascertaining the change in nutritional status over a period of time, particularly when dietary indicators could not be relied on to reflect the change(s) because of their large variations. BMI can be a reasonably good substitute not only for assessing energy status of the subject but also for evaluating

the nutritional status of the child. Moreover, BMI has been used to diagnose undernutrition, controlling for age and gender (Cederholm et al. 2015; Bailey and Ferro-Luzzi 1995). It has been opined that BMI is closely associated with the weight rather than the height of the individual because weight is the responsive variable to energy balance (NIN 1990). The measurement of chest circumference of young children is useful parameter for assessing the nutritional status (Jelliffe 1996). The chest, thigh, and mid-calf circumferences are most useful measurements for grading of body fat. In girls, thigh circumference is highly correlated with fat mass and body fat percentage (Konstantynowicz et al. 2011).

Skinfold thickness measurements are said to provide an estimate of the size of the subcutaneous fat deposition, which in turn provides an estimate of the total body fat. The variations in distribution of subcutaneous fat in different locations like triceps, biceps, subscapular, suprailiac, and calf occur with changes in nutritional status (Lee and Nieman 2007). The skinfold thickness is affected within a short duration of inadequate nutrient intake and is responsive to acute nutritional deficiency or acute undernutrition. Hence, these parameters are sensitive makers and good indicators to assess nutritional status in children. Several indices of body fat/fat-free mass like upper arm muscle circumference (UAMC), upper arm muscle area (UAMA), fat-free mass index (FFMI), and upper arm fat area (UAFA) are calculated from MUAC and skinfold measurement, and these are useful parameters for nutritional measurement in children (Chowdhury and Ghosh 2009; Chowdhury et al. 2006; Frisancho 1990). Nutritional anthropometry has been applied widely to assess the magnitude of undernutrition in children as the effect of undernutrition on different anthropometric parameters is well documented and has been classified in standard grades. But the influence of undernutrition on the growth of skinfold thickness in children has not been studied adequately. Santals are backward tribal community of India, and in the present review, the growth of the skinfold thickness of Santal children has been considered to evaluate the status of skinfold in undernutrition.

The Santals

There are several socially backward communities in India such as scheduled castes and scheduled tribes. The term “scheduled tribe” refers to specific indigenous people whose status is acknowledged to some formal degree by national legislation. A tribe viewed historically or developmentally consists of a social group existing before the development of states (Bagchi 1981). There are 645 types of scheduled tribes or tribal populations in India, and few groups were identified as more backward communities among the tribal population. These groups have been categorized as “primitive tribal groups” (PTGs) by the Government in the Census of 1975. So far, 75 tribal communities have been identified as “primitive tribal groups” in different states of India (Sanyal 2006). Santals have been recognized as one of the primitive tribes of India. Santals, the third largest tribe of India, live in remote places of different states. In West Bengal, they are spread over in vast areas of Purba and

Paschim Medinipur, Bankura, and Purulia. This tribe is characterized by poverty, illiteracy, and nutritional problems.

Nutritional Status of Santal Children

The nutritional and health status of Santals were measured long time ago in Midnapore of West Bengal (Bagchi 1981) by using anthropometric parameters like height and weight. It was reported that more than 60% of Santal children suffered from undernutrition in this study (Bagchi 1981). Another study conducted in Purnia district of Bihar reported that 6% of Santal children were found in severe grade of acute undernutrition (Rao and Vijay 2006). The nutritional status of Santal children in some areas of Purulia district of West Bengal has been measured on the basis of their height and weight, and a high percentage of undernutrition (42.27% stunting, 66.81% underweight, and 61.95% wasted) has been reported in this population (Chowdhury et al. 2008). In further study, about 17.13% Santal boys and 20.63% Santal girls were identified as truly undernourished based on height-for-age, weight-for-height, and upper arm muscle area by height (UAMAH) (Chowdhury and Ghosh 2009). In addition, the growth pattern of Santal children as assessed from height-for-age and weight-for-age growth curves showed that undernutrition prevailed in these children compared to international standard (NCHS). The poor growth pattern of Santal children on the basis of NCHS data of height and weight was further supported from other anthropometric parameters like MUAC in these subjects (Chowdhury and Ghosh 2009).

Nutritional Status of Other Tribal Communities

The undernutrition in children of different countries has been assessed in terms of stunting (from height-for-age) and underweight (from weight-for-age). The prevalence of stunting and underweight showed wide variation, in the children of different countries like Mexico (Tejas et al. 2001), Chile (Ivanovic et al. 1995), Malaysia (Marjan et al. 1998), and Nigeria (Ukoli et al. 1993) and Nepal (Ghosh et al. 2009). Even reports from different regions of India indicate the variability in stunting and underweight among children (Joseph et al. 2002; Laxmaiah et al. 2002; Abel and Sampathkumar 1998) and thus indicate regional difference in the nutritional status of the children. The prevalence of undernutrition among the tribal children in India has not been investigated sufficiently except in few studies (Table 1). Rao et al. (2005) reported a widespread undernutrition (51.6% stunting and 61.6% underweight) among the preschool children of Gond tribe of Madhya Pradesh. Mitra et al. (2007) showed that Kamar children (4–12 years) of Chhattisgarh suffered from extensive undernutrition (63.5% stunting, 57.8% underweight, and 57% wasting). A large percent of undernutrition (54.9% stunting and 62.8% underweight) had been reported in Saharia preschool children of Rajasthan (Rao et al. 2006). Similarly, children of Sugali tribe of Andhra Pradesh are also found to be suffering from

undernutrition (46.4% stunting and 65.4% underweight) (Reddy and Rao 2000). In West Bengal, the children (6–12 years of age) of Oraon tribe were getting less energy from their food even after their enrolment in the midday meal program at the local primary school (Mittal and Srivasatava 2006). As a result, 54% of the children were suffering from severe malnutrition as measured by BMI. The variability of undernutrition in different regions may be due to socioeconomic conditions, environmental factors, and ethnic differences (Frongillo et al. 1997). The number of stunted and underweight (moderate and severe grade) Santal children of Purulia district is less than that of many tribes (e.g., Gond (Madhya Pradesh), Saharia, and Oraon tribes) (Chowdhury et al. 2008). It seems that the Santals children of Purulia district are not affected maximally in their nutritional status among the different tribes of India. The socioeconomic status of Santals was found to be in lower and upper-lower category (Chowdhury et al. 2008), and they send their children to local primary schools where midday meal program is in operation. The different anthropometric parameters (e.g., height, weight, BMI MUAC) of Santal children have been studied to evaluate the grade of undernutrition in this population. Hence these Santal children are suitable subjects to evaluate the influence of undernutrition on the skinfold thickness.

Growth Curve of Skinfold Thickness in Santal Children

The assessment of nutritional status of Santal children from skinfold thickness was based on the changes of subcutaneous fat in different locations. The calorie reserve of the body is reflected on the subcutaneous fat. The growth curves of skinfold-for-age from different locations were employed to assess the nutritional status of Santal children (Chowdhury and Ghosh 2013).

TRSF-for-Age and SBSF-for-Age Growth Curve

The nutritional status of Santal children was assessed from the location of the TRSF-for-age and SBSF-for-age growth curve in the respective skinfold-for-age reference growth curve of NHANES (Lee and Nieman 2007). A poor nutritional status of Santal children was evident from the location of growth curves of TRSF-for-age and SBSF-for-age in the reference values of NHANES, and the effect of undernutrition on these two skinfolds was almost similar. It was observed that SBSF values of Santal boys remained around 5th–10th percentile and TRSF values remained between 5th and 10th percentile of the reference. The poor growth pattern of skinfold thickness was also observed in girls, but unlike boys the TRSF was affected more (below 5th percentile) than that of SBSF, i.e., around 15th percentile (Chowdhury and Ghosh 2013). Previously, it was reported that the height-for-age and weight-for-age growth curves of Santal children remained at 5th–10th percentile of the WHO reference (Chowdhury et al. 2008). Therefore, the age-related growth curves of TRSF and SBSF were affected in undernourished children in a similar way to that of height-for-age and weight-for-age growth curves.

Growth of SPSF, BCSF, and CSF

As the reference values of SPSF, BCSF, and CSF for NHANES are not available, the growth pattern of these skinfold parameters cannot be assessed like that of TRSF and SBSF in Santal children. The effect of undernutrition on these skinfolds was measured by the difference of the mean values between well-nourished and undernourished children (which were identified on the basis of height-for-age z-score) in different ages.

Skinfold Thickness Between Well-Nourished and Undernourished Santal Children

It has been widely accepted that height-for-age z-score (HAZ) is one of the sensitive parameters for measuring chronic undernutrition (WHO 1986). According to criteria of WHO, children with HAZ below 1 were considered as undernourished (WHO 1986). This criterion has been used in skinfold, and the age-related mean values of skinfold parameters were compared between well-nourished ($HAZ > -1$) and undernourished ($HAZ < -1$) Santal boys and girls to find out the effect of undernutrition on the growth of different skinfold thickness (Chowdhury and Ghosh 2013). It was found that the mean values of BCSF (except 6 and 12 years) and CSF (except 10–12 years) in the well-nourished and undernourished groups of boys and girls were similar, and there was no significant change between these two groups of children having different nutritional status. These results probably indicate that these skinfolds are less sensitive in undernutrition. However, the skinfold thickness in SPSF showed significant difference between well-nourished and undernourished groups of boys and girls. Thus, the undernourished children ($HAZ < -1$) showed the lower thickness of TRSF, SBSF, and SPSF compared to that of well-nourished children. Similar difference in the thickness of TRSF and SBSF between well-nourished and undernourished groups of boys and girls was also reported in American black children (Curran and Barness 2000) and in Turkish children (Yuca et al. 2011). It appears that these skinfolds are sensitive parameters for assessing undernutrition. Therefore, undernutrition does not affect the skinfold thickness in different locations uniformly. The sensitivity of skinfold thickness of some locations are identified as good markers (TRSF, SBSF, and SPSF), while others may not be changed with undernutrition (BCSF and CSF).

Growth Velocity of Different Skinfold Thickness in Santal Children

Measurement of growth velocity of skinfold parameters is important to evaluate the growth of skinfold thickness of a subject. Growth velocity curves for skinfold thicknesses represent the increase of these parameters during a fixed period of time. Skinfold thickness velocity curves depict the age-dependent changes in velocity that characterize the postnatal growth of these children. Pubertal growth spurt was also observed in the velocity growth curves of different skinfold thickness.

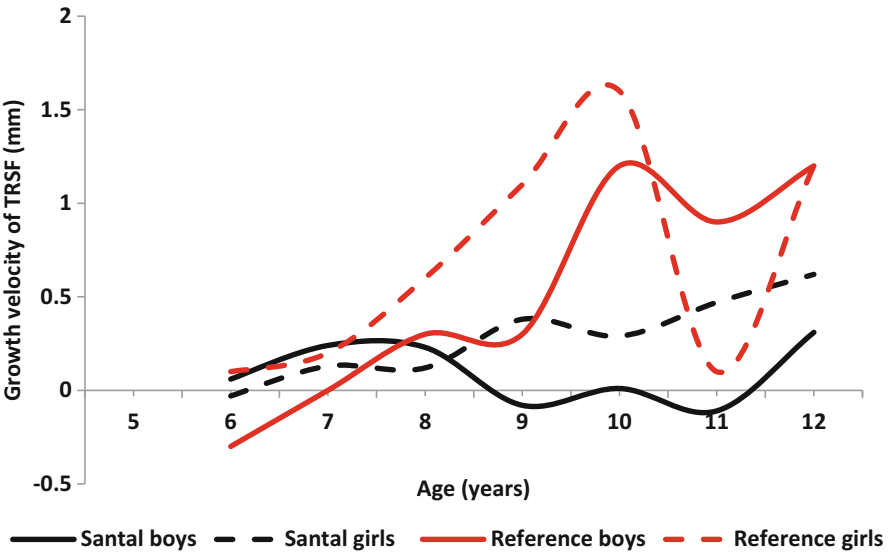

Fig. 1 Velocity of growth curve in triceps skinfold (TRSF) thickness for Santal children and reference children (Frisancho 1990)

Velocity of Growth in TRSF Thickness

The velocity of growth in TRSF thickness for Santal boys (9–12 years of age) was found to be lower than that of reference curve (Frisancho 1990). In Santal girls, velocity of growth in TRSF thickness was lower than that of reference values, except in 11 and 12 years of age. The velocity curve of TRSF thickness for Santal boys and girls showed a progressive growth from 6 years of age, followed by decrease in boys at 8 and 11 years of age, and in girls the velocity was lower at 8–10 years of age than that of the reference curve (Fig. 1). The total gain of growth (from 6 to 12 years) in TRSF of Santal boys and girls was about 0.25 mm and 0.58 mm, respectively. The growth spurt in TRSF was started at 11 years in boys and at 10 years of age in girls.

Velocity of Growth in SBSF Thickness

The velocity of growth in SBSF was lower at 6–7 years of age in boys compared to reference curve, and then the velocity was decreased at 10–11 years of age. In girls, the velocity was lower at 8–10 years of age compared to that of reference curve (Fig. 2). The velocity of growth in SBSF thickness of Santal boys and girls was comparable in 6–10 years of age, but thereafter the velocity was steeply increased in girls at 10 years of age and in boys at 11 years of age, which might be the indicator of growth spurt (Fig. 2). The total gain of growth in SBSF of Santal boys and girls (from 6 to 12 years) was about 0.63 mm and 0.32 mm, respectively.

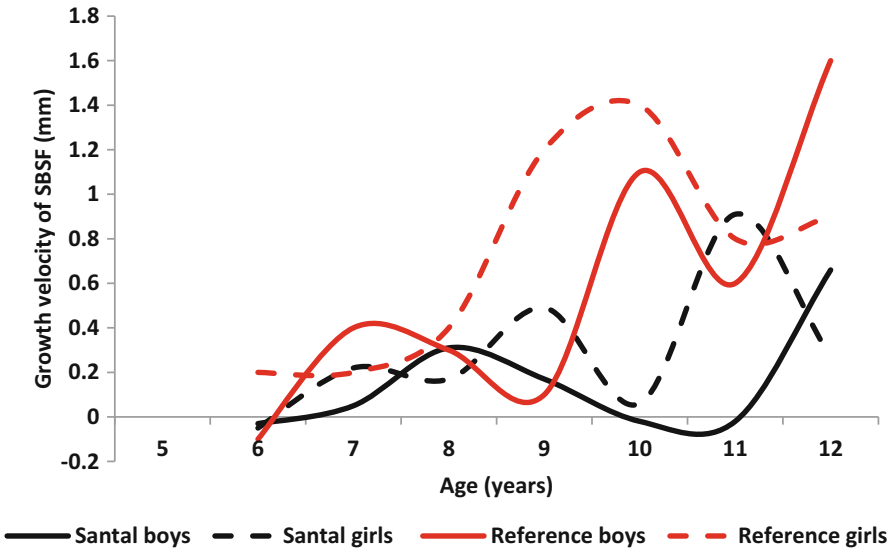

Fig. 2 Velocity of growth curve in subscapular skinfold (SBSF) thickness for Santal children and reference children (Frisancho 1990)

Velocity of Growth in SPSF Thickness

The velocity of growth in SPSF thickness in Santal boys and girls is shown in Fig. 3. As the reference values of SPSF thickness are not available, the velocity of growth in SPSF thickness is shown in well nourished and undernourished in Santal boys and girls. The nutritional status was identified from height-for-age z-score of reference (WHO 2007). The velocity of growth in SPSF of well-nourished and undernourished girls was not markedly different from each other at 6–9 years of age, and thereafter the velocity in undernourished girls was decreased; however at 11 years of age an increase of growth velocity was noted which might be indicator of growth spurt. In Santal boys, the velocity of growth in SPSF was totally different at 6–12 years of age in well- and undernourished boys; probably the growth spurt in SPSF is absent in undernourished boys. Santal girls gained higher SPSF (0.37 mm) than that of boys (0.18 mm) between 6 and 12 years of age groups.

Velocity of Growth in BCSF Thickness

The velocity of growth in BCSF thickness is shown in well-nourished and undernourished Santal boys and girls in Fig. 4. The pattern of velocity of growth in BCSF during 6–12 years of age is similar in well- and undernourished Santal girls, but the velocity values were lower at 8–9 and 11 years of age (Fig. 4). Though the velocity

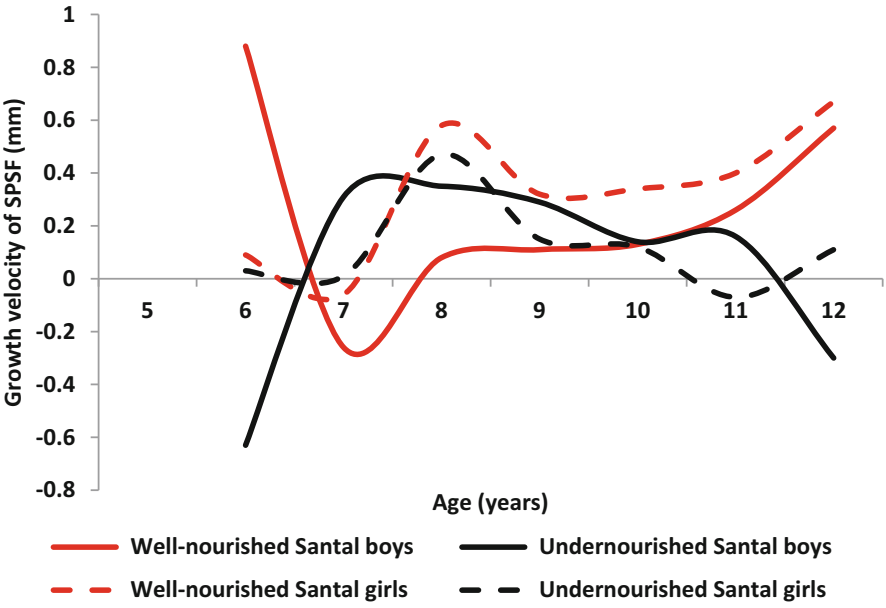

Fig. 3 Velocity curve for growth of suprailiac skinfold (SPSF) for well-nourished and undernourished Santal children

of growth in BCSF thickness showed undulation during 6–10 years of age in undernourished Santal boys, it took higher velocity at 11 years of age indicating the growth spurt. The velocity of growth in BCSF thickness in well-nourished Santal boys was steady during 6–10 years of age, and velocity was increased at 11 years of age. The total gain of growth in BCSF thickness in Santal girls was about 0.25 mm, but in boys it is negligible.

Velocity of Growth in CSF Thickness

The velocity of growth in CSF thickness in well-nourished boys showed steady velocity during 6–10 years of age after which the velocity was increased but again attained steady level at 12 years of age (Fig. 5). In undernourished boys, the velocity was always lower than that of well-nourished boys though the trend was similar. The velocity of growth in CSF thickness in well- nourished Santal girls showed undulation during 6–10 years of age, and then a steep increase in velocity was noted at 11–12 years of age. In undernourished girls, the velocity showed variation during the observed period (6–12 years of age), and the trend was different from that of well-nourished girls. The total gain of growth in CSF in Santal boys and girls was about 0.28 mm and 0.72 mm, respectively, during the observed period (6–12 years of age).

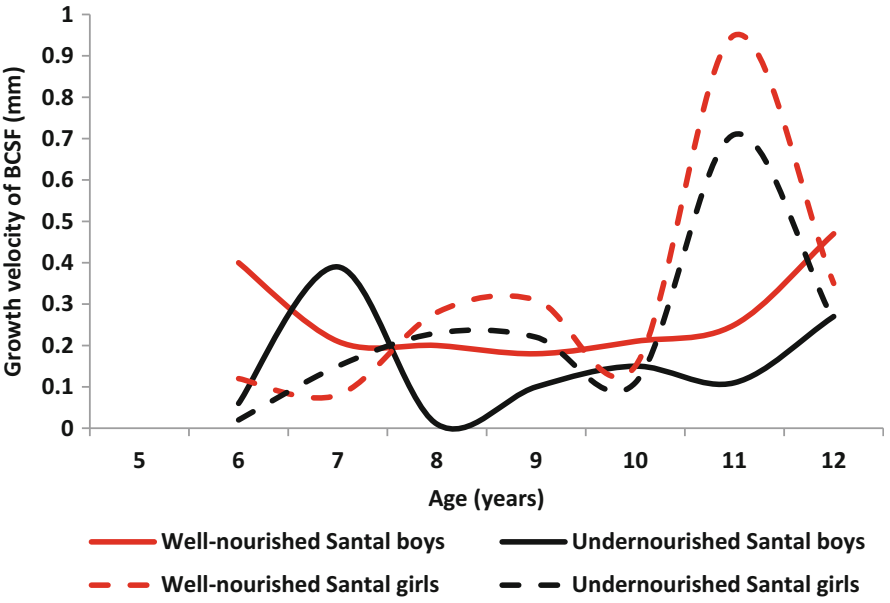

Fig. 4 Velocity curve for growth of biceps skinfold (BCSF) for well-nourished and undernourished Santal children

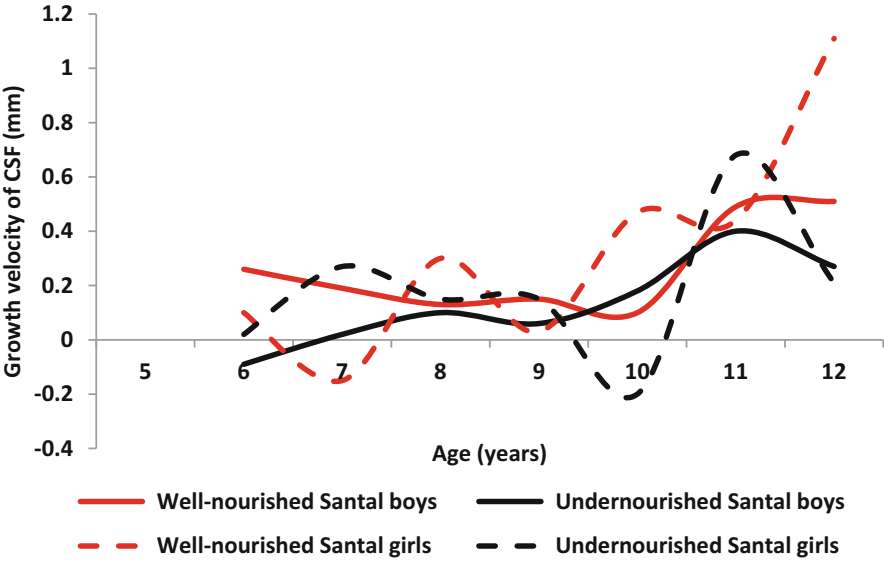

Fig. 5 Velocity curve for growth of calf skinfold (CSF) for well-nourished and undernourished Santal children

Correlation Study Among Skinfold Thickness

Pearson's correlation analyses were used to evaluate the relationship among skinfold parameters in well-nourished and undernourished children separately (Chowdhury and Ghosh 2013). In well-nourished (HAZ > -1) boys, four skinfold thicknesses (TRSF, BCSF, SBSF, and SPSF) showed significant correlation with each other but not with CSF. Such correlation was not observed in the undernourished (HAZ < -1) boys. BCSF showed significant correlation with SPSF and SBSF, and SBSF showed significant correlation only with CSF in undernourished boys. In well-nourished (HAZ > -1) girls, all the five skinfold parameters (TRSF, BCSF, SBSF, SPSF, and CSF) showed significant correlation with each other. The undernourished girls on the other hand showed different types of correlations than that of undernourished boys. In undernourished (HAZ < -1) girls, the four skinfold thickness (TRSF, BCSF, SBSF, and SPSF) showed significant correlation with each other, but CSF was not significantly correlated with SBSF and SPSF. Chowdhury and Ghosh (2013) concluded from these results that the growth of different skinfold thickness in well-nourished children was found to be changed in undernourished boys and girls. Additionally, it was observed that the pattern of growth in skinfold thickness of two locations may not be similar in well-nourished or undernourished boys and girls, and therefore significant correlation in some skinfold parameters between children of two nutritional statuses was not observed.

Association Between Nutritional Status and Skinfold Thickness

The association between nutritional status (well-nourished and undernourished according to the height-for-age z-score) and five different skinfold parameters (TRSF, SBSF, SPSF, BCSF, and CSF) was analyzed by multiple regression using four incremental models where the outcome variable was nutritional status (Chowdhury and Ghosh 2013). The results of regression analyses suggested that SBSF and TRSF were strongly associated with the nutritional status (HAZ) in boys, whereas TRSF and SPSF in girls appeared to be strong predictor to assess nutritional status. In the Santal girls, thickness of SBSF was not associated with their nutritional status suggesting, a poor indicator of undernutrition. It may be noted that the SBSF-for-age growth curve was also less affected than that of TRSF-for-age in girls. The association of BCSF and CSF with nutritional status (HAZ) seems to be much weaker as its association with nutritional status failed to show significant involvement after their inclusion in the models of regression.

Body mass index (BMI) has been used to measure the nutritional status in children of different countries (Nething et al. 2007; Wolney and Carlos 2006). BMI proved to be useful in ascertaining the change in nutritional status over a period of time, when dietary indicators could not be relied on to reflect the change(s) because of their large variations. BMI can be a reasonably good substitute not only for assessing energy status but also for evaluating the nutritional status of the child. BMI is closely associated with the weight rather than the height of the

Table 2 Regression analyses between different skinfold parameters and BMI-for-age z-score (dependent variable) in boys

	Beta (95% CI)	p-value	R^2	Change in R^2 from previous model

individual because weight is the responsive variable to energy balance (NIN 1990). In the present study, regression analyses were done to find out the association between skinfold thickness and nutritional status in terms of BMI-for-age z-score (BMIAZ). Results showed a similar outcome in case of association between BMIAZ and skinfold thickness as it was found in the association between HAZ and skinfold thickness. It has been observed that SBSF for boys and TRSF and SPSF for girls were significantly associated with the BMI-for-age z-score (Tables 2 and 3). Researchers have already established that skinfold thickness is also a good predictor for assessing nutritional status in terms of assessment of energy balance like BMI (Chowdhury et al. 2013; Booyens et al. 1997) and both of these parameters are strongly associated with body fatness (Freedman et al. 2007; Freedman and Sherry 2009).

Z-Score Analyses of Skinfold Thickness for Assessing Nutritional Status

The nutritional status of Santal children was assessed by the nutritional categories based on z-scores of skinfold thickness of TRSF and SBSF (Frisancho 1990). The subjects having the thickness of the skinfolds above +1 z-score and below −1 z-scores were identified as well-nourished and undernourished, respectively. A high prevalence of undernutrition was found in Santal children (Fig. 6). Percentage of undernourished boys and girls (<−1 z-score) was found to be higher in SBSF (75.1%) and TRSF (92.3%), respectively. Similarly, percentage of severe

Table 3 Regression analyses between different skinfold parameters and BMI-for-age z-score (dependent variable) in girls

	Beta (95% CI)	p-value	R^2	Change in R^2 from previous model
Model 1			0.547	0.547
TRSF	0.514	0.001		
Model 2			0.578	0.031
TRSF	0.531	0.001		
SPSF	0.221	0.023		
Model 3			0.561	0.017
TRSF	0.543	0.001		
SPSF	0.183	0.041		
SBSF	0.094	0.241		
Model 4			0.552	0.009
TRSF	0.538	0.001		
SPSF	0.164	0.037		
SBSF	0.081	0.177		
BCSF	0.037	0.351		
CSF	0.026	0.542		

TRSF triceps skinfold, *BCSF* biceps skinfold, *SBSF* subscapular skinfold, *SPSF* suprailiac skinfold, *CSF* calf skinfold

undernutrition (<−1.6 z-score) for boys and girls was also found to be higher in SBSF (35.9%) and TRSF (70.1%), respectively. Results of Figs. 1 and 2 pointed out that TRSF for girls and SBSF for boys seemed to be sensitive marker for assessing nutritional status in Santal children. This conclusion is also supported from the observation made by Chowdhury and Ghosh (2013) as well as from the observation of regression analysis for the association between BMIAZ and skinfold thickness (Tables 2 and 3).

The nutritional categories of Santal boys and girls were further analyzed on the basis of z-score for TRSF-for-age (TAZ), SBSF-for-age (SAZ), and sum of triceps and subscapular skinfold thickness-for-age (STSAZ) (Chowdhury and Ghosh 2013) as per Frisancho (1990). The results indicated that the percent of undernourished boys according to TAZ (61.5%) and SAZ (61.3%) were similar, but in the girls TAZ (90.8%) was higher than that of SAZ (44%). Therefore, this analysis (TAZ and SAZ) further supports the previous conclusion that SBSF is less sensitive to identify undernutrition in girls but not in boys, and TRSF is a sensitive indicator of undernutrition in both the boys and girls. The number of undernourished children according to STSAZ (66.3% boys and 66.5% girls) was similar in boys and girls, and hence this parameter may be good to assess undernutrition in both boys and girls. The number of undernourished children according to STSF-for-age z-score (STSAZ, 66.3% boys and 66.5% girls) were again little bit higher than that of height-for-age (HAZ < -1, 52.9% boys and 62.6% girls) and weight-for-height (WHZ < -1, 57.5% boys and 63.6% girls). Therefore, STSAZ appears to be good indicator for assessing undernutrition in children and may be equally potent in this regard to HAZ and WAZ. It may be

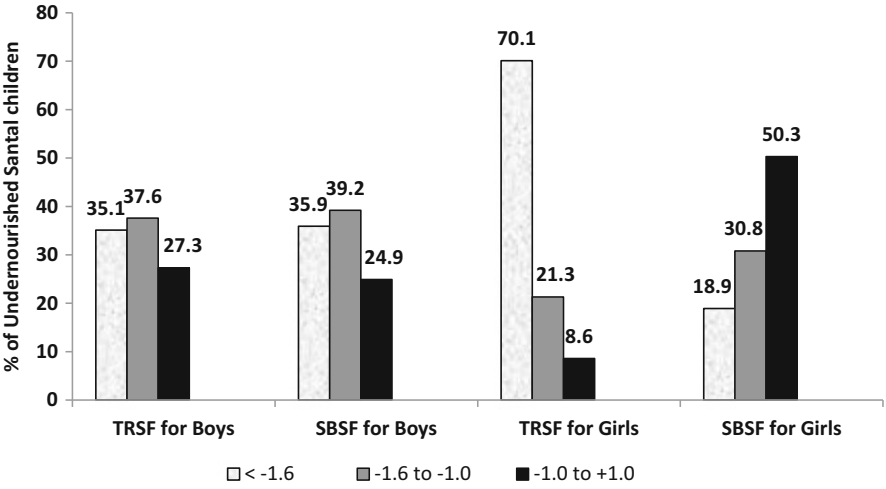

Fig. 6 Distribution of percentage of Santal boys in different nutritional categories (in terms of z-scores) developed by Frisancho (1990) for TRSF and SBSF in boys and girls

noted here that TAZ (61.5% boys and 90.8% girls) appears to be better indicator of undernutrition than that of HAZ (52.9% boys and 62.6% girls) and WAZ (57.5% boys and 63.6% girls) in this population (Chowdhury and Ghosh 2013).

Skinfold Thickness and Socioeconomic Status in Santal Children

Santal children belong to the lower and upper-lower socioeconomic status (Chowdhury et al. 2008). Previously, it has been found that undernutrition (as measured by height-for-age, weight-for-age, and weight-for-height parameters) in Santal children was directly associated with their poor socioeconomic status (Chowdhury et al. 2008). A significant association between socioeconomic factors and fat area in Santal children was found in further study (Chowdhury et al. 2009). Similarly, the significant relationship between socioeconomic factors with skinfold thickness was also identified in Santal children (Chowdhury and Ghosh 2013). A strong relationship between TRSF and socioeconomic status was also observed when Santal children were distributed in different socioeconomic classes according to the nutritional categories measured by TRSF (Fig. 7). A higher percent of undernourished (<-1 z-score of TRSF) boys (42.5%) and girls (53.3%) was observed in lower socioeconomic class which was found to be much higher than undernourished children present in upper-lower (26.4% boys and 35.4% girls) and lower-middle (3.8% boys and 2.7% girls) socioeconomic classes. Results showed that children in lower socioeconomic class suffered in undernutrition more than that of comparatively higher socioeconomic classes. These findings are in agreement with the observation of Ryan et al. (1990) and Garn and Ryan (1981) who reported

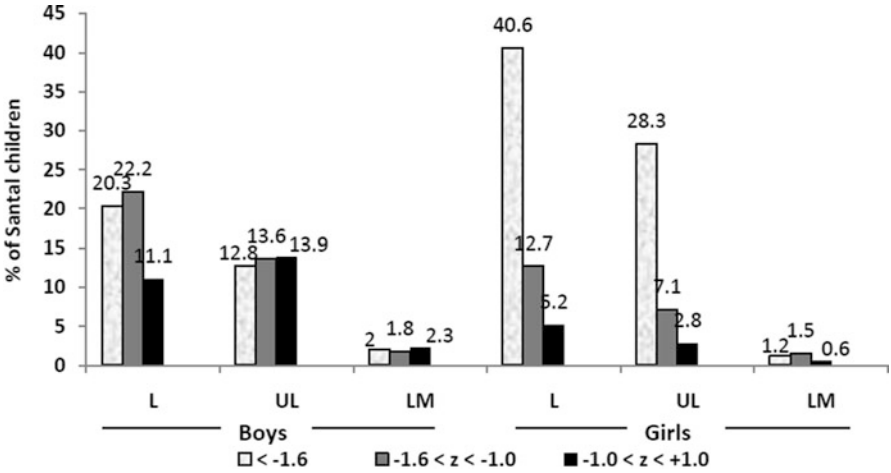

Fig. 7 Distribution of percentage of Santal children of different socioeconomic classes in different nutritional categories of TRSF developed by Frisancho (1990)

that children of higher-income group families had greater skinfold thickness than children of lower-income group families. A positive association between skinfold thickness and socioeconomic characteristics has also been reported in British children (Tauleria et al. 1995). It may be inferred that socioeconomic status is another significant factor, in addition to the nutritional status, that affects skinfold thickness of Santal children.

The question may arise whether the height, weight, and skinfold thickness of undernourished children from other communities, especially from the tribal community, will be affected similar to that of Santals. Some studies were carried out on the height, weight, and selected skinfolds in tribals such as Sugali and Bharia. The location of height-for-age and weight-for-age growth curves of Sugalis (below 5th percentile) in the reference curve of WHO indicated undernutrition in these children. But the thickness for TRSF and SBSF of these Sugali boys and girls (around 25th percentile of NHANES reference) appears to be less affected (Reddy and Rao 2000). Bharia, like the Sugali, is another primitive tribe of Madhya Pradesh. Children of this tribe also suffered from undernutrition as it is evident from the location of their height and weight curves (around 5th percentile) relative to the WHO reference (Tiwari et al. 2007). Again, the thickness of TRSF and SBSF of Bharia tribal children (around 25th percentile for both boys and girls in NHANES reference) is less affected than that of Santal children. However, the skinfold thickness in well-nourished children of Sugalis and Bharia are not available, and the magnitude of the effect of undernutrition on the skinfold of these children cannot be ascertained. Probably the skinfold thickness varies in the children of different tribal communities having similar nutritional status. Manshande et al. (1985) suggested that the environmental conditions can play an adaptive role in accumulation of subcutaneous fat. Thus it appears the

skinfold thickness in well-nourished and undernourished children of other tribal and non-tribal communities should be investigated to get information on the influence of undernutrition on the skinfold thickness of the different locations of the children.

Conclusion

Thus it appears that the growth curves and velocity of growth curves of skinfolds of different locations are changed in undernourished Santal Children. SBSF and TRSF are sensitive parameters and probably good markers for undernutrition in Santal children (from growth, velocity of growth, and association).

Policies and Protocols

Policies

The Government has accorded high priority to the issue of undernutrition and is implementing several programs (such as Integrated Child Development Scheme ICDS, Indira Gandhi Matritva Sahyog Yojana IGMSY, National Rural Health Mission NRHM, etc.) of different Ministries/Departments through State Government/UT Administration, which have the potential to improve the current nutritional situation in India. For better access to nutrition and health services, frontline workers (Anganwadi Workers AWW, Accredited Social Health Activist ASHA, Auxiliary Nurse Midwife ANM) have been appointed by health department and ICDS; these functionaries are an interface between the community and the Government systems. In spite of such endeavor, undernutrition probably exists in observed population, and additional preventive program should be undertaken by policy maker.

Protocols

Measurement and Calculation of BMI-for-Age z-Score

Height and weight of each child were measured by standard technique (Lee and Nieman 2007). BMI was calculated from height (m) and weight (kg; weight/height2). Sex-specific BMI-for-age z-score values based on World Health Organization reference z-score values for each child were used (WHO; World Health Organization 2007).

Measurement of Skinfold Thickness

Skinfolds were measured using the Harpenden skinfold caliper with a constant spring pressure of 10 g/mm^2. All sites were measured on the right side of the body. Mean of the three measurements was taken in every skinfold location.

- Triceps skinfold (TRSF)
  The subject's arm hanged loosely at the side, with the palm of the hand facing anteriorly to properly determine the posterior midline. The skinfold site was marked along the posterior midline of the right upper arm, over the triceps muscle, midway between the lateral projection of the acromion process of the scapula and the inferior margin of the olecranon process of the ulna. The measurer stood behind the subject and grasped the skinfold with the thumb and index finger of the measurer's left hand about 1 cm proximal to the skinfold site; the caliper was kept perpendicular to the long axis of the skinfold and recorded.
- Subscapular skinfold (SBSF)
  The subscapular site of each subject was marked 1 cm below the lowest angle of the scapula. The site was located by gently feeling for the inferior angle of the scapula. The skinfold was measured with the subject standing with arms relaxed to the sides. The skin was grasped 1 cm, above and medial to the site along the axis.
- Suprailiac skinfold (SPSF)
  This skinfold was measured just above the iliac crest at the midaxillary line. The subject stood erect with feet together and arms hanging by the sides. The measurer grasped the skinfold about 1 cm posterior to the midaxillary line, and the reading was recorded.
- Medial calf skinfold (MCS)
  The measurement was taken with the subject sitting; the right leg was flexed about 90° at the knee with the sole of the foot flat on the floor. The point of the maximum calf circumference was marked at the medial aspect of the calf. A vertical skinfold grasped about 1 cm proximal to the marked site, and the reading was recorded.
- Biceps skinfold (BCSF)
  The subjects faced the measurer with the arm held relaxed at the side, and the palm was facing forward. The skinfold was picked up over the belly of the biceps and 1 cm above the line marked for MUAC and TRSF on a vertical line, joining the center of the antecubital fossa to the head of the humerus. The caliper jaws were applied at the marked level, and the skinfold reading was recorded.

Assessment of Socioeconomic Status

Socioeconomic status (SES) of Santal children was assessed using the updated Kuppusswami scale (Kumar et al. 2007). The scale is based on monthly family income, parental education, and parental occupation. Structured questionnaires were used to collect information on socioeconomic characteristics of subjects' families from their parents and/or school authorities.

Measurement of Nutritional Status

Nutritional status was calculated by z-scores using the age- and sex-specific skinfold thickness reference values of World Health Organization (2007). Nutritional categories were assessed according to the classification referred by Frisancho (1990). Children with a z-score below −1 of any skinfold-for-age were considered to be

undernourished, children with a z-score between −1 and + 1 of any skinfold -for-age were considered to be nutritionally normal, and children with a z-score below −1.6 were considered to be severely undernourished.

Statistical Analyses

Descriptive statistics were used to compute the mean and standard error of mean (SEM) for different parameters by age and sex. Stepwise forward regression was employed to find out the association of nutritional and socioeconomic status with different skinfold thickness parameters. The statistical analyses were performed using statistical package for social science (SPSS software, Version 20.0.).

Dictionary of Terms

- **Undernutrition** – A poor nutritional status developed due to inadequate consumption or malabsorption of one or more nutrients.
- **Skinfold** – The skin over a particular location is folded and measured by skinfold caliper to assess the nutritional status. The skinfold thickness is a measure of the underlying subcutaneous fat.
- **Santal** – A primitive tribe of India inhabiting mostly in the state of West Bengal, Bihar, Jharkhand, and Orissa. Santal is the third largest tribe of India.
- **Growth curve** – A graphical representation of the changes of any physical dimension with time in developing subjects.
- **Stunting** – A reduced growth rate in terms of height for a particular age group in human development.
- **Underweight** – A type of undernutrition where the body weight of a subject is low considering his/her age.

Summary Points

- Different anthropometric parameters are affected by the poor nutritional status in growing children.
- Height-for-age, weight-for-age, BMI, and MUAC are used to evaluate the grade of undernutrition in children.
- Santals, the third largest tribe of India, live in remote places of different states and is characterized by poverty, illiteracy, and nutritional problems.
- A large number of Santal children suffer from stunting, underweight, and wasting.
- Skinfold thickness parameters are sensitive makers and good indicators to assess nutritional status in children.
- The growth curves of skinfold-for-age from different locations (triceps, biceps, subscapular, suprailiac, and calf) may be used to assess the nutritional status of Santal children.

- Undernutrition does not affect the skinfold thickness in different locations uniformly, and the sensitivity of skinfold thickness of some locations are good markers (TRSF, SBSF, and SPSF), while others may not be changed in undernutrition (biceps skinfold, BCSF, and calf skinfold, CSF).
- Subscapular skinfold (SBSF) was strongly associated with the nutritional status (BMIAZ and HAZ) in Santal boys, whereas in Santal girls, TRSF appeared to be strong predictor to assess nutritional status.
- Triceps skinfold (TRSF) is a sensitive indicator of undernutrition in both the boys and girls, and SBSF is less sensitive to identify undernutrition in girls but not in boys.
- The triceps-for-age z-score (TAZ) appears to be better indicator of undernutrition than that of height-for-age z-score (HAZ) or weight-for-age z-score (WAZ) in Santal children.
- The growth of different skinfold thickness in well-nourished Santal children was found to be different than that of undernourished Santal boys and girls.
- In well-nourished Santal boys, four skinfold thicknesses (TRSF, BCSF, SBSF, and SPSF) showed significant correlation with each other but not with CSF, whereas in undernourished boys, significant correlation was found between BCSF and SPSF/SBSF and between SBSF and CSF.
- In well-nourished Santal girls, all the five skinfold parameters (TRSF, BCSF, SBSF, SPSF, and CSF) showed significant correlation with each other but, in undernourished girls, significant correlation was found between TRSF and BCSF/SPS/SBS/CSF and between BCSF and SPSF/SBSF/CSF.
- The socioeconomic status is another significant factor, in addition to the nutritional status, that affects skinfold thickness of Santal children.

Abstract

Dysphagia is caused by various diseases and results in malnutrition, dehydration, and death. Dysphagia screening tools, a method for classifying severity, and a diagnostic test are necessary to identify and treat dysphagia in older adults with disabilities. The Eating Assessment Tool-10, water swallowing test, the repetitive saliva swallowing test, pulse oximetry, and cervical auscultation are used commonly in clinical practice to screen for dysphagia. Assessing dysphagia severity using the functional oral intake scale and the Food Intake LEVEL Scale are recommended for classifying patients' swallowing function and deciding therapeutic strategies. Videofluorography and fiber-optic endoscopic evaluation of swallowing are considered to be the gold standard for definite dysphagia. Sarcopenia potentially causes dysphagia, namely sarcopenic dysphagia, in which it is difficult to swallow due to sarcopenia of the generalized and swallowing muscles. Both rehabilitation and nutritional care should be used to treat sarcopenic dysphagia, based on the concept of rehabilitation nutrition. Rehabilitation nutrition includes comprehensive evaluation and intervention using rehabilitation and nutritional care of people with disabilities. It is necessary to first screen for dysphagia in older adults and then classify its severity and/or make a dysphagia diagnosis. Sarcopenia should be classified using consensus-based criteria such as the European Working Group on Sarcopenia in Older People or the Asian Working Group for Sarcopenia. Malnutrition can cause dysphagia or delayed recovery of swallowing function. Validated nutritional screening tools are useful. It is important to recognize that older adults with malnutrition require evaluation of dysphagia and sarcopenia in clinical practice.
